Meet the editor

Dr Rumelt received his medical degree and diploma in ophthalmology from Tel Aviv University, Israel. He completed his ophthalmology residency program at Western Galilee - Nahariya Medical Center in Nahariya, Israel, and then an oculoplastics fellowship at Massachusetts Eye and Ear Infirmary, Boston, MA, and vitreoretinal fellowship at Boston University. He earned his Master's degree in Public Administration (Health Systems) from Clark University, Worcester, MA. Dr Rumelt is a senior ophthalmologist at the Western Galilee - Nahariya Medical Center and is engaged in various fields in ophthalmology. He is involved with clinical activities, surgery, research, teaching medical students, residents, and fellows.

Contents

Preface XIII

Part 1 Basic Concepts in Ophthalmology 1

Chapter 1 **Lasers in Ophthalmology 3**
Magdalena Zdybel,
Barbara Pilawa and Anna Krzeszewska-Zaręba

Chapter 2 **Microsurgical Techniques in Ophthalmology – Current Procedures and Future Directions 25**
Pradeep Prasad, Allen Hu,
Robert Beardsley and Jean-Pierre Hubschman

Chapter 3 **Transient Receptor Potential (TRP) Channels in the Eye 35**
Zan Pan, José E. Capó-Aponte and Peter S. Reinach

Part 2 Cornea and Ocular Surface 47

Chapter 4 **Recent Advances in Mucosal Immunology and Ocular Surface Diseases 49**
De-Quan Li, Zuguo Liu, Zhijie Li,
Zhichong Wang and Hong Qi

Chapter 5 **Trafficking of Immune Cells in the Cornea and Ocular Surface 79**
Yureeda Qazi, Aslihan Turhan and Pedram Hamrah

Chapter 6 **Keratoconus Layer by Layer – Pathology and Matrix Metalloproteinases 105**
Dasha Nelidova and Trevor Sherwin

Chapter 7 **Corneal Surgical Techniques 119**
Miroslav Vukosavljević,
Milorad Milivojević and Mirko Resan

Part 3 Refraction and Refractive Correction 133

Chapter 8 **Incidence of Refractive Error and Amblyopia Among Young Adults – A Hospital Based Study 135**
Ashok Kumar Narsani, Shafi Muhammad Jatoi, Mohan Perkash Maheshwari and Khairuddin Shah

Chapter 9 **Myopia, Light and Circadian Rhythms 141**
John R. Phillips, Simon Backhouse and Andrew V. Collins

Chapter 10 **Etiology and Clinical Presentation of Astigmatism 167**
Sanja Masnec Olujić

Chapter 11 **Wavefront Aberrations 191**
Mirko Resan, Miroslav Vukosavljević and Milorad Milivojević

Chapter 12 **Non-Surgical Treatment of Astigmatism 205**
Luciane B. Moreira

Chapter 13 **Treatment Strategies and Clinical Outcomes of Aspheric Surgery for Astigmatism Using the SCHWIND Amaris Platform 217**
Maria C. Arbelaez and Samuel Arba-Mosquera

Chapter 14 **Comparing Nomograms of Two Symmetric and Two Asymmetric Intacs® Segments Implantation for Treatment of Pellucid Marginal Degeneration 249**
Luis A. Rodriguez and Anny E. Villegas

Chapter 15 **Toric Intraocular Lenses for the Correction of Astigmatism 267**
Milorad Milivojević, Miroslav Vukosavljević and Mirko Resan

Chapter 16 **Amblyopia and Foveal Thickness 279**
Elina Landa, Shimon Rumelt, Claudia Yahalom, Elaine Wong and Lionel Kowal

Part 4 Glaucoma 289

Chapter 17 **Trabecular Surgery 291**
Antonio Fea, Giulia Consolandi, Giulia Pignata, Davide Turco, Paola Cannizzo, Elena Bartoli, Teresa Rolle and Federico M. Grignolo

Part 5 Retina and Vitreous 305

Chapter 18 **A Novel Artificial Vitreous Substitute – Foldable Capsular Vitreous Body 307**
Qianying Gao

Chapter 19 **Endophthalmitis 319**
Phillip S. Coburn and Michelle C. Callegan

Chapter 20 **Retinal Detachment – An Update of the Disease and Its Epidemiology – A Discussion Based on Research and Clinical Experience at the Prince Charles Eye Unit, Windsor, England 341**
Irina Gout, Faye Mellington, Vikas Tah, Mahmoud Sarhan, Sofia Rokerya, Michael Goldacre and Ahmed El-Amir

Chapter 21 **Retinal Vascular Occlusions 357**
Mario Bradvica, Tvrtka Benašić and Maja Vinković

Chapter 22 **Induction of Branch Retinal Vein Occlusion by Photodynamic Therapy with Rose Bengal in a Rabbit Model 399**
Xiao-Xu Zhou, Yan-Ping Song, Yu-Xing Zhao and Jian-Guo Wu

Chapter 23 **Regulation of Angiogenesis in Choroidal Neovascularization of Age Related Macular Degeneration by Endogenous Angioinhibitors 409**
Venugopal Gunda and Yakkanti A. Sudhakar

Chapter 24 **NRF2 and Age-Dependent RPE Degeneration 427**
Yan Chen, Zhenyang Zhao, Paul Sternberg and Jiyang Cai

Chapter 25 **Retinitis Pigmentosa in Northern Sweden – From Gene to Treatment 451**
Irina Golovleva and Marie Burstedt

Chapter 26 **Mechanisms of RDH12-Induced Leber Congenital Amaurosis and Therapeutic Approaches 473**
Anne Kasus-Jacobi, Lea D. Marchette, Catherine Xu, Feng Li, Huaiwen Wang and Mark Babizhayev

Part 6 Eye Plastics and Orbital Disorders 497

Chapter 27 **Eyelid and Orbital Infections 499**
Ayub Hakim

Chapter 28 **Extended Applications of Endoscopic Sinus Surgery to the Orbit and Pituitary Fossa 521**
Balwant Singh Gendeh

Preface

This book covers selected topics in ophthalmology, providing a glimpse into the advancements in different aspects of the field. It is not aimed to cover the whole field of ophthalmology, and hopefully, more topics will be covered in future books. The book is intended for the general ophthalmologists, sub-specialists, researchers, residents, and fellows. It covers both basic and clinical concepts of ophthalmology. Each author incorporated his/her own perspectives on each topic adding his/her won theories, future trends, and research. Therefore, the book should enable researchers and clinicians to adopt new ideas for further basic research and clinical practice.

This book, arranged in a systematic approach, discusses first the general aspects of ophthalmology (surgery), and then disorders affecting different structures of the eye from the cornea and ocular surface backwards to the retina and the structures surrounding the globe. It is a product of a balance between the expedited publishing process and encompassing broad aspects of the field.

This book is a result of multi-national ophthalmologists from around the globe, with a common desire to take care of patients. Some of the authors have been involved for many years within this field, some are just at their beginning. Some authors are researches, others are clinicians. Some are world leaders, others will be. I hope that our readers will be as much a wide variety as our authors are.

The book is accessible online to allow free access to as many readers as possible, and is also available on print for those who do not have online access, or are interested in having their own hard copy. This will definitely contribute to the worldwide distribution of the knowledge on ophthalmology between researchers and clinicians.

I would like to acknowledge each and every one of the contributors for their excellent work on each chapter. Each one of them devoted time and effort to write a chapter, contributing to the success of this book and the advancement of ophthalmology. I would thank Ms. Martina Durovic and Mr. Jan Hyrat, the book Publishing Process Managers for their expert assistance in all the issues concerning this book, to Ms. Ana Nikolic, the Head of Editorial Consultants for her useful assistance, and for all for choosing me to be the editor of the book. My gratitude to the technical editors for arranging the book in a uniform format and for the publisher InTech, for undertaking this mission. Lastly, thanks to my family, teachers, and students from whom I studied throughout the years.

I hope that this book will be part of a series of books in all the sub-specialties of ophthalmology, and that it will be an example for global collaboration, not only between physicians, but also between everyone for the betterment of the humankind. I wish you, the reader, an enjoyable journey throughout ophthalmology and I hope that you will find the book interesting.

Basic Concepts in Ophthalmology

1

Lasers in Ophthalmology

Magdalena Zdybel, Barbara Pilawa and Anna Krzeszewska-Zaręba
Medical University of Silesia in Katowice
Poland

1. Introduction

Lasers emit electromagnetic waves of characteristic properties and energies (Gilmour, 2002; Krzeszewska & Zdybel, 2010; Podbielska et al., 2004; Sieroń et al., 1994; Ziętek, 2009). These specific features are used in the modern ophthalmology (Dick et al., 2010; Evans & Abrahamse, 2009; Gilmour, 2002; Schmidt-Erfurth, 2010; Seitz & Langenbucher, 2000; Soong & Malta, 2009). In this work we described theoretic problems of lasers as the quantum systems, the propagation of laser radiation, the lasers parameters and ranges of them. The historical data about laser apparatus and their applications are cited. The biophysical effects caused by laser radiation in biological structures during therapy are mentioned.

The applications of lasers in ophthalmology are widely taking to account. We described widely the two laser applications in ophthalmology which are connected with paramagnetic species and singlet oxygen. We chose these subjects, because of our experimental experience in spectroscopic studies of paramagnetic centers (Beberok et al., 2010; Buszman et al., 2003, 2005a, 2005b, 2006; Chodurek et al., 2003; Domagała et al., 2008; Latocha et al., 2004, 2005, 2006; Matuszczyk et al., 2004; Najder-Kozdrowska et al., 2009, 2010; Pilawa et al., 2002, 2003a, 2003b, 2005a, 2008c; Zdybel et al., 2009, 2010) and singlet oxygen O_2 with zero spin (Bartłomiejczyk et al., 2008; Latocha et al., 2008; Pilawa et al., 2005b, 2006, 2008a, 2008b). In this work the view of the information in scientific papers is done.

2. Lasers as the quantum systems – Basic theory

2.1 Energy levels

The quantum theory describes the energy levels of atoms and molecules (Glinkowski & Pokora, 1993; Sieroń et al., 1994; Ziętek, 2009). Electrons may move only between these levels, and these transitions are accompanied by emission or absorption of energy by the optical system. The emitted or the absorbed energies reveal the values related to the distances between the energy levels. The system will not absorb the energy, when the energy is lower or higher than the value of the energetic band between the levels. Energy levels of the optical active medium play an important role in laser irradiation. The energy levels of the materials used in laser construction determine the energy necessary to their excitation and the energy of emitted electromagnetic waves is dependent on these levels. The energy (E) of the electromagnetic waves produced by lasers is presented according to the formulas (Bartosz, 2006; Hatfield, 1976; Hewitt, 2001; Jaroszyk, 2008; Ziętek, 2009):

$$E = h\nu \quad (1)$$

$$E = hc/\lambda \quad (2)$$

where h is the Planck constant (h = 6,626 x 10^{-34} Js), c is the speed of the waves (c = 299 792 458 m/s), ν is the frequency of electromagnetic waves in Hertz, λ is the wavelength in meters. The frequency and wavelength determine the color of laser radiation.

The emitted energy is fitted to the biological structures treated by the individual lasers, so the reason of the majority of lasers used in ophthalmology is understandable. Summing up, the lasers produce electromagnetic waves with the given energy correspond to the energy levels of their optical systems, and it interact on the specific tissues or cells.

2.2 Optical pumping

Condition of absolute emission of radiation by laser is the previous excitation of its active optical system e.g. molecules formed in this system (Glinkowski & Pokora, 1993; Sieroń et al., 1994; Ziętek, 2009). This excitation is called the optical pumping. Excitation of molecules in laser may be done by electromagnetic waves emitted by lamps, by heating or by energy of electrical field (Podbielska et al., 2004; Sieroń et al., 1994).

2.3 Inversion of electron location on the energy levels

As the result of the optical pumping of the quantum molecular system, higher amount of electrons are located on the levels of the higher energy than those of the lower energy (Glinkowski & Pokora, 1993; Podbielska et al., 2004; Sieroń et al., 1994; Ziętek, 2009). The continuous propagation of energy to the system of electrons in molecules causes that the electrons upon absorption of this energy moves to the higher energy levels. Afterwards they return to the lower energy states via relaxation processes. The time of electron-lattice relaxation processes depends on the molecular structure of the optical system in lasers. Electron-lattice relaxation is the transition of the electrons from the excited energy levels to the ground energy levels via magnetic interactions with diamagnetic lattice molecules (Stankowski & Hilczer, 2005; Wertz & Bolton, 1986). The long time of interactions of electrons with the lattice causes the mentioned above inversion. The pumped electrons stay on the higher energetic level and the former irradiation of the molecular system in laser do not pump electrons to the higher levels, because of their absence in the lower energy levels (Ziętek, 2009). The inversion of electrons location on levels is useful to the former effective stimulation emission of radiation in laser apparatus (Glinkowski & Pokora, 1993).

2.4 Stimulated emission of radiation

The name of the **LASER** apparatus comes from the roles of its work as the "**L**ight **A**mplification of **S**timulated **E**mission of **R**adiation" (Maiman, 1960). Two types of emission of electromagnetic waves, the spontaneous and stimulated emissions, are known (Bartosz, 2006; Hatfield, 1976; Hewitt, 2001; Jaroszyk, 2008; Krzeszewska & Zdybel, 2010; Morrish, 1970; Sieroń et al., 1994). Spontaneous emission is the ordinary effect of energy loosening by the excited electrons at the non defined moment. Spontaneous emission is the result of the principle that the optimal state of the system is the state with the lowest energy (Glinkowski & Pokora, 1993; Jóźwiak & Bartosz, 2008; Sieroń et al., 1994; Ziętek, 2009). The stimulated

emission is the most important effect to produce laser irradiation. The scheme of stimulated emission of radiation is shown in Figure 1, which was prepared according to the definition of this effect presented in (Sieroń et al., 1994). The stimulated emission of radiation is the controlled effect of energy loosening by the electrons. Before the proper effect of stimulated emission the electron is excited, for example by pumped photons, to the higher energy level. After this the stimulated photon is emitted to the system and at this moment two photons of the same energy are emitted. The energy of the individual emitted photon is equal to the difference between energy of the excited and ground state energy levels. The amplification of the energy of radiation is the effect of emission of these two photons after absorption of one exciting photon by electron. The radiation comes from stimulated emission consist of photons of the same energy so of the same frequency. It means that laser produce monochromatic electromagnetic waves. Monochromatic electromagnetic waves are the same frequency waves (Ziętek, 2009).

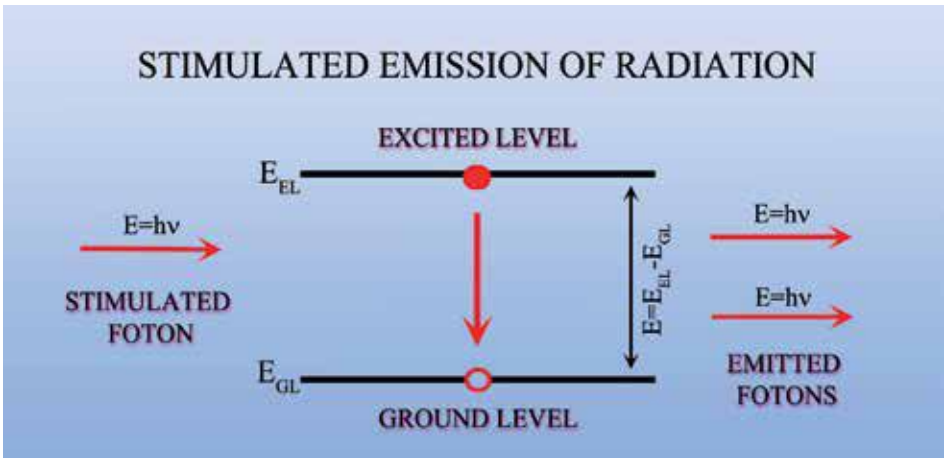

Fig. 1. The scheme of the stimulated emission of radiation prepared according to its definition in (Sieroń et al., 1994).

The exemplary way of the electrons between the three energy levels during laser action is described in work of Sieroń et al. (Sieroń et al., 1994). The main energy levels of electrons are the ground, non-stabile excited, and the quasi-stabile levels, respectively. Electrons are pumped by photons to the non-stabile level with the highest energy in this quantum system. Energy of the pumped photons is equal difference between energy of the non-stabile level and the ground level. Afterwards the electrons without radiation come to the quasi-stabile energy level located lower than the non-stabile level. During the optical pumping there is an increase in number of electrons on quasi-stabile level. At the moment dependent on the type of laser the effect of inversion of distribution of electrons in the energy levels occurs. The higher number of electrons stays on the quasi-stabile level than on the ground level with the lowest energy. The pumping is stopped then and the stimulating photons are sent to the electrons system. At the same time, at the moment of interactions of electrons with stimulated photons the stimulated emission appears. All the electrons located on the quasi-stabile energy level come to the ground energy level. The photons connected with the transition and the stimulated photons are irradiated. The emitted electromagnetic waves have properties of laser radiation, which are described in the next part of this chapter.

3. The properties of laser radiation

Laser radiation as electromagnetic waves differs from the light emitted by the ordinary lamp (Hewitt, 2001). The white light emitted from bulb is superposition of electromagnetic waves with frequencies and wavelengths corresponding to the background colors: red, orange, yellow, green, blue, and violet. The frequencies of the waves increase in the previously given order, and the wavelengths decreases in this manner. The summing of these electromagnetic waves of different colors gives the effect of white light. The component waves in the white light are not coherent. Coherent waves are the waves with the same phase shift (Ziętek, 2009). The component electromagnetic waves in the beam of white light are shown in Figure 2a constructed according to (Hewitt, 2001).

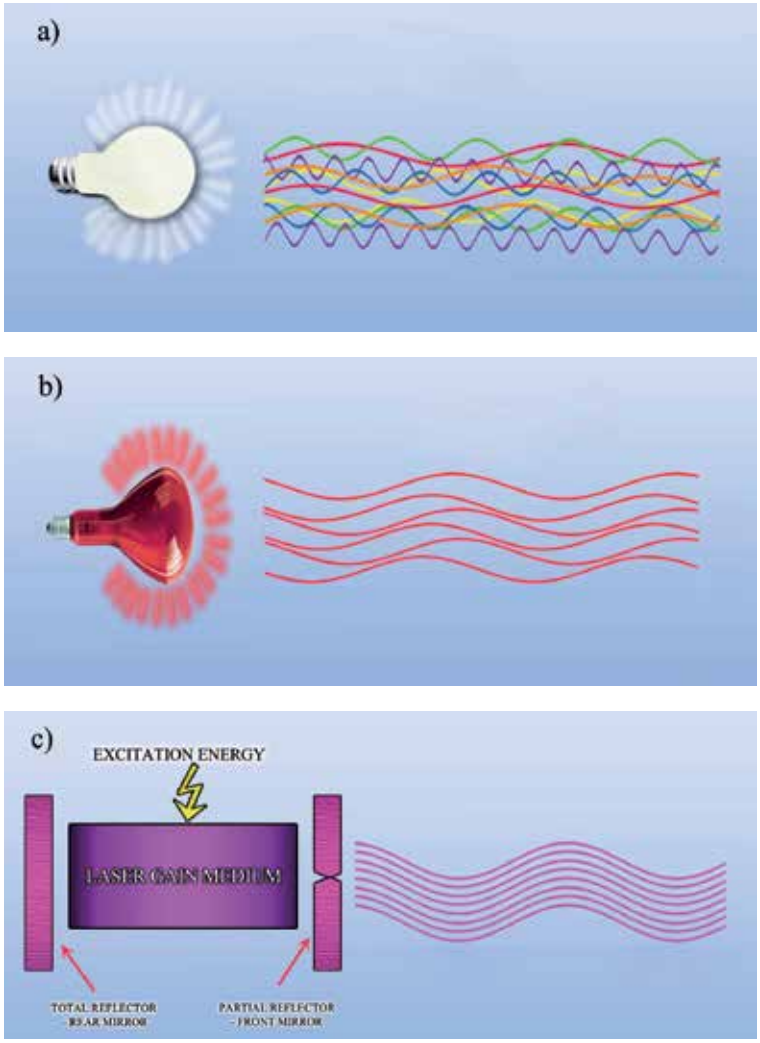

Fig. 2. The electromagnetic waves emitted by: the ordinary lamp produced the white light (a), the source of the monochromatic light (b), and laser (c). The scheme is prepared according to (Hewitt, 2001).

The monochromatic light from the lamp consists of electromagnetic waves of the same frequencies and the same wavelengths (Hewitt, 2001). The waves are not coherent. The electromagnetic waves in the beam of monochromatic light reveal different phases. The monochromatic and incoherent waves are presented in Figure 2b, which was prepared according to (Hewitt, 2001). The fine examples of monochromatic light are the red waves emitted by SOLLUX lamp (Hewitt, 2001).

Lasers produce monochromatic electromagnetic waves (Glinkowski & Pokora, 1993; Hewitt, 2001; Sieroń et al., 1994; Ziętek, 2009). The properties of laser radiation distinguish it from the ordinary white or monochromatic light (Figure 2c) (Hewitt, 2001). The laser waves are monochromatic and coherent. Contrary to white light, laser radiation is monochromatic and in the same phase.

Laser radiation differs from electromagnetic waves sending by the therapeutic BIOPTRON lamps (Straburzyńska-Lupa & Straburzyński, 2004). The BIOPTRON lamp produces electromagnetic waves of the same frequency, but they are incoherent (Figure 3) (Straburzyńska-Lupa & Straburzyński, 2004). The maxima and minima of energy appear on the area of the tissue exposed to coherent laser irradiation. The homogeneous distribution of energy on irradiated area is characteristic for BIOPTRON light.

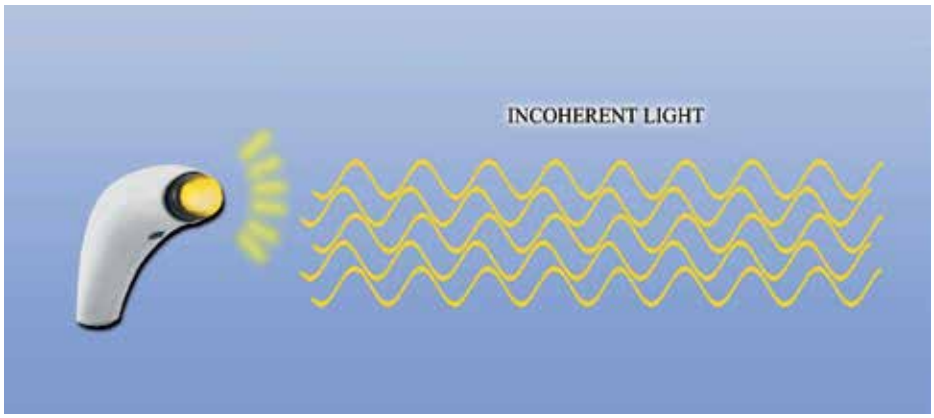

Fig. 3. The electromagnetic waves emitted by BIOPTRON lamps. Prepared according to (Straburzyńska-Lupa & Straburzyński, 2004).

Laser electromagnetic waves in the environment propagate as perpendicular electric and magnetic fields (Hewitt, 2001). The ranges of wavelength of electromagnetic waves emitted by lasers are showed on figure 4. The values of the wavelengths are cited from (Gilmour, 2002; Ziętek, 2009). The biophysical and biological effects on tissues depend on the energy and the wavelengths of electromagnetic waves (Gilmour, 2002; Jaroszyk, 2008).

There are three basic effects of lasers on biological tissues: photochemical (photoablation and photoradiation), thermal (photocoagulation and photovaporation), and ionizing (photodisruption) (L'Esperance, 1983; Podbielska et al., 2004). The photochemical effects are the result of absorption of energy of laser radiation by molecules in tissues without their destruction. During photoablation the absorption of laser energy causes the increase of temperature of the tissues. Practically the photoablation is caused by the short laser pulses

of high energy. Photoradiation is the effect which appears after the transition of the excited by laser molecules in tissues to the ground or the lower energy levels with accompanied radiation of electromagnetic waves. These electromagnetic waves may be responsible for biostimulation effects and tissue temperature rise. Thermal effects interact mainly by the increase of temperature of the tissues after laser irradiation. Photocoagulation causes the increase of temperature in tissues up to 80-90°C via absorption of the laser energy.

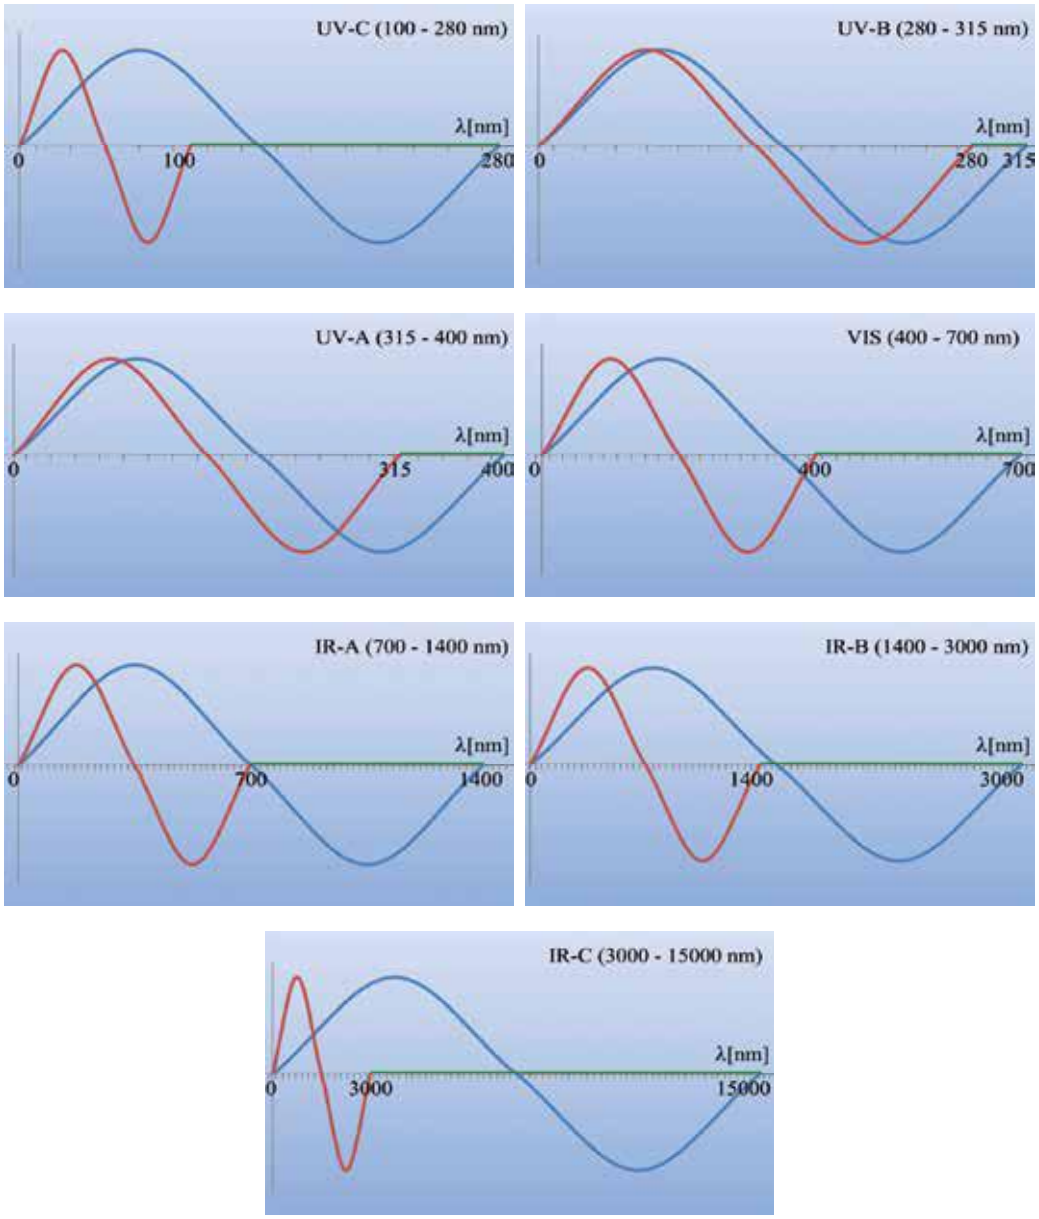

Fig. 4. The ranges of length of electromagnetic waves emitted by lasers. The values of the wavelengths (λ) are cited from (Gilmour, 2002; Ziętek, 2009).

The photocoagulation closes blood and lymphatic vessels, and causes of the necrosis of tissues. Photocoagulation denatures proteins and inactivates enzymes. The laser irradiation of high energy which causes the increase of temperature of the tissues up to 100-300°C is called as the photovaporation. The using of lasers with the high energy of pulse lead to photodisruption effects via ionization in tissues. The ionization is accompanied by the formation of shock waves. The photodisruption effects play an important role in the microsurgery of the front part of the eye.

UV-C and UV-B waves cause increase of pigmentation, burns and photokeratitis (Ziętek, 2009). UV-A waves cause burns, photosensitizing reactions, intensification of dark pigment production, and cataract (Ziętek, 2009). The visible light may destruct retina, lead to burn, and photosensitizing reaction. IR-A and IR-B waves may be responsible for burns and the others thermal destruction of epithelium and cataract. IR-B and IR-C waves may destruct cornea (Ziętek, 2009).

4. History of lasers application in ophthalmology

The history of lasers is connected with the basic theory of quantum radiation presented by Albert Einstein in 1916 (Wróblewski, 2006). This theory defines and characterizes spontaneous and stimulated emission of radiation by atoms. The method of optical pumping of atoms was discovered by Alfred Kastler and Jean Brossel in 1949 (Wróblewski, 2006) and in 1966 Kastler received the Nobel Prize. The inversion of electron localization on energy levels and the effect of stimulated emission of radiation were practically discovered by Edward Purcell and Robert Pound in 1950 (Wróblewski, 2006). In 1960 Theodore Harold Maiman constructed the ruby laser (Al_2O_3:Cr^{3+}) emitting light of 694 nm, which is still used in ophthalmology (Seitz & Langenbucher, 2000; Wróblewski, 2006; Ziętek, 2009). In Poland the first ruby laser was constructed by Zbigniew Puziewicz group from Military University of Technology in 1963 (Podbielska et al., 2004). The following types of lasers: helium-neon (He-Ne) (1150 nm), semiconducting, carbon dioxide (CO_2) (10600 nm), argon (476.5 nm, 488.0 nm, 514.5 nm), hydrogen (H_2) (102.5-123.9 nm), excimer (172 nm), and gallium nitride (GaN) (365 nm), were built in 1961, 1962, 1963, 1964, 1970, 1974, 1991, respectively (Ziętek, 2009). The krypton (647.1 nm, 568.2 nm, 530.8 nm) and neodymium: yttrium-aluminum-garnet (Nd:YAG) (1064 nm) lasers were introduced to clinical applications in 1972 and 1980, respectively (L'Esperance, 1983).

The ruby (694 nm) laser is used in the therapy of the following ocular structural defects: retinal tears, peripheral pigmentary degeneration and lattice degeneration of the retina (L'Esperance, 1983). Argon laser is used in the structural defects of the retina and choroid (L'Esperance, 1983). Krypton (647.1 nm) laser is mainly used in outer retinal structural diseases (L'Esperance, 1983). Krypton red laser photocoagulation is exemplary performed in retinal hemorrhagic diseases, retinal edematous diseases, pigment epithelial abnormalities (L'Esperance, 1983). Carbon dioxide laser is applied in operations with the high blood loss (L'Esperance, 1983).

In 1940 light was used in ophthalmology to coagulation of the retina by Gerd Meyer-Schwickerath (Seitz & Langenbucher, 2000). In Poland the first ruby (694 nm) laser coagulator to ophthalmology was constructed in 1965 (Podbielska et al., 2004). In 1961 Campbell applied confocal laser system to retinal coagulation. In 1971 argon laser was by the first used in eye surgery (Seitz & Langenbucher, 2000). In 1977 Nd:YAG (1064 nm) laser was used to microexplosion by Franz Fankhauser and Daniele Aron-Rosa. The history of

lasers in ophthalmology is broadly described in the paper of Berthold Seitz (Seitz & Langenbucher, 2000).

5. Types of lasers using in ophthalmology

The group of lasers used in ophthalmology produces coherent electromagnetic radiation of different wavelengths (Dick et al., 2010; Evans & Abrahamse, 2009; Gilmour, 2002; Schmidt-Erfurth, 2010; Seitz & Langenbucher, 2000; Sieroń et al., 1994; Soong & Malta, 2009). Optical systems of ophthalmologic lasers are: CO_2, excimer, argon, tunable dye, Nd:YAG (Gilmour, 2002). Optical systems of excimer lasers contain molecules of dimmers of noble gases as argon fluoride (ArF), krypton fluoride (KrF) and xenon fluoride (XeF) (Ziętek, 2009).

The therapeutic effects as photocoagulation, photoablation, ablation via plasma, interact on eye structures. Photocoagulation is performed by the following lasers: blue-green (488-514 nm) and green (514 nm), argon, krypton red (647 nm), diode infrared (810 nm), Nd:YAG infrared (1064 nm) (Gilmour, 2002). Photoablation is carried on by lasers: excimer ultraviolet (193 nm), holmium: yttrium-aluminum-garnet (Ho:YAG) infrared (2060 nm), erbium: yttrium-aluminum-garnet (Er:YAG) infrared (2940 nm), and CO_2 infrared (10,600 nm). Ablation by plasma is done by pulsed infrared neodymium: yttrium lithium fluoride Nd:YLF (1053 nm) laser (Gilmour, 2002).

6. Parameters of lasers radiation using in ophthalmology

The power of laser is the energy emitted by laser during one second (L'Esperance, 1983; Sieroń et al., 1994). The lasers of low (4-5 mW), medium (6-500 mW), and high (above 500 mW) powers are used in medicine (Sieroń et al., 1994). The examples of lasers of low, medium and high powers are ruby, Nd:YAG, semiconducting (Podbielska et al., 2004; Ziętek, 2009). The lasers of low powers are called the soft lasers, and lasers which emit electromagnetic wave of high power are called hard lasers. The classification of lasers correspond to their irradiated power are shown in Figure 5 (Glinkowski & Pokora, 1993; Sieroń et al., 1994).

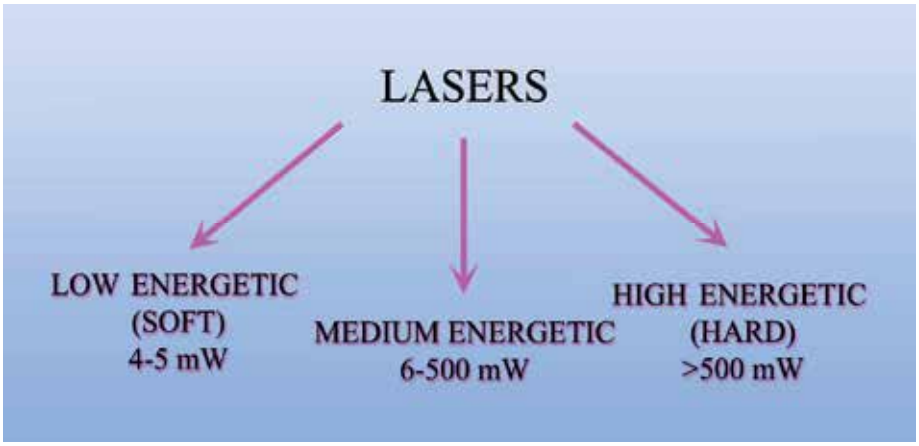

Fig. 5. Classification of lasers corresponds to power of radiation. The values of electromagnetic powers are sited from (Glinkowski & Pokora, 1993; Sieroń et al., 1994).

The biophysical effects in biological systems under laser irradiation are described by Sieroń et al. (Podbielska et al., 2004; Sieroń et al., 1994). Photochemical, thermal and acoustic effects appear during laser radiation propagation in biological samples. Photochemical reactions mainly exist in melanin biopolymers, enzymes, photosensitizers, and hemoglobin, which strongly absorb its energy. Thermal effects take place not only in the irradiated units, but they are also observed in the neighboring structures, because of thermal conductivity of the tissues. The lasers of the highest power cause heating, strong electric field, microplasma formation, increase of pressure, and as the result acoustic effects appear in the tissues.

The soft lasers with the low energy emitted to tissues during one second are used to biostimulation effects (Podbielska et al., 2004; Sieroń et al., 1994). The soft ruby lasers with low energy may be used to biostimulation (Podbielska et al., 2004). The light initiates and increases biochemical reactions. Lasers of medium power are applied in photodynamic therapy. Hard lasers are used to destruction of tissues mainly via thermal effects (Sieroń et al., 1994). Non-thermal effect of photo-destruction occurs in the irradiated structures, when the laser of high power interacts with biological system during the very short time (Podbielska et al., 2004; Sieroń et al., 1994). Free radicals may be produced by lasers of the three mentioned above ranges of power.

The power dose, time, methods, and pulse frequency should be taken to account during planning the laser therapy (Podbielska et al., 2004; Sieroń et al., 1994; Ziętek, 2009). The power, density of power, and density of energy should be correlated to the application of laser. Density of laser power I [W/m^2] is the power related to one square meter of the irradiated area. Density of laser energy H [J/m^2] is the power related to one square meter of the irradiated area (Podbielska et al., 2004; Sieroń et al., 1994; Ziętek, 2009).

7. Application of lasers in ophthalmology

The large amount of laser applications in ophthalmology is known. In that kind of medicine the excimer, argon, krypton, Er:YAG, Nd:YAG and semiconductor lasers are usually used (Dick et al., 2010; Evans & Abrahamse, 2009; Gilmour, 2002; Schmidt-Erfurth, 2010; Seitz & Langenbucher, 2000; Soong & Malta, 2009). The use of lasers in ophthalmology comes down to coagulate, cut and leads to photoablation. Laser radiation can reach the eyeball and focus on the retina and other locations within the eye without surgical intervention. The most common disease which are treated with laser light are glaucoma, cataract, retinal detachment, diabetic retinopathy (Fankhauser & Kwasniewska, 2003; Gilmour, 2002).

Glaucoma is an eye disease in which the optic nerve suffers damage (Chung & Guan, 2006; Eckert, 2010; Herdener & Pache, 2007; Hoffmann & Schulze, 2009; Juzych et al., 2004; Kanamori et al., 2006; Keicher & Stoffelns, 2010; Ngoi et al., 2005; Preußner et al., 2010; Schlote et al., 2008; Wilmsmeyer et al., 2006). It causes permanently decay of vision and if it is untreated it progresses to complete blindness. Glaucoma is often associated with increased pressure of the eye fluid (Gilmour, 2002). The cases in which there is constantly raise of intraocular pressure without any associated optic nerve damage are called ocular hypertension. In that case there is no glaucoma damage. The cases in which there is normal or low ocular pressure with typical for glaucoma visual field are called normal or low tension glaucoma. However, raised intraocular pressure is still the most significant risk factor for glaucoma progression. The permanent damage of the optic nerve and blindness are the effects of untreated glaucoma (Chung & Guan, 2006; Eckert, 2010; Herdener & Pache,

2007; Hoffmann & Schulze, 2009). There are two main categories of glaucoma - open or closed angle. First of them progresses much slower than the other and in this case patient can have any notice of vision lose. In the closed angle glaucoma, the symptoms of disease can appear rapidly (Chung & Guan, 2006). Gradual loss of vision occurs with open angle and chronic angle-closure glaucoma and with acute angle-closure glaucoma. That is why that kind of disorder it is recognized when the disease is quite advanced. In glaucoma once lost visual field cannot be recovered. There is about two percent chance of glaucoma progression in people with a family history of this eye disease. Both laser surgeries and conventional surgeries are performed to treat glaucoma. Selective laser trabeculoplasty (SLT) is one of the newest, efficient methods for the treatment of open angle glaucoma, pseudoexfoliative glaucoma and pigmentary glaucoma. In that kind of treatment Q switch Nd:YAG laser with a wavelength of 532 nm is usually used (Eckert, 2010; Gilmour, 2002). This laser affects on the cells of the trabecular meshwork but it does not cause any destruction or coagulation. The second method of laser treatment in glaucoma is argon laser trabeculoplasty (ALT). That method is focused on drainage correction of fluid from the eye. As a result the intraocular pressure is lower (Wilmsmeyer et al., 2006). In open angle glaucoma the drainage site of the eye does not function normally. In that disorder the iris is encircled by the trabecular meshwork of an eye. The increase of pressure is the result of difficult in drainage. In ALT therapy an argon laser beam is directed at the trabecular meshwork. As the effect the trabecular meshwork drain fluid more effectively (Eckert, 2010; Wilmsmeyer et al., 2006). Nd:YAG and argon lasers are used in iridotomy (L'Esperance, 1983). Argon lasers may be used in iridoplasty (L'Esperance, 1983).

Laser therapy is used in cataract too (Baratz et al., 2001; Çinal et al., 2007; Gilbert, 2011; Hille et al., 2001; Kanellopoulos & Group, 2001; Mahdavi, 2011; Shammas & Shammas, 2007; Verge´s & Llevat, 2003). The cataract is a disease that develops in the crystalline lens of an eye. It can block the passage of light and causes problems from slight to complete opacity. In age-related cataract the power of the lens may be increased, causing near-sightedness called myopia. The opacification of the lens may also reduce the perception of blue colors. Cataract typically progresses slowly and causes vision loss (Gilmour, 2002). That kind of disease potentially induces blinding if it is untreated. Cataract usually affects both eyes, but in most cases one eye is affected earlier than the other. A senile cataract which occurs in the elderly is characterized by an initial opacity and subsequent edema of the lens. One of the most popular cataract treatments nowadays is laser surgery, which uses light to dissolving cataract. The most popular method of cataract surgery is phacoemulsification. In that kind of treatment nucleus is cracking or chopping into smaller pieces. This fragmentation makes emulsification easier. Emulsification of the lens using the Er:YAG laser is very effective for performing small incision cataract surgery in eyes with soft and medium nuclei. The small ablation zones which are created during treatment can help prevent damage to surrounding ocular structures. The Er:YAG technique causes low ablation energy and does not result in thermal injury (Duran & Zato, 2001). Another method involves the removal of almost the entire natural lens while the elastic lens capsule is left intact to allow implantation of an intraocular lens. It is called conventional extracapsular cataract extraction (ECCE). That kind of treatment may be indicated for patients with very hard cataracts or other situations in which phacoemulsification is problematic. Increasingly to remove the pupillary membranes developed after ECCE is used Nd:YAG laser (Kozobolis et al., 1997). Intracapsular cataract extraction (ICCE) is rarely performed kind of cataract surgery, because of high rate of complications. It involves the removal of the lens and the surrounding lens capsule in one

piece. After lens removal, an artificial plastic lens - implant is placed (Gilbert, 2011; Kanellopoulos & Group, 2001).

Lasers are also used in medical operations in the field of refractive eye surgery (Gilmour, 2002; Glinkowski & Pokora, 1993; Kim et al., 2011). The main aim of that kind of treatment is to achieve the correct relationship between the length of the eyeball and the power of its optical centers. This is possible by modifying the other shell knobs and intraocular tissues. Refractive surgery can eliminate the necessary of use the contact lenses or glass (Krzeszewska & Zdybel, 2010).

At the beginning of the development of refractive eye surgery procedures used CO_2 lasers (Glinkowski & Pokora, 1993; Kim et al., 2011). However, because of emerging adverse effects they were abandoned. Currently pulsed excimer laser emitting a beam with a wavelength of 193 nm is used during surgeries. The pulses from the beam which is transmitted last from 10 ns to 20 ns. This laser radiation penetrates the cornea to a depth of 1 μm leading to photoablation of the tissue (Krzeszewska & Zdybel, 2010). This is the most common refractive method nowadays. Excimer laser ablation is done under a partial-thickness lamellar corneal flap. While refractive surgery is becoming more affordable and safe, it may not be recommended for everybody. Patients that have medical conditions such as glaucoma, diabetes uncontrolled cardiovascular disease, autoimmune disease, pregnant women or people with certain eye disease are not good candidates for refractive surgery (Kim et al., 2011). Although the risk of complications is decreasing compared to the early days of refractive surgery, there is still a small chance for serious problems. It may appear vision problems such as double-vision, ghosting, halos, starbursts and dry-eye syndrome. Refractive surgery is used in myopia, hyperopia and astigmatism treatment (Gilmour, 2002; Seitz & Langenbucher, 2000).

Myopia is an eyes disease with a refractive defect (Gilmour, 2002). In that kind of disorder while accommodation relaxes, the collimated light produces image focus in front of retina. In other words it is a condition of the eye where the light that comes in does not directly focus on the retina. Because of that the image that one sees is out of focus when looking at a distant object but comes into focus when looking at a close object (Seitz & Langenbucher, 2000).

Hyperopia is a vision defect caused by an imperfection of an eye causing difficulty focusing on near objects and in extreme cases causing a sufferer to be unable to focus on objects at any distance. In that kind of disease power of the cornea and lens is insufficient and the image appears blurred (Gilmour, 2002).

Astigmatism is the visual defect, which is the result of an inability of the cornea to properly focus an image onto the retina. As the effect the image is blurred (Seitz & Langenbucher, 2000).

Laser subephithelial keratomileusis (LASEK) and laser in-situ keratomileusis (LASIK) processes are very common in laser surgery (Gilbert, 2011; Hille et al., 2001; Kanellopoulos & Group, 2001; Verge´s & Llevat, 2003). In LASEK which is the laser epithelial keratomileusis, the cornea's surface layer is treated with alcohol and peeled back to reshape the layer underneath. LASIK prevents most problems of postoperative pain, slow rehabilitation and corneal haze (Kanellopoulos & Group, 2001; Shammas & Shammas, 2007).

Lasers are also very useful tools in the management of malignant and benign intraocular lesions, nowadays. One of the most popular methods for small melanomas treatment is transpupillary thermotherepy (TTT) using 810 nm infrared laser. That kind of treatment can

be used in medium and large melanomas as combination therapy with other treatment modalities (Gilmour, 2002).

The important application of lasers in the modern ophthalmology is their use in photodynamic therapy (PDT) (Podbielska et al., 2004). Photodynamic therapy was recently used to treat wet age-related macular degeneration (AMD). That kind of therapy was used for monitory of cases in AMD (Gilmour, 2002; Nakata et al., 2011). Now PDT is used in polypoidal choroidal vasculopathy (Akaza et al., 2007; Nakata et al., 2011; Podbielska et al., 2004). In PDT lasers with the medium range of electromagnetic radiation power are used (Podbielska et al., 2004). The molecules of photosensitizers and their excitation by laser play the most important role in this method. Laser radiation of the proper energy excites the photosensitizer molecules, which come to the next excited energy level, and after it comes to the lower energy level via sending the energy to the eye structures. The scheme of the processes in photodynamic therapy is presented in Figure 6. This scheme was prepared according to the work (Podbielska et al., 2004).

These optical processes form reactive free radicals and oxygen molecules O_2 in the singlet state in eye (Fig. 6) (Podbielska et al., 2004). Free radicals and oxygen molecules damage the pathologically changed structures in eye. Free radicals are the paramagnetic molecules containing unpaired electrons and the short lifetime characterize them, because of free radicals interactions with both dia- and paramagnetic molecules in tissues. Mainly the reactive oxygen species are formed upon laser irradiation during photodynamic therapy, especially hydroxyl radicals (OH) and superoxide radical anion (O_{2^-}) (Podbielska et al., 2004). Single oxygen molecules are diamagnetic, but this oxygen form is higher reactive than paramagnetic oxygen molecules in the ground state, because of the most molecules in the environment are diamagnetic, so the reactions between the similar units go easier (Bartosz, 2006; Podbielska et al., 2004).

Free radicals and singlet oxygen in the physiology are not expected, but their formation in the pathological state of organism during photodynamic therapy is the most important effect (Bartosz, 2006; Jóźwiak & Bartosz, 2008; Podbielska et al., 2004). Free radicals and singlet oxygen damage the pathologically changed tissue. The condition of laser irradiation should be fitted to the conditions of the highest formation of free radicals and singlet oxygen.

Free radicals (S = 1/2) may be directly detected by electron paramagnetic resonance (EPR) spectroscopy (Eaton et al., 1998; Jóźwiak & Bartosz, 2008; Kęcki, 1999; Kirmse & Stach, 1994; Morrish, 1970; Stankowski & Hilczer, 2005; Symons, 1987; Wertz & Bolton, 1986). Electron paramagnetic resonance effect is characteristic for unpaired electrons located in magnetic field of magnetic induction B (Stankowski & Hilczer, 2005; Symons, 1987; Wertz & Bolton, 1986). The electromagnet and the cavity of EPR spectrometer is presented in Figure 7. The Zeeman splitting of energy levels occurs in magnetic field. The spin magnetic moments orientations - parallel and anti-parallel to magnetic field are responsible for Zeeman Effect. Zeeman Effect is the effect of splitting of energy levels of unpaired electrons in the magnetic field as the result of parallel or non parallel electron magnetic moments orientations in this field (Stankowski & Hilczer, 2005; Wertz & Bolton, 1986). The quantization of magnetic moments of unpaired electrons with spin S in magnetic field results from the 2S + 1 (S, S-1, …, -S) possible values of magnetic spin quantum number M_S. Energy of these states is given by the following formula (Stankowski & Hilczer, 2005; Wertz & Bolton, 1986):

$$E(M_S) = g\,\mu_B\,B\,M_S \quad (3)$$

where: E – energy, M_S – magnetic spin number, g – spectroscopic factor, μ_B – Bohr magneton, B – induction of magnetic field.

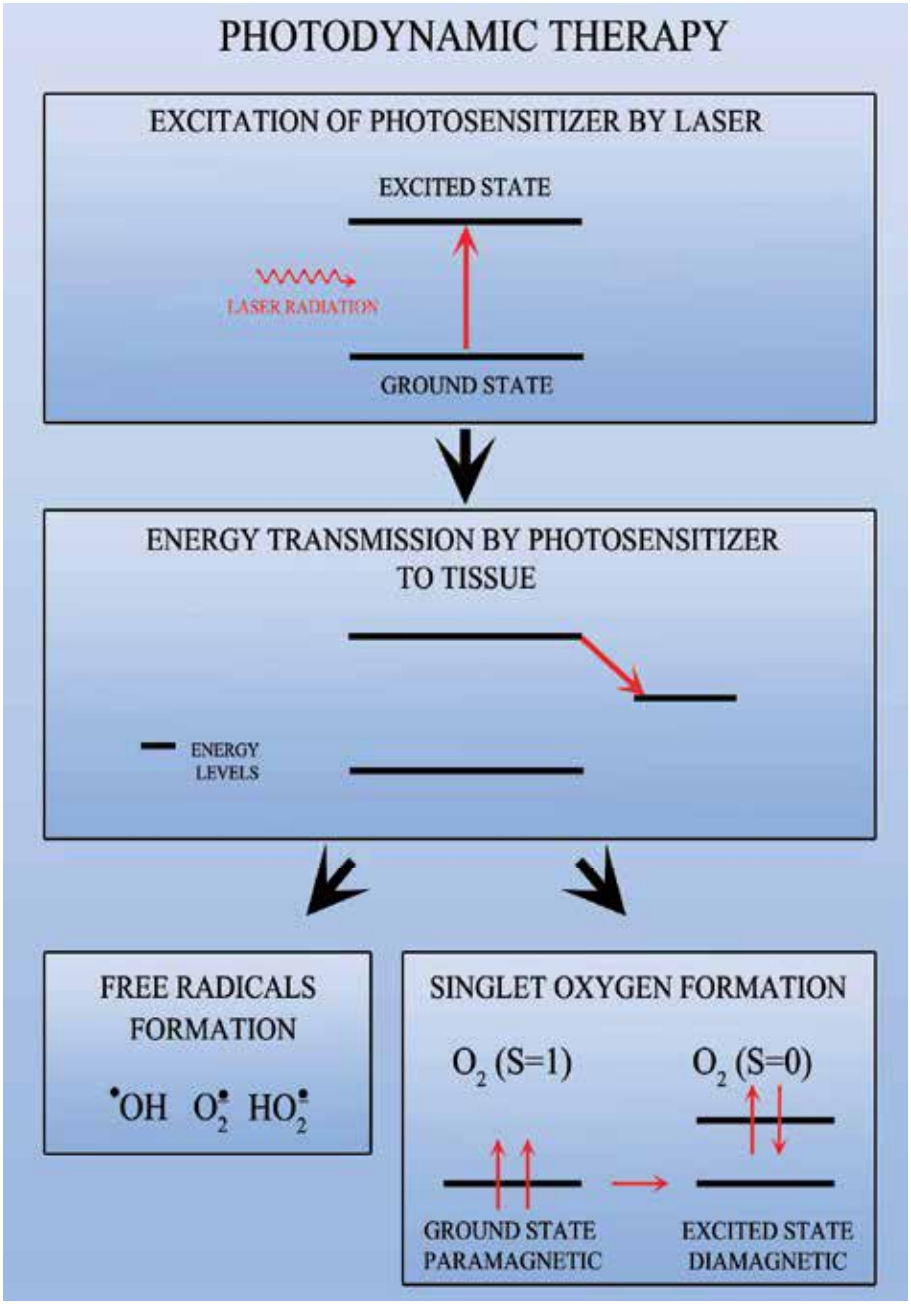

Fig. 6. Photodynamic therapy processes. Prepared according to (Podbielska et al., 2004).

Unpaired electrons are excited to the higher energy levels in magnetic field by microwaves (Stankowski & Hilczer, 2005; Symons, 1987; Wertz & Bolton, 1986). The energy of microwaves (hv) must be fitted to the distances between energy levels (ΔE) of unpaired electrons (Stankowski & Hilczer, 2005; Wertz & Bolton, 1986):

$$h\nu = \Delta E = g\,\mu_B\,B \tag{4}$$

where v is the frequency of microwaves.

The frequency of microwave from the basic X-band is 9.3 GHz. The equation (4) is called the electron paramagnetic resonance equation. The absorbed energy by unpaired electrons is presented in EPR spectroscopy as the resonance spectrum. The EPR spectra inform about the type and number of paramagnetic centers in the sample. The individual paramagnetic centers give EPR signals in characteristic magnetic field. The amplitude and integral intensity of EPR lines increase with the increasing of paramagnetic centers concentration in the sample. Multi-component EPR spectra as the superposition of several lines are measured for the samples with complex paramagnetic centers system consisting of different types of paramagnetic species (Stankowski & Hilczer, 2005; Wertz & Bolton, 1986).

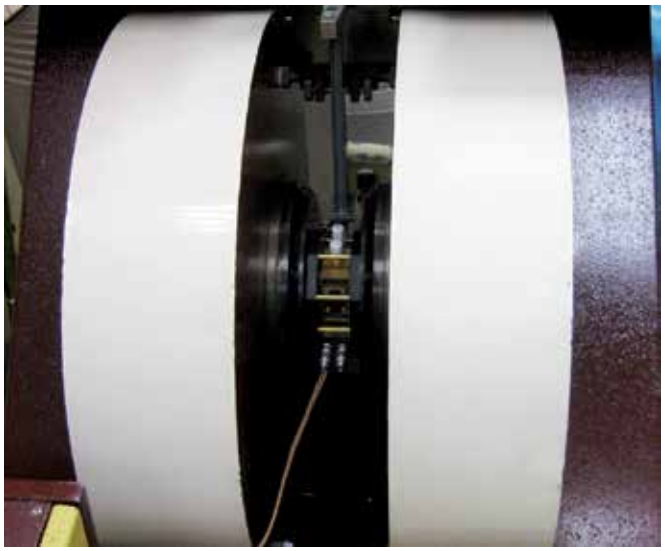

Fig. 7. The resonance cavity and electromagnet of EPR spectrometer.

Free radicals formation during laser irradiation of tumor cells with photosensitizers was studied by us earlier (Latocha et al., 2004, 2005, 2006). The observation of the changes of the amount of free radicals in eye structures irradiated by lasers is proposed in this work. The optimal conditions of PDT in ophthalmology may be search by EPR spectroscopy as the conditions with the highest free radical formation. Similar application was discussed by us for PDT of different tumor cells (Latocha et al., 2004, 2005, 2006).

The optimal conditions of photodynamic therapy are also accompanied by the highest formation of singlet oxygen. Singled oxygen as the diamagnetic molecule may be measured by EPR spectroscopy only by the use of oximetric probes. Oximetric probe is the paramagnetic sample which EPR spectrum strongly changes under changes of the concentration of singlet oxygen in its environment. Our previous results indicates that coal multi-ring aromatic samples may be used as the oximetric probes (Bartłomiejczyk et al., 2008; Latocha et al., 2008; Pilawa et al., 2005b, 2006, 2008a, 2008b). The coal oximetric probes were synthesized by Helena Wachowska group from Institute of Chemistry of Adam Mickiewicz University in Poznań (Poland). Scheme of the idea of application of EPR method and coal oximetric probe is shown in Figure 8. Coal paramagnetic probe contains chemical structures with unpaired electrons with the high probability of interactions with oxygen molecule O_2. Before laser irradiation paramagnetic molecules in the ground triplet state with spin of 1 mainly exist in the environment of the oximetric probe. Paramagnetic oxygen quenches EPR lines of coal probe. After laser irradiation the amount of paramagnetic oxygen molecules decreases, so the amplitudes of the EPR lines of coal probe increase. Under laser irradiation the paramagnetic oxygen molecules become diamagnetic, so the increase of the EPR line of coal probe is proportional to the singlet oxygen formation (Bartłomiejczyk et al., 2008; Latocha et al., 2008; Pilawa et al., 2005b, 2006, 2008a, 2008b). Such methods may be proposed in ophthalmology.

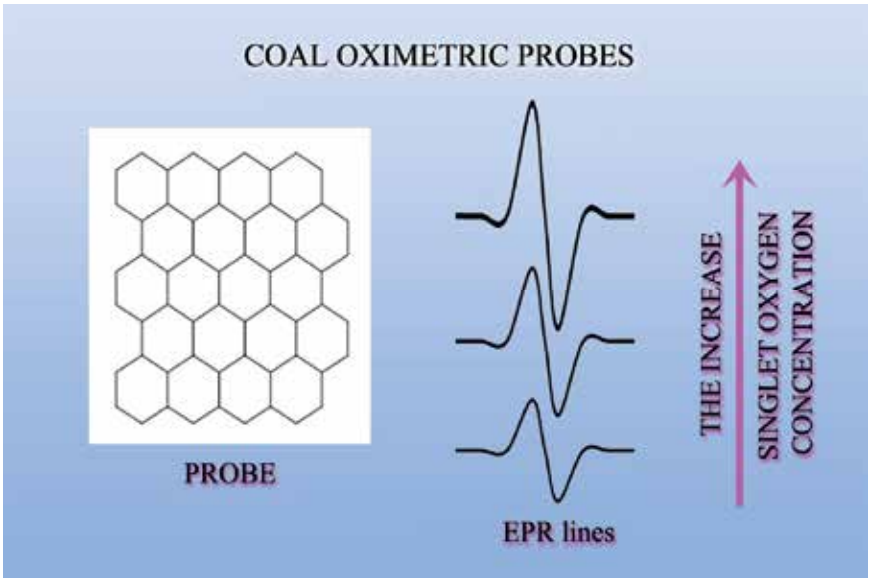

Fig. 8. Potential coal oximetric probe and the changes of its EPR line with increasing of singlet oxygen concentration in the environment.

Lasers in ophthalmology is used to the damage the eye structures via conducting of the energy from melanin biopolymer to them (Gilmour, 2002). Mainly eumelanins with the chemical structure presented in Figure 9 exist in eye (Bilińska et al., 2002; Pasenkiewicz-Gierula, 1990; Sarna, 1981; Zdybel, 2008).

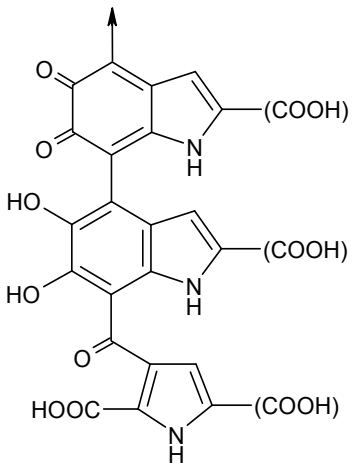

Fig. 9. The chemical structure of eumelanin polymer (Wakamatsu & Ito, 2002).

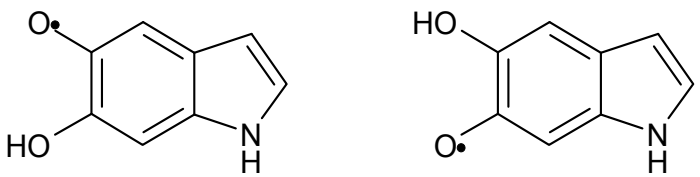
Melanins are the paramagnetic polymers with o-semiquinone free radicals with spin of 1/2 and biradicals with spin of 1 incorporated in their structure (Kozdrowska, 2006; Najder-Kozdrowska et al., 2009, 2010; Pilawa et al., 2004; Sarna, 1981; Zdybel, 2008). o-Semiquinone free radicals structure is presented in Figure 10 (Kozdrowska, 2006; Pasenkiewicz-Gierula, 1990; Sarna, 1981). Our earlier EPR studies of human retinal pigment epithelium melanosomes from young and old donors pointed out that the amount of free radicals depend on the age and method of irradiation (Bilińska et al., 2002). It seems that free radical reactions in melanin of eye influences on therapeutic effect of laser irradiation. This problem is the interesting proposition of the future electron paramagnetic resonance studies of free radicals and melanin biopolymer and laser application in ophthalmology.

a)



b)

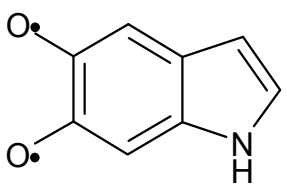


Fig. 10. o-Semiquinone free radicals (a) (Pasenkiewicz-Gierula, 1990; Sarna, 1981) and biradicals (b) (Kozdrowska, 2006) existing in melanin.

The second types of paramagnetic centers – biradicals in melanin were discovered in the last years (Kozdrowska, 2006; Najder-Kozdrowska et al., 2009, 2010; Pilawa et al., 2004; Zdybel, 2008). It is possible that biradicals of melanin could play the role in interactions of laser radiation with eye structures.

The free radicals and biradicals may be differentiated and detected by electron paramagnetic resonance spectroscopy (Kozdrowska, 2006; Najder-Kozdrowska et al., 2009, 2010; Pilawa et al., 2004; Zdybel, 2008). Integral intensities of EPR lines of free radicals and biradicals change differently with the increasing of the measuring temperature (Fig. 11) (Hatfield, 1976). Such dependences were obtained for melanin paramagnetic centers differ in spins (S: 1/2 and 1) (Hatfield, 1976; Kozdrowska, 2006; Najder-Kozdrowska et al., 2009, 2010; Pilawa et al., 2004; Zdybel, 2008).

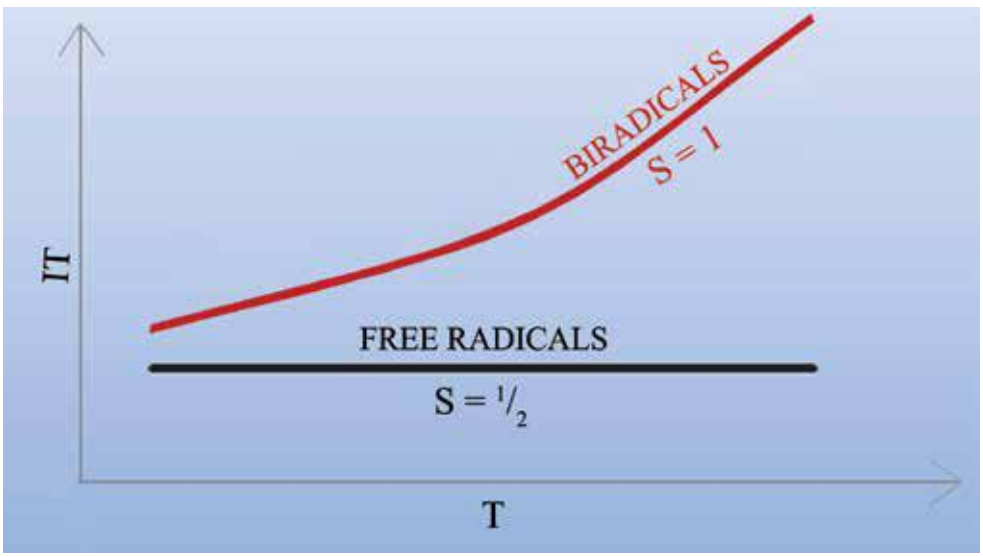

Fig. 11. Changes of integral intensity of EPR lines of free radicals (S = 1/2) and biradicals (S = 1) with the measuring temperature according to functions in (Hatfield, 1976).

The following theoretical functions for free radicals and biradicals in melanin were used (Hatfield, 1976; Kozdrowska, 2006; Zdybel, 2008):

$$IT = C \quad \text{for } S = ½ \tag{5}$$

$$IT = D/(3 + \exp(J/kT)) \quad \text{for } S = 1 \tag{6}$$

where: I – integral intensity of EPR lines, T – temperature, S – spin, k – Boltzmann constant, C, D, J – coefficients in the equations.

The electron paramagnetic resonance spectroscopy could be very useful in modern ophthalmology. EPR is the physical method of examination of paramagnetic species which does not damage the sample. The conditions of the laser therapy may be spectroscopically found and the reactions in the eye structures may be tested.

1. Introduction

Given the small dimensions of the human eye, ocular surgery demands the ability to both visualize and precisely manipulate delicate tissue within a microscopic space. Microsurgical technological advancements have rapidly changed the way in which ophthalmic microsurgery is performed and have provided for greater surgical efficiency and improved functional outcomes.

A thorough understanding of normal ocular anatomy is critical to define pathologic anatomic conditions, to delineate surgical goals, and to develop and utilize surgical tools to optimize patient outcomes. The anatomy of the eye and orbit can be broadly categorized as extraocular structures (including the eyelids, lacrimal gland, canalicular system, conjunctiva, and extraocular muscles) and intraocular structures, located within the globe of the eye. Intraocular structures are further grouped based on their location in the anterior or posterior segments of the eye (figure 1). The anterior segment consists of (from anterior to posterior): the cornea, anterior chamber, iris, and crystalline lens. The crystalline lens is suspended in place by hundreds of zonular fibers, which extend from the ciliary body to a thin capsule surrounding the lens. Contraction of the ciliary body changes the tension of the zonular fibers on the lens, allowing the lens to change its shape and focusing power. The cornea and lens are of particular importance as a majority of ophthalmic surgical interventions are performed on these structures, such as corneal transplantation, refractive corneal surgery, and cataract extraction.

The posterior segment of the eye consists of the vitreous humor (a clear gelatinous substance composed primarily of water, type II collagen, and hyaluronic acid), the neurosensory retina, the retinal pigment epithelium (which promotes the function and viability of the neurosensory retina), and the choroid (a vascular layer interposed between the retinal pigment epithelium and the sclera). The neurosensory retina is a highly organized extension of the central nervous system composed of photoreceptors and multiple layers of interconnected neurons. These neurons ultimately synapse on ganglion cells, whose axons coalesce into the optic nerve. Posterior segment ophthalmic surgery generally involves

removal of the vitreous humor to: 1) relieve traction of the vitreous on the retina, 2) remove visually-significant opacities within the vitreous, or 3) to gain access to the retina or sub-retinal space for further surgical manipulation.

The origins of ophthalmic surgery date back as far as the sixth century B.C. when ancient Indian surgeons used curved needle-like instruments to dislodge a cataract, a technique termed "couching". Further contributions by Greek, Middle Eastern and European physicians provided detailed functional knowledge of the eye and intraocular structures.

Development of the surgical microscope further revolutionized ophthalmic microsurgery. Although initially little more that a binocular telescope worn by the surgeon, the modern ophthalmic microscope provides a well-lit binocular stereoscopic view with a high-level optical clarity (figure 2). Foot pedal controls allow the surgeon to adjust magnification (approximately 10-30x), illumination intensity, x-y axis movement and level of focus. Furthermore, both contact and non-contact lens based systems are now employed to provide a wide-angle stereoscopic view of the posterior segment. Indeed, the ophthalmic microscope has enabled precise visualization of both anterior and posterior segment structures making modern ophthalmic microsurgery possible. Two such ophthalmic surgeries, cataract extraction and pars plana vitrectomy, are described below in detail.

1.1 Cataract extraction

1.1.1 Technique overview

Over two million cataract extractions are performed yearly in the United States making it the most common ophthalmic surgery, and among the most frequently performed surgeries in any field. A "cataract" refers to a focal or diffuse opacification of the crystalline lens, a structure that is normally optically clear and measures approximately 10mm wide and 6mm deep. Opacities within the lens limit the normal focusing ability of the lens resulting in blurred vision. Although cataract formation is most commonly an age-related process, cataracts may form at any age due to a number of different etiologies including medications, systemic metabolic disease, and ocular trauma. Although many methods have been developed to remove cataracts, the most common technique employed in modern ophthalmic microsurgery is "phacoemulsification".

Standard phacoemulsification for cataract extraction typically begins with the creation of a 2.2 to 3 mm tunnel or wound in the peripheral cornea to gain access to the anterior chamber. The anterior chamber is stabilized during intraocular manipulation with an ophthalmic viscoelastic device (a clear, removable, gel-like substance composed primarily of water and hyaluronic acid). A circular opening is then created in the anterior face of the lens capsule, termed a "continuous curvilinear capsulorrhexis". With the lens contents now accessible, the tip of a handpiece connected to a phacoemulsification machine is placed within the anterior chamber. This handpiece performs three functions: 1) administration of ultrasonic energy to fracture the lens material into small pieces; 2) aspiration to remove the small lens particles; 3) irrigation of a saline-like solution to maintain the volume of the anterior chamber (Figure 3).

Once the lens material is successfully removed, a clear artificial lens is typically placed within the intact capsule of the lens. Although early intraocular lenses were composed of

rigid polymethylmethacrylate (PMMA) requiring enlargement of the corneal wound for intraocular placement, modern intraocular lenses are composed of silicone or acrylic, both of which are biologically inert and can be folded and placed into the eye through a small corneal incision.

2. Principles of phacoemulsification

The fluid dynamics of phacoemulsification require constant fluid irrigation into the anterior chamber to maintain normal depth while lens material is aspirated. Due to the small volume of the anterior chamber, fluid circulation during phacoemulsification is critical to ensure efficient removal of the cataract while preventing complications due to anterior chamber collapse. Indeed, if outflow, or aspiration through the handpiece is allowed to exceed inflow, or irrigation, even for a fraction of a second, anterior chamber instability may result in unintended damage to intraocular tissue.

The formula that governs fluid flow during phacoemulsification surgery is Poiseuille's law:

$$Q = \Delta P \pi r^4 / 8 \eta L,$$

where Q is flow rate, ΔP is the pressure gradient, r is the radius of instrument tip, η is fluid viscosity, and L is length of the tubing. Given that the viscosity of the fluid and length of the tube are constant, flow is essentially proportional to the change in pressure and radius of the tubing.

In the case of phacoemulsification surgery, ΔP is the pressure gradient between the infusion pressure and the vacuum driving aspiration. The source of fluid inflow is a bottle of balanced salt solution, the height of which can be adjusted relative to the patient's eye to control infusion pressure. Fluid outflow is dependent on the vacuum level generated by the machine. The surgeon can control both the infusion pressure and vacuum or aspiration.

3. Phacoemulsificaiton instruments

The primary tool of phacoemulsification is the handpiece (figure 4). The tip of this tool delivers ultrasonic energy to break up the lens, aspirate fluid and lens material, and provide inflow of fluid to the anterior chamber. The handpiece is connected to a machine that regulates the aspiration pressure, the infusion pressure, and the intensity of the ultrasonic energy delivered by the handpiece. The design of the handpiece tip varies with respect to the angle and size of the lumen. Steeper tip bevels (less angled) provide better cutting ability into dense lens nuclear material whereas flatter tip bevels provide a larger surface area for improved aspiration of large lens fragments.

Modern phacoemulsification machines also employ foot pedal controls with at least three positions that allow the surgeon to control the fluidics of phacoemulsification. The first position typically provides irrigation only, which cools the handpiece and keeps the anterior chamber formed. The second position, in addition to irrigating, engages the aspiration mode at a constant or variable rate, depending on the settings selected by the surgeon. In the third position, ultrasound energy is delivered in addition to irrigation and aspiration. Many other microsurgical instruments are also utilized in conjunction with the phacoemulsification probe to facilitate manipulation of the lens material and to improve the efficiency of cataract extraction.

Ultrasonic power for phacoemulsification is generated by applying a time-varying electric field across a piezoelectric crystal in the phacoemulsification handpiece. The oscillating crystal deforms in response to the electric field, resulting in the conversion of electrical to mechanical energy. Oscillation of the tip occurs at a preset frequency that varies from 27 kHz to 60 kHz. The amplitude of the movement, or stroke length, ranges from 50 μm to 100 μm and is modulated when the phacoemulsification power is changed. As the tip retracts, a vacuum is created resulting in the formation of "cavitation bubbles". When the bubbles implode, they release heat and shock waves that fracture the lens material. Phacoemulsification power can also be modulated by varying the duty cycle; the period of time when the phacoemulsification power is being delivered. Varying the duty cycle allows for efficient administration of phacoemulsification energy to promote fracturing of lens material while minimizing excess heat and energy that may damage the cornea or other intraocular structures.

4. Phacoemulsification systems

While there are a variety of phacoemulsification machine manufacturers and configurations, they all generate the required vacuum and aspiration based on one of two pump types: Venturi and peristaltic.

A peristaltic system (figure 5) utilizes a series of rollers to displace fluid, producing flow in a compressible tube that is wound tightly around a rotating wheel. As the wheel turns, a segment of fluid trapped between two rollers is moved, resulting in more fluid being drawn into the tubing. Therefore, the flow rate is directly proportional to the speed of the rotary mechanism. Significant vacuum is generated only when the tip is occluded. The surgeon sets a desired flow rate and vacuum limit. The flow rate determines how rapidly the vacuum builds up when the handpiece tip is occluded and flow is restricted.

The Venturi pump (figure 6) utilizes the Venturi effect to create vacuum. The Venturi effect refers to the creation of vacuum secondary to the flow of a fluid (typically nitrogen or air in a phacoemulsification machine) over an opening. Thus, a Venturi pump allows a given vacuum level to be generated immediately, without occlusion of the phacoemulsification tip as is required in the peristaltic system. As such, flow cannot be directly modulated and is dependent on the vacuum level generated. The Venturi system provides the surgeon with near instantaneous vacuum levels and potentially higher flow rates.

5. Femtosecond laser technology and the future of phacoemulsification

In the near future, a new application of an existing technology may alter the way in which cataract surgery is performed. The femtosecond laser is a device that emits coherent optical pulses with a wavelength of 800nm and duration on the order of 10^{-15} seconds. It has been used extensively in ophthalmology due to its ability to alter delicate tissue in a precise and predictable way. In addition to its precision, the femtosecond laser can cut tissue with practically no heat development. Clinical trials utilizing the femtosecond laser to perform the incisional steps of cataract surgery, including cornea wound creation, capsulorrhexis creation, and disassembly of the lens are currently ongoing. Future applications of this laser may allow many steps of phacoemulsification to be automated, thus minimizing risk and error while increasing surgical efficiency.

5.1 Vitreoretinal surgery

5.1.1 Basic techniques

Vitreoretinal surgery, in its modern form, is a minimally invasive technique similar to laparoscopic surgery whereby small entry ports or trocars are placed on the surface of the eye to gain surgical access to intraocular structures. A variety of instruments including surgical manipulators, illuminating probes, laser probes, and infusing and aspirating devices can be placed through the trocars for a variety of surgical procedures. The trocars are placed at a safe anatomic entry point, the pars plana, located within a narrow band around the eye 3 to 4 mm posterior to the corneoscleral junction. This space lies just posterior to the highly vascularized ciliary body but anterior to the retina. Placing trocars too far anteriorly or posteriorly can lead to significant complications and surgical failure.

The vitreous body, a clear gelatinous structure located between the crystalline lens and the retina, occupies approximately 80% of the volume of the human eye. It is mainly composed of water (99%), collagen fibrils (type II collagen), and hyaluronic acid. The vitreous gel is integral in the pathogenesis of many posterior segment diseases. For example, in diabetic retinopathy, bleeding into the vitreous cavity can severely reduce visual acuity since dense hemorrhages can become loculated within the vitreous body. In some instances where the hemorrhage does not dissipate on its own, vitrectomy is necessary to remove the vitreous and blood. The vitreous body is adherent to a number of structures in the posterior segment including tight adhesions over the optic disc, the macula, retinal blood vessels and the ora serrata (a band which straddles the anterior retina and the pars plana where the vitreous and retina are anatomically fused and cannot be surgically separated). Thus, vitreous removal must be performed in a precise and controlled fashion to minimize excessive traction of the retina, which may result in complications such as retinal tears and detachment. Although the vitreous plays an important role in ocular development *in utero*, removal of the vitreous in the adult eye has no deleterious effects on the health of the retina. Once vitrectomy is performed, the vitreous cavity is typically replaced by the surgeon with balanced salt solution, which is eventually replaced by the eye with aqueous humor. Therefore, the vitreous body does not reform once it is removed.

5.2 Principles of vitreoretinal surgery

Surgery within the posterior segment of the eye is bound by the same principles as anterior segment surgery: the volume of the eye must be maintained as material is removed. Adding complexity to vitreoretinal surgery is the difficulty in visualization of the posterior segment during intraocular surgical maneuvers. External illumination is generally inadequate to visualize the retina and, despite advances in modern lens systems, the surgeon's view of the retinal periphery can be limited while operating near the posterior pole.

The first pars plana vitrectomy was performed by Robert Machemer in 1970 using a 17-gauge (1.42 mm diameter) one-port system that combined an infusion cannula and vitreous cutter in one handpiece. Since that time, numerous innovations have improved the efficiency and outcomes of this procedure and led to the development of the modern 3-port 20-gauge pars plana vitrectomy. In this procedure, three 20-gauge sclerotomies are created within the pars plana. One sclerotomy is used to anchor a cannula that infuses balanced salt

solution into the posterior cavity while the vitrectomy is performed, thus maintaining intraocular pressure. The remaining ports are used for the vitrectomy probe and a light probe to remove the vitreous and illuminate intraocular structures respectively. Following removal of the vitreous, the sclerotomy can be used to introduce other instruments such as intraocular forceps and laser probes to further manipulate and treat the retina (figure 7).

Visualization during pars plana vitrectomy is performed using the operating microscope in conjunction with a contact lens (which can be held by the assistant or sewn onto the eye at the corneoscleral junction) or a non-contact lens viewing system. Direct contact visualization systems allow for greater field of view and enhanced three-dimensional perception. Non-contact lens viewing systems are easier to use and do not require an assistant or additional surgical maneuvers to anchor the lens to the ocular surface, but sacrifice some field of view and three-dimensional perception.

5.3 Vitrectomy instruments

The basic tools of pars plana vitrectomy are a vitreous cutter, illuminating device, laser probe, various tissue manipulators such as micro-forceps for delicate intraocular work, and an infusion cannula to maintain intraocular pressure. The workhorse of pars plana vitrectomy is the vitreous cutter, whose basic function is to remove the vitreous in a controlled fashion. Because the vitreous is a semi-solid structure with adhesions to the retina, simple aspiration of the vitreous results in excess traction on the retina. To minimize such traction, the vitrectomy probe is designed with both an aspiration port and a cutting mechanism to aspirate a small volume of vitreous into the handpiece and to cut and remove it. High cut speeds allow for incremental removal of small amounts of vitreous while minimizing tractional forces of the vitreous on the retina. Lower cut speeds result in removal of larger volumes of vitreous, thereby increasing the rate at which vitreous is removed. Most modern high-speed (600-5000 cuts per minute) vitrectomy probes are pneumatically driven with a side-cutting guillotine port near the tip of the instrument (figure 8).

Most vitrectomy machines are equipped with a built-in light source employing either yellow or white light from a halogen or metal-halide light source. The light probe, a fiberoptic cable encased in a plastic handpiece, is connected to the light source and can function as a separate instrument or, in some cases, can be combined with the infusion cannula to simultaneously illuminate and irrigate the posterior segment. A recent innovation has been the introduction of a xenon light source, which can provide bright illumination through a narrow probe. This has facilitated the performance of smaller gauge surgery and eliminated light wavelengths under 400 nm that can be phototoxic to the retina.

Many surgical instruments have been developed to facilitate surgical procedures on the macula. The macula is located at the center of the posterior pole of the retina and has the highest concentration of photoreceptors. It is responsible for fine central visual acuity needed for such tasks as reading, driving and other activities of daily living. Pars plana vitrectomy may be required to treat a variety of macular diseases including epiretinal membranes, macular holes, vitreo-macular traction, and hemorrhagic age-related macular degeneration. Instruments used to manipulate and treat the macula include a variety of micro-forceps (e.g. end-grasping and pick forceps), scissors, needles and cannulas.

The intraocular laser probe allows for minimally invasive and precise ablation of retinal tissues and is used in a wide variety of surgical procedures. Similar to the light probe, the "endolaser" probe is also a fiber-optic cable encased in a plastic handpiece. The intensity of the laser ablation is controlled by the surgeon by modulating the power and duration of the laser as well as by altering the distance of the probe tip to the retina. Intraocular laser is typically employed for two key purposes: 1) to treat retinal tears by creating a fibrous scar between the retina and the underlying choroid thus preventing fluid in the eye from collecting underneath the retina; and 2) to ablate non-perfused or ischemic retinal tissue (as in diabetic retinopathy and other occlusive retinal vascular diseases) to decrease the pathologic production of growth factors that result in retinal neovascularization, intraocular hemorrhage and retinal edema.

5.4 Vitrectomy systems

Vitrectomy machines, similar to phacoemulsification machines, are complex devices that drive the vitreous probe cutter, provide irrigation at an adjustable level to control intraocular pressure, aspirate and remove intraocular material, and provide a light source for intraocular illumination. Many of these functions are controlled via foot pedal by the surgeon, similar to the previously-described phacoemulsification machine.

Two major types of systems are used to drive the vitrectomy probe cutter: electric guillotine and pneumatic guillotine. The electric guillotine employs an electric drive motor with a sinusoidal transmission, translating the rotary motion of an electric motor shaft to the linear guillotine motion of the cutter tip. The profile of motion of the guillotine remains constant as the cut rate is altered. That is to say, the duty cycle, or ratio of time the cutter port is open or closed, remains constant regardless of the cut rate.

The second type of handpiece, which is pneumatically driven, uses pulses of air or gas to close the cutter tip. The pneumatically-driven guillotine is attached to a diaphragm. When a pulse of air is delivered, the diaphragm and guillotine extend, closing the cutter tip and completing a cut. The guillotine then retracts to its original position either through a spring mechanism or through a "dual drive" system where an additional pulse of air pushes the guillotine back, thus opening the cutter tip. In the spring mechanism, as the cut rate is increased, the duration of open time per cut decreases, while the closed time remains constant (decreasing the duty-cycle). The "dual drive" system allows for improved duty cycle compared with the spring mechanism, but the duty cycle still decreases at high cut rates.

6. Current directions

Recent advances in vitreous surgery have resulted in the development of smaller instruments: the 23- and 25-gauge transconjunctival suture-less vitrectomy systems (figure 9). A standard 20-gauge (0.9 mm diameter) vitrectomy requires removal of the conjunctiva and sutures to close the sclerotomies used to access the posterior segment. 23-gauge (0.6 mm diameter) and 25-gauge (0.5 mm diameter) entry wounds, when constructed properly, are small enough to self-seal and thus can be placed through the conjunctiva and sclera without the need for closing sutures. To allow for easy entry and exit of surgical instruments during vitrectomy and to align the entry holes in the conjunctiva and sclera, a 23- or 25-gauge trocar

is placed at the site of the desired sclerotomy. The trocar consists of two components: a polyimide cannula and a polymer hub. The polyimide cannula maintains the transconjunctival and transcleral tunnel through which surgical instruments are passed. The polyimide cannula material provides both strength and flexibility, allowing the cannula wall to be thin while avoiding collapse or buckling. The polymer hub is the part of the trocar visible on the surface of the eye and prevents the trocar from sliding into the vitreous cavity. The hub has a central hole that is continuous with the cannula, allowing for instruments to be inserted into the vitreous cavity.

Many surgeons believe the potential advantages of smaller gauge, suture-less techniques include shortened operative time and faster patient recovery. However, the reduction in port diameter results in reduced flow rates compared with 20-gauge cutters, and therefore, smaller-gauge surgery may require more time to remove the same amount of vitreous or may be inadequate to remove dense or highly organized vitreous. Other concerns with suture-less techniques include the increased risk of post-operative hypotony and infection if the sclerotomies are not constructed properly.

7. The future of ophthalmic surgery – Robot-assisted microsurgery?

With recent innovations in engineering and the demands for increasingly precise and efficient ophthalmic microsurgery, the next major advancement in ophthalmic surgery may be the integration of mechanization and robotics into ophthalmic microsurgical techniques. The potential benefits of robotic surgery in ocular surgery include increased precision, reduction of human error, task automation and the capacity for remote surgery.

Guerrouad and Vidal described one of the first ocular robotic systems in 1989. Named the "Stereotaxical Microtelemanipulator" (SMOS), it provided relatively good range of motion for basic surgical tasks but the technology was too premature at that time to raise tangible interest for further development. In the 1990s, Steve Charles and researchers at Northwestern University demonstrated the use of robotic platforms for ophthalmic surgery with precise position measurement and fine incremental motion but these prototypes were limited by the complexity of its software control and the need for increased robotic responsiveness to human controls.

Presently, the Food and Drug Administration has approved the *da Vinci* Surgical System (Intuitive Surgical, Sunnyvale, CA), which has become the most commonly employed robotic platform in human surgery (figure 10). Although it has been used in the fields of general surgery, urology, gynecology and cardiac surgery, its use in ophthalmic surgery is in its early phases. Preliminary studies have demonstrated good robot arm responsiveness to human controls for external and intraocular surgical tasks. However, the remote center of motion (pivot point) and limited range of motion of the robot arm make intraocular manoeuvrability difficult with excessive distortion of the globe of the eye. Furthermore, while the visualization system of the *da Vinci* system is adequate for extraocular and some anterior segment surgical procedures, posterior segment surgery is hampered by a limited field of view. Finally, the surgical instruments of the *da Vinci* instruments are not well-suited to ophthalmic microsurgery due to their bulkiness. Recent studies have better defined the range of motion required for robot-assisted ophthalmic surgery and further refinements to the robot surgery platform are underway to make this technology a tangible option in the near future.

Ocular robotic surgery poses a myriad of unique challenges and the application of this technology will undoubtedly require many stages of evolution. Further work will be required to continue to integrate traditional surgical techniques with new devices to bring the advantages of robotics to the field of ophthalmology.

8. Conclusion

Ophthalmic microsurgery has rapidly evolved in recent history as advances in medical device technology have led to the development of numerous minimally invasive procedures for the treatment of ocular diseases. The multi-disciplinary integration of technology and knowledge from the fields of biomaterials, optics, lasers, ultrasonics and pneumatics have helped to refine the surgical tools available to ophthalmic surgeons, increasing their efficiency and surgical outcomes. As life expectancy and the prevalence of various systemic diseases continue to rise, so too will the burden of ocular disease. Further advances to better address these demands will undoubtedly lead to novel surgical techniques and devices, expanding the role of ophthalmic surgery to undiscovered heights.

1. Introduction

The first member of transient receptor potential (TRP) channel superfamily was discovered in photoreceptors of *Drosophila* over 30 years ago.[1] Since then this protein superfamily has been extensively characterized based on exponential increases in the number of publications related to TRP channels. With 28 TRP homologous genes identified in mammals, TRP channels have been detected in both neural and non-neural tissues.

In humans, 27 different TRP genes are classified into two groups and six different subfamilies based on their amino acid homology and phenotypes associated with mutant genes. The genes of TRP channel in Group 1 and Group 2 are only distantly related. The Group 1 of TRP genes are comprised of TRPC (canonical), TRPM (melastatin), TRPV (vanilloid) channel subfamilies, with TRPA (ankyrin) being more recently assigned to this group.[2] Such categorization is based on their resemblance to the amino acid sequence of the *Drosophila* TRP channel. The nomenclature of TRP channel genes in Group 2 is based on the human phenotypes generated by the mutation of the founding genes of each subfamily, including polycystic kinase disease (PKD) and mucolipidosis type IV (MCOLN, mucolipin). Their encoded proteins have also been referred to as TRPP (polycystin) and TRPML (mucolipin), respectively (Figure 1).

The TRP superfamily is evolutionally conserved from nematodes to mammals.[3] The common features of TRP channels are six putative transmembrane spanning domains and a cation-permeable pore formed by a short hydrophobic region between transmembrane domains 5 and 6. They are configured as homo- or hetero-tetramers to form non-selective cation channels (Figure 2). Their permeability ratios to Ca^{2+}/Na^{+} vary significantly among individual members. TRPV5 and TRPV6 channels exhibit a Ca^{2+}/Na^{+} permeability ratio of greater than 100, indicating high Ca^{2+} selectivity.[4] In contrast, TRPM4 and TRPM5 channels are impermeable to Ca^{2+} but are selective for monovalent cations (Na^{+}, K^{+}).[5, 6] Such intra-family variability is unique to the TRP channel superfamily whereas most other ion channel families have little difference in ionic permeability within a family.[7]

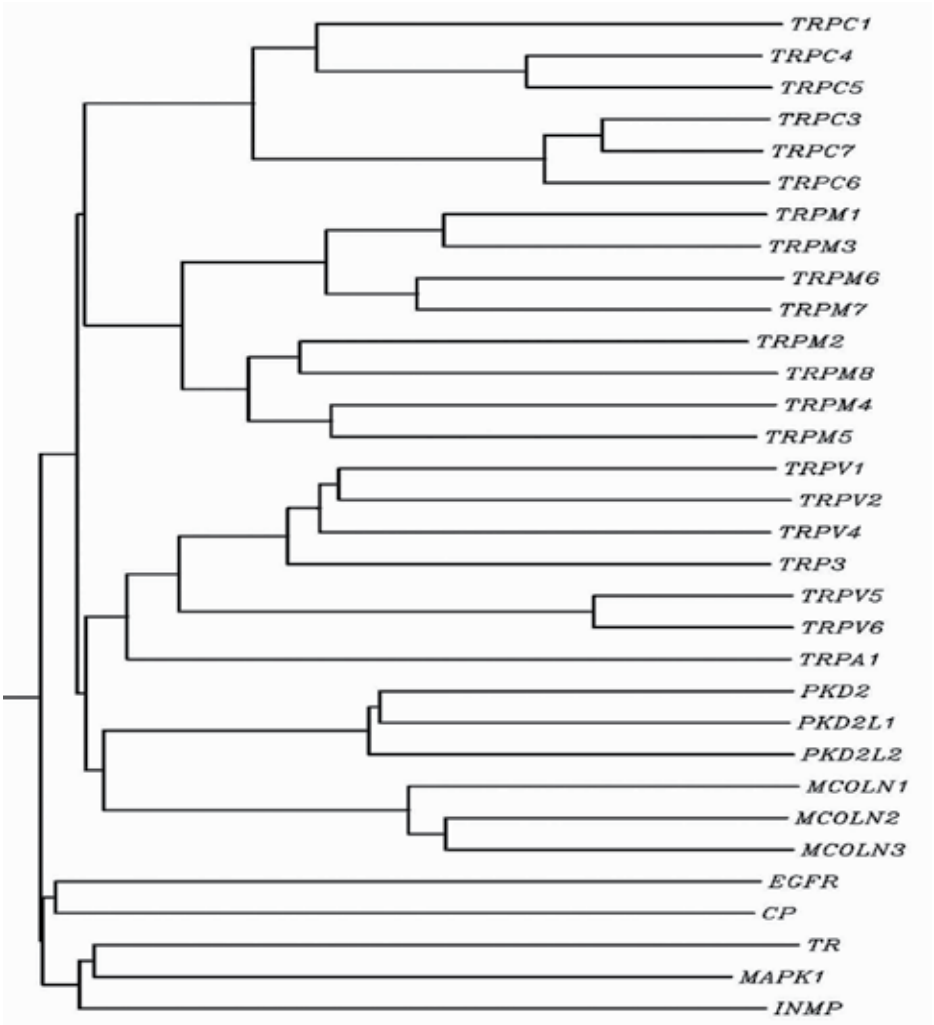

Fig. 1. Human TRP channel superfamily dendrogram. Random proteins bound to the plasma membrane (i.e., EGF receptor, EGFR), endoplasmic reticulum (i.e., calreticulin precursor, CP), mitochondria (thioredoxin reductase, TR), cytosolic protein (i.e., mitogen-activated protein kinase 1, MAPK1) and nuclear membrane (i.e., inner nuclear membrane protein, INMP) are shown to illustrate that PKD and MCOLN are evolutionarily related to TRP channels or are the results of convergent evolution. The dendrogram shows that PKD and MCOLN belong to the TRP channel superfamily, since random genes extend from branches distinct from the TRP channel superfamily.[8]

TRP channel subfamilies in Group 1 share substantial sequence homology in the transmembrane domain 6. What divides each subfamily is differences in their intracellular domains. TRPC, TRPV and TRPA channels contain ankyrin repeats near the intracellular N-terminal domain, whereas the TRPC and TRPM channels subfamilies possess proline-rich 'TRP domain' in the region of the C-terminal near the putative transmembrane segment. TRPM6 and TRPM7 channels have a protein kinase domain in the C-terminal.

The TRPC subfamily consists of seven genes (TRPC1–7) in mammals, but TRPC2 channel is a pseudogene in humans. TRPC channels are widely expressed in multiple systems. TRPC4, TRPC5, TRPC6 and TRPC7 channels are identified in the various ocular tissues of mammals.[9-12] The TRPM channel subfamily comprises eight genes (TRPM 1–8), of which three encode channel-like proteins and five non-channel proteins. TRPM1 channels are expressed in retinas and TRPM8 channels in corneas.[13, 14] The TRPV channels subfamily contains six members (TRPV1–6). TRPV1, TRPV2, TRPV3 and TRPV4 channels are expressed in the cornea whereas TRPV1, TRPV2, TRPV5 and TRPV6 channels are expressed in the retina.[15-20] The TRPA channel subfamily has only one member, TRPA1.

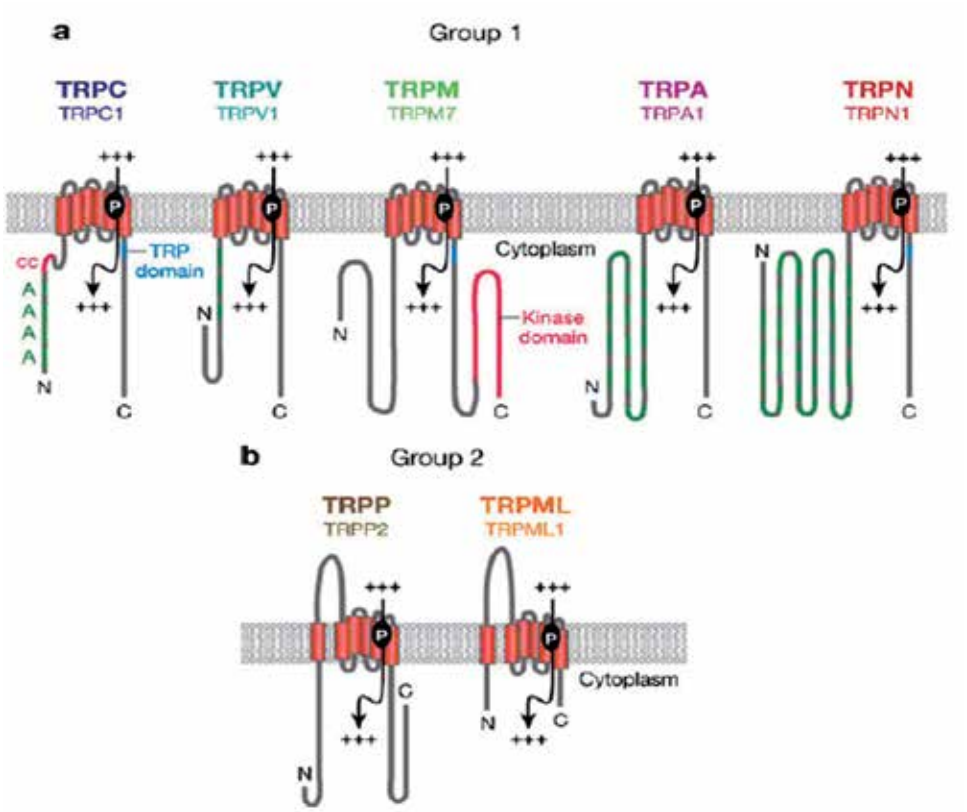

Fig. 2. Domain structure of the TRP channel superfamily. There are five TRP channel subfamilies in Group 1 (TRPN, no mechanoreceptor potential C channels are expressed in mammals) (a) and two TRP channel subfamilies in Group 2 (b). All subfamilies contain a six-transmembrane domain unit with a cation-permeable pore between domains 5 and 6. Four of such units are assembled as a homo- or hetero-tetramer to form a TRP channel. Domain indications: ankyrin repeats (A), coiled-coil domain (cc), protein kinase domain (TRPM6 and TRPM7 channels only), cation-permeable pore (P), transmembrane (TM) domain, cation-permeable (+++), TRP channels domain (TRPC and TRPM channels only), large extracellular loop between transmembrane domains 1 and 2 (TRPP and TRPML channels only). Adapted with permission from Venkatachalam and Montell.[21]

TRPP and TRPML channel subfamilies belong to Group 2. They contain limited sequence homology to TRP channels in Group 1, although such resemblance to classical TRP channels is still larger than those of random genes (e.g., EGFR, INMP) (Figure 1). TRPP channel proteins share 25 percent amino acid sequence homology to TRPC3 and TRPC6 channels over a region including transmembrane domains 4 and 5 and the hydrophobic pore loop between domains 5 and 6. TRPML channel proteins consist of three small proteins compared with other TRP channel proteins. Homology of their amino acid sequence with TRPC channels proteins is restricted to the region spanning transmembrane domains 4 to 6 (amino acids 331 to 521). TRP channels in Group 2 have a unique large extracellular loop between their first and second transmembrane domains. They are named as TRP channels based on the six transmembrane domains that they contain and function as cation-permeable channels.

The activation mechanisms of TRP channels are unique in that there are a diverse host of stimuli that can activate TRP channels and exhibit sharp differences in stimulatory modes even within each TRP channel subfamily. TRP channels were initially recognized as sensory mechanisms to a variety of stimuli, ranging from light, temperature, osmotic pressure, smell, taste, mechanical stress and acidity. There is also increasing awareness of their roles in mediating wound healing, inflammation, apoptosis and excretion. These channels are sensitive to intracellular and extracellular messengers, as well as declines in the calcium content of intracellular calcium stores (ICS).

Their activation following conformation changes modulates Ca^{2+}/Na^{+} cell permeability ratios, which is dependent on TRP channel subunit composition. Transient increases in intracellular calcium concentration trigger intracellular activation of mediators including: 1) phospholipase C (PLC) by coupled GTP-binding protein, leading to stimulation of store-operated Ca^{2+} channels; 2) transactivation of EGF tyrosine receptors through MMP-mediated HB-EGF shedding.[4, 10, 16] The physiological significance of TRP channel expression is indicated by the finding that TRP channel mutations are linked to human diseases.[22]

There is compelling evidence that the TRP channel superfamily plays a critical role in ocular homeostasis and pathogenesis. Functional importances of TRP isotypes expressed in different ocular tissues are multi-faceted. Their activation is essential for retaining corneal deturgescence and clarity, mediating aqueous humor outflow through trabecular meshwork and ciliary body as well as inducing light sensation in retina. Mutation of TRP channels is associated with ocular pathological phenotypes either due to loss of its homeostatic role or over-activation of its function. The realization of the importance of TRP channel has prompted much research effort to investigate novel strategies for regulating TRP channels function in a number of ocular diseases.

2. Roles of TRP channels in corneal sensation and wound healing

Continuous renewal of corneal epithelial layer is essential to maintain corneal transparency. The intact epithelium not only offers a smooth and clear optical surface, but also provides corneal barrier function. This property protects the underlying stroma from swelling and pathogenic invasion. Should such protection become compromised by ocular surface diseases, outcomes can range from mild symptoms, such as irritation, photophobia, to severe consequences including corneal opacity, ulceration and even perforation. TRP

channel functions have been indicated to associate with maintaining corneal sensation and integrity. Corneas express ample collection of TRP channel isotypes in various mammalians. There are TRPC1, TRPC3, TRPC4, TRPC6 and TRPC7 as well as TRPV1–4 channels in the corneal epithelium, TRPV1-4 in the corneal endothelium, TRPV1, TRPA1, and TRPM8 in the corneal nerves.[10, 15-17, 23, 24, 25-27] These channels are involved in corneal regenerative, protective and sensory mechanisms.

TRPC4 channels protein is localized in plasma membranes of cultured human corneal epithelial cells (HCEC) and mediate epidermal growth factor (EGF)-promoted epithelial proliferation. They are activated by EGF-induced depletion of ICS content in the endoplasmic reticulum. This depletion occurs as a consequence of stimulation of PLC activity which results in increases in inositol 1,4,5-trisphosphate (IP3) formation. This response leads to declines in ICS content and activation of TRPC4 store operated channel (SOC) function. Its activation induces intracellular Ca^{2+} influx leading to stimulation of downstream signalling cascades. They include the mitogen activated protein kinase (MAPK) cascade composed of ERK, JNK and p38 casettes as well as protein kinase A (PKA), protein kinase C (PKC), JAK/STAT and PI3-K/AKT/GSK-3. All of their activations contribute to the control of increases in cell survival and proliferation elicited by EGF. The importance of TRPC4 channels activation to mediate EGF-induced mitogenic responses is indicated by the finding that knockdown of its gene expression in HCEC eliminated the mitogenic response to EGF.[10]

TRPV1 channel expression was first identified on the ophthalmic branch of the trigeminal nerve. More recently, the functional expression of this channel was also identified in the corneal epithelial and endothelial layers. A hallmark of its activity is that the vanilloid compounds (such as capsaicin isolated from hot chilli pepper), hyperosmolarity, acidity (pH below 6) and high temperatures (above 43°C) stimulate TRPV1 channels. In the mouse corneal epithelium, severe chemical injury to corneal epithelium induces TRPV1 channel activation leading to dysregulated inflammation, scarring and loss of corneal transparency. On the other hand, its activation stimulates in HCEC proliferation and migration through EGF receptor (EGFR) transactivation.[28] The involvement of TRPV1 channel activation in inducing these diverse responses is indicated by the finding that in homozygous TRPV1 knockout mice the wound healing response to an alkali burn does not result in losses of corneal transparency. Similarly, TRPV1 channel activation in some types of dry eye disease resulting from exposure to hyperosmolar tears may account for chronic inflammation since TRPV1 channels activation caused by exposure to a hyperosmolar challenge induced large increases in a host of proinflammatory cytokines (e.g., IL-6, IL-8, TNFα and IL-1β) and chemoattractants (e.g., MCP-1) in HCEC. On the other hand, pre-exposure to a selective TRPV1 channel antagonist obviated all of these responses, suggesting that TRPV1 channels are potential drug target for the treatment of dry eye syndrome because suppression of its activation may reduce ocular surface inflammation.[16, 23]

In contrast with TRPV1, its cohort, TRPV4 channel reacts to a different spectrum of stresses. Unlike TRPV1, which is thought to only be activated by a hyperosmolar stress, TRPV4 channels may instead be an osmosensor for a hypoosmolar challenge.[17] Such a stress is encountered by the cornea during exposure to fresh water (e.g., swimming, bathing, use of some eye drops). This hypotonic exposure results initially in corneal epithelial swelling due to obligatory water influx in order to reach equilibration between the cell interior and

surface tears. However, excessive swelling can lead to cell lysis. To counter the initial swelling, corneal epithelial cells mediate regulatory volume decrease (RVD) behavior by stimulating volume-sensitive potassium and chloride channels as well as potassium-chloride co-transporter (KCC) activity to restore isotonic cell volume through osmotically coupled net fluid efflux.

TRPV1–4 channel isoforms also serve as thermosensors over defined temperature ranges in the corneal epithelium. In addition, TRPV3 channel activation, either by temperatures above 33°C or by its selective agonist, carvacrol, not only contributes to thermosensation, but also accelerates epithelial wound recovery by enhancing cell survival, proliferation and migration.[15, 29] TRPV1–3 and TRPC4 channels are also expressed in corneal endothelial cells.[9, 30] TRPV1–3 channels are sensitive to temperatures from 25 to 40°C, similar to their epithelial counterparts.

TRP channels play an important role in mediating corneal sensations. The cornea has the highest sensory nerve density of any tissue in the body. The corneal sensory nerves originate from the ophthalmic branch of the trigeminal ganglion and are responsible for eliciting nociception to thermal, chemical and mechanical stimuli.[31] TRPV1 channels colocalize with substance P (SP) and calcitonin-gene-related peptide (CGRP) in the ophthalmic branch of the trigeminal nerve indicating their role in eliciting nociceptive perception. This realization makes TRPV1 channel tenable as a potential drug target for treating neurotrophic keratopathy.[31, 32] Additionally, the TRPM8 channel contributes to corneal cold sensation and basal tear secretion required to maintain corneal surface hydration.[14, 33]

Taken together, these studies on the corneal epithelial, endothelial cells and corneal nerves indicate that functional expression of TRP channels are essential for maintaining corneal transparency and eliciting adaptive responses to stresses. This indicates the importance of further studies on TRP channel regulation since such insight may lead to novel strategies for treating corneal diseases and better management of ocular surface inflammatory pain.

3. Roles of TRP channels in glaucoma

Some members of the TRPC and TRPV channel subfamilies are expressed in trabecular meshwork, ciliary muscle and retinal ganglion cells.[34, 35] Their roles have been associated with regulating intraocular pressure through modulation of aqueous humor flows and ganglion cell survival. The trabecular meshwork contains contractile elements whose tension modulation changes fluid drainage rate from the anterior chamber into the Canal of Schlemm. The contractile state of trabecular meshwork is governed by tension imparted from the ciliary muscle and possibly trabecular meshwork itself.[35, 36] The trabecular meshwork and the ciliary muscle act as functional antagonists. Such opposition is evident since ciliary muscle contraction leads to relaxation of the trabecular meshwork with subsequent increases in fluid outflow whereas trabecular meshwork contraction has the opposite effect.[35] Malfunction of trabecular meshwork and ciliary muscle contractility often leads to ocular hypertension and glaucoma.[37] Their contractile states are modulated by changes in intracellular Ca^{2+} concentration and Ca^{2+} channel activity. Specifically, increases in cytoplasmic Ca^{2+} resulting from the stimulation of TRP channels enhance contractility. Other types of Ca^{2+} channels that regulate intracellular Ca^{2+}concentration include L-type voltage-gated Ca^{2+} channels, receptor operated Ca^{2+} channels and store-operated calcium

entry (SOCE) pathways. In bovine trabecular meshwork cells, TRPC1 and TRPC4 channels are implicated in the formation of heteromeric SOCE channels which contribute to rises in cytoplasmic Ca^{2+} store and therefore trabecular meshwork contractility during exposure to bradykinin or endothelin-1.[4]

Similarly TRPC1, TRPC3, TRPC4 and TRPC6 channels are also present in ciliary muscle cells. The ciliary muscle is densely innervated by parasympathetic nerves that stimulate muscle contraction through acetylcholine-mediated muscarinic receptor stimulation on neighboring muscle cells. Such activation leads to a surge in intracellular Ca^{2+} concentration resulting in membrane voltage depolarization via receptor-operated non-selective cation channels. TRPC1, TRPC3, TRPC4 and TRPV6 channels are considered as potential candidates for such channels as they are co-localized with muscarinic receptor type 3 in ciliary muscle fibres.[38, 39]

Modulation of TRPC channel activity in turn alters aqueous humor outflow and therefore intraocular pressure through changes in trabecular meshwork contractility. The dual localization of TRPC channels on ciliary muscles and trabecular meshwork cells suggests that strategies targeted towards their selective modulation may prove to be advantageous in providing better control of intraocular pressure in patients with ocular hypertension or glaucoma. Such an outcome is possible once there is definitive identification of the TRP channels subtypes on each of these tissues. At this point, it may be possible to maximize fluid outflow rates by selectively decreasing trabecular meshwork resistance through a decrease in its contractile state. Accordingly, additional studies are needed to map the TRP channels subtypes and characterize their mechanisms of regulation in the ciliary muscle and trabecular meshwork.

Chronic intraocular hypertension is a risk factor which in some cases can induce glaucoma due to damage to retinal ganglion cells. Such damage can result from either increased hydrostatic pressure, declines in retrograde neutrophin flow, ischemic or oxidative stress. Irreversible loss of retinal ganglion cells leads to gradual and often insidious vision impairment and possible blindness. Elevated intraocular pressures can activate TRP channels in retinal ganglion cells. TRP channel sensitivity to hydrostatic pressure has been described in the bladder, lungs and skin.[40-42] Sappington et al. showed *in vitro* that exposure of retinal ganglion cells to elevated hydrostatic pressure induced transient rises of intracellular Ca^{2+} accumulation due to TRPV1 channel activation. This effect promoted apoptosis of retinal ganglion cells whereas suppression of TRPV1 channel activation protected retinal ganglion cells from pressure-induced death.[34] Recently, similar stresses were identified to stimulate TRPV4 channel and induce apoptosis in retinal ganglion cells.[43] The increased levels of cytoplasmic Ca^{2+} are the underlying mechanism leading to retinal ganglion cells apoptosis.[44] Ca^{2+}-dependent calcineurin and calpain are a phosphatase and a protease, respectively, that trigger apoptosis signalling. Both of them induce cytochrome c release from mitochondria and trigger pro-apoptotic signalling. In contrast, the TRPV1 channel in the retinal microglia appears to have a retinoprotective effect. Retina microglia cells are essential to neuronal homeostasis and provide innate immunity for retina to defend against pathogenic infiltration. Exposure of microglia to chronic stress is associated with various neurodegenerative diseases, including retinal dystrophies. TRPV1 channel activation in the cultured retinal microglia cells by hydrostatic pressure induces increases in IL-6 and TNF-α release through transient rises in intracellular Ca^{2+} levels. Rises in IL-6 suppress pro-apoptotic signalling pathways and cell

death.[45] Therefore, provided strategies can be devised to selectively induce increases in microglial TRPV1 channels expression, TRPV1 channels may be a potential drug target in managing pressure-induced retinal ganglion cell loss in glaucoma.

4. Possible roles of TRP channels in cataract development

Maintenance of intracellular Ca^{2+} levels is imperative to crystalline lens clarity.[46] Lenses with cortical cataracts have intracellular Ca^{2+} levels that are above those in the physiological range.[47] Accordingly, a better understanding of the mechanisms mediating control of lens intracellular Ca^{2+} levels is pertinent for identifying economical and novel drug strategies to preserve lens transparency or slow cataract progression.

As previously described, store-operated calcium entry (SOCE) channels are composed of TRP subunits and are heterogeneously expressed in the lens epithelial cells. Epithelial cells in the lens equatorial region have higher SOCE expression than that in the central anterior region. This difference is attributable to the fact that the size of the intracellular calcium storage is larger in the equatorial than the central anterior epithelial cells.[48] The higher intracellular Ca^{2+} load in the equatorial epithelium is required for its more rapid proliferative rate than other parts of the lens epithelium. However, the equatorial epithelium is more susceptible to damage that can induce cortical cataracts since the development of such cataracts is associated with Ca^{2+} overload in the lens epithelial cells. The identity of the TRP channels isoforms constituting SOCE channels is elusive since drugs that modulate SOCE channels activity have poor selectivity for each of the different TRP subunits in the TRPV and TRPC channel subfamilies. For example, the inhibitory effects of lanthanum are used as a criterion to distinguish between SOCE and TRPC channel involvement in the development of cataract. At lower concentrations (i.e., in the nanomolar range), lanthanum inhibits SOCE channels, whereas at higher concentrations it blocks TRPC-containing channels.[49, 50] However, this approach is problematic because a cut-off between lanthanum concentration ranges having the inhibitory effect on either SOCE or TRPC channel is poorly defined. Another complication is that, in the micromolar range, Ca^{2+} influx is potentiated through TRPC4- and TRPC5-containing pathways. Nevertheless, the current understanding is that SOCE channels are the major pathway for Ca^{2+} influx in the lens. Better insight into the specific involvement of TRP channels dysfunction in cataractogenesis will be clarified once either more selective Ca^{2+} channel modulators become available or genetic approaches are employed to selectively modulate levels of TRP channel isoform expression.

5. Roles of TRP channels in retinopathy

TRP channels are abundantly expressed in the entire retinal layer including the retinal pigment epithelium (RPE), photoreceptors, retinal ganglion cells, Müller cells, and microglia. Initially, TRP channel-mediated phototransduction was identified in *Drosophila* and 13 of the known 28 homologues of the mutant insect channels were next identified in the mammalian retina.[51] For example, the TRPC channels in mammals are most closely related to the *Drosophila* TRP channels. The difference is that in mammals the six TRPC subfamily genes (i.e., trpc 1, 3–7) encode seven proteins (TRPC1–7 channels), since TRPC2 is a pseudogene.

In *Drosophila* retinal photoreceptors, TRPC channels lead to photoexcitation. Light absorption converts rhodopsin to active metarhodopsin, which activates PLC. PLC hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to IP_3 and diacylglycerol (DAG). DAG can be degraded to release polyunsaturated fatty acids and protons. TRPC channel activation occurs as a consequence of phosphoinositide depletion and acidification resulting from PLC-induced PIP_2 hydrolysis and proton release associated with IP_3 formation.[34] TRPC channel activation by phosphoinositide metabolites suggests that these channels are part of the light-sensing mechanism for *Drosophila,* but their role in humans is still unclear.

TRP channel dysfunction has been implicated in mammalian retinopathy. Mutation of TRPM1 channels in ON bipolar cells has been linked to autosomal-recessive congenital stationary night blindness (CSNB), a heterogeneous group of retinal disorders characterized by non-progressive impaired night vision and variable decreased visual acuity.[52] On the other hand, Wang et al. reported that TRPC6 channel activation has a neuroprotective effect on retinal ischemia-reperfusion (IR) injury in the rat.[53] Following IR, the expression of TRPC6 channels decreases in retinal ganglion cells. Activation of TRPC6 channels before IR reduces retinal ganglion cell losses whereas suppression of TRPC6 channels has an opposite effect. Such protection by TRPC6 channels of retinal ganglion cells is dependent on brain-derived neurotrophic factor (BDNF) signalling.

The RPE layer has essential roles in sustaining normal retinal function. It regulates the hydration and ionic composition of the subretinal space, as well as rod outer segment function. RPE also secretes cytokines that are essential for retinal health. TRPV5 and TRPV6 expressions were identified *in vitro* in the human RPE, implicating that these two most calcium-selective channels of the TRP channel superfamily contribute to the regulation of the subretinal space calcium composition accompanying light/dark transitions.[19] TRPV2 channels were shown in another study to control RPE release of vascular endothelial growth factor (VEGF). Insulin-like growth factor-1 (IGF-1) is a TRPV2 channel activator that selectively induces the intracellular Ca^{2+} transients required for inducing VEGF release. Control of this response is needed to reduce retinal neovascularization, since wet age-related macular degeneration (AMD) is decreased or stabilized by treatment with anti-VEGF antibodies. These results suggest that reducing TRPV2 channels activity may provide another option for managing wet AMD.[54]

6. Summary

TRP channels are involved in ocular sensory and cellular functions. In mammals, TRP channel subunit proteins are encoded by 27 genes and are classified into two groups and six different subfamilies, based on differences in amino acid sequence homology. Group 1 and Group 2 of TRP channels are only remotely related, but share similar cation channel-forming structures of six transmembrane domains. Their cation selectivity and activation mechanisms are very diverse and depend on individual TRP channel. TRP channel activation induces a host of responses to variations in ambient temperature, pressure, osmolarity and pH. In addition, their activation by injury induces inflammation, neovascularization, pain and cell death, as well as wound healing. There is emerging interest in characterizing their roles in inducing ocular surface disease, glaucoma, cataracts and retinopathy. Such efforts could lead to the identification of novel drug targets for improving management of many ocular diseases.

1. Introduction

The mucosa, a mucus-secreting membrane, is linings of surface and cavities that are exposed to the external environment and internal organs. The mucosal immune system has a unique anatomy and physiology, which provides protection to an organism's various mucous membranes from invasion by potentially pathogenic microbes. It provides three main functions: protecting the mucus membrane against infection, preventing the uptake of antigens, microorganisms, and other foreign materials, and moderating the organism's immune response to that material. The mucosal epithelium forms the initial interface between the environment and host, and functions not only as a barrier but also as a sensor providing bidirectional communication with other resident mucosal lymphoid cells with the capacity to respond to pathogenic microbes and other injurious agents.

It has become increasingly clear that epithelial cells play important roles not only in host defense and inflammation, but also in regulation of immune responses. The mammalian immune system is comprised of two branches, the innate immune system and the adaptive immune system, that work in tandem to provide resistance to infection. The innate immune cells, represented primarily by monocytes, macrophages, dendritic cells and granulocytes, are the first line of host defense and are responsible for immediate recognition and control of microbial invasion. In contrast, the adaptive immune system, represented by B and T lymphocytes, has a delayed response, which is characterized by clonal expansion of cells that bind to a highly specific antigen and have immunological memory [1]. Substantial new evidence now indicates that epithelial cells are central participants, as initiators, mediators and regulators, in the innate and adaptive immune responses, as well as in the transition from innate immunity to adaptive immunity.

* Corresponding Author

This new concept has been recently generated from studies mainly in skin and airway epithelial cells. In addition to its function as a physical barrier, human skin has been shown to be an important immune organ displaying various defense mechanisms, which can be divided into three major functional compartments: natural epithelial defense, innate immunity and antigen-elicited adaptive immunity [2-4]. Airway epithelial cells have been recognized to be at the interface of innate and adaptive immunity [5-7]. Airway epithelial cells produce antimicrobial host defense molecules and proinflammatory cytokines and chemokines in response to microbial pathogens. Recruitment of immune cells, including dendritic cells, T cells and B cells into the proximity of epithelium results in the enhancement of adaptive immunity through interactions with epithelial cells. Epithelial cells are also responsible for mucus production in both protective immune responses and allergic airway inflammatory diseases. The crucial roles of epithelial cells in the innate and adaptive immune responses for host defense have also been recognized in other epithelia, including gastrointestinal mucosa [8-10] and ocular surface [11-13]. This chapter is focused on recent advances of this new concept that mucosal epithelium plays a central role in initiating and regulating innate and adaptive immune responses in ocular inflammatory diseases, based on literature review and our new findings. These novel breakthroughs in mucosal immunology would facilitate new therapeutic strategies for treating ocular inflammatory diseases.

2. Toll-like receptors and ocular mucosal innate immunity

The innate immune response relies on evolutionarily ancient germline-encoded receptors, the pattern recognition receptors (PRRs) [14], which recognize highly conserved microbial structures (Table 1). PRRs recognize microbial components, known as pathogen-associated molecular patterns. A breakthrough in the understanding of the ability of innate immune system to rapidly recognize pathogens occurred with the discovery of the Toll-like receptors (TLRs), which is the most important family among the PRRs. At least 10 human TLRs have been identified to date. Each TLR has unique ligand specificity. In general, TLRs 1, 2, 4, 5 and 6 present on the cell plasma membrane and respond to a variety of components of bacteria and fungi (Table 1); and TLRs 3, 7, 8 and 9 mainly present on endosomal membranes inside cells and recognize viral nucleic acids [12]. Among 4 types of transmembrane proteins structurally, TLRs are single-pass type I transmembrane proteins with leucine rich repeats in the extracellular domain for ligand recognition, and a Toll/IL-1 receptor (TIR) domain in the cytoplasmic portion for intracellular signaling [12, 15-17]. TLRs are expressed on immune cells that are most likely to first encounter microbes, such as neutrophils, monocytes, macrophages, and dendritic cells [15]. Ligand recognition by TLRs facilitates the dimerisation of TLRs that triggers the activation of signaling pathways, which originates from the cytoplasmic TIR domain, and culminates in the activation of the nuclear transcription factor NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells), which leads to the expression of pro-inflammatory molecules, such as TNF-α, IL-1β, IL-6 [16, 18-20]. In addition to innate immune cells, an array of TLRs is expressed by epithelial cells at interfaces between host and environment including that of the skin [2, 21], respiratory tract [5, 6], gastrointestinal tract [9], and ocular surface [12, 13]. Strategic expression of TLRs at such host/environment interfaces appears to play an important role in the first line of defense against microbial invasion at these sites.

TLR	Microbial components	Ligands used for study
TLR1/TLR2	Triacylated lipopeptide (LP)	Pam3CSK4 (1-100 μg/ml)
TLR2*	Bacterial lipoprotein	
	Peptidoglycan	peptidoglycan-BS (1-50 μg/ml)
	lipoteichoic acid	LTA-SA (0.1-10 μg/ml)
	Zymosan (fungi)	Zymosan (1-100 μg/ml)
TLR3	Double stranded RNA (viruses dsRNA)	Poly I:C (5-50 μg/ml)
TLR4	LPS (Gram negative bacteria)	LPS (1-50 μg/ml)
	Bacterial HSP60	
	Respiratory syncytial virus coat protein	
TLR5	Flagellin (flagellated bacteria)	Flagellin-ST (1-25 μg/ml)
TLR6/TLR2	Diacylated lipopeptides	FSL-1 (0.1-10 μg/ml)
TLR7	Imidazoquinolone antiviral drug	Imiquimod (R837, 1-50 μg/ml)
TLR8	Single stranded RNA (viruses ssRNA)	ssRNA40 (0.1-10 μg/ml)
	Imidazoquinolone antiviral drug	
TLR9	Unmethylated CpG motifs of bacterial DNA	C-CpG-ODN (1-50 μg/ml)
TLR10	Unknown	

* TLR2 forms heterodimers with TLR1 and TLR6: TLR1 associates with TLR2 to recognize tri-acyl lipopeptides; TLR6/TLR2 heterodimer recognizes diacyl lipopeptides.

Table 1. Human Toll-like receptors (TLRs) and their microbial ligands

Ocular mucosal epithelial cells have been identified to express an array of functional TLRs [12, 13]. The production of pro-inflammatory cytokines, chemokines and antimicrobial peptides is stimulated via TLR2 by corneal epithelial cells exposed to yeast zymosan [22] and peptidoglycan of Staphylococcus aureus [23]. This pathway may have a role in the pathogenesis of Gram positive bacterial keratitis. Signaling through TLR9 appears important in P. aeruginosa keratitis, and silencing TLR9 signaling reduces inflammation, but likely contributes to decreased bacterial killing in the cornea [24]. Stimulation of TLR3 can induce the expression of proinflammatory cytokines, chemokines and antiviral genes that help to defend the cornea against viral infection [25, 26]. However, the distinctive role of ligand-stimulated TLR signaling in epithelium on regulation of innate and adaptive immunity remains to be elucidated.

3. Ocular epithelial cytokine TSLP links innate and adaptive immunity via Th2 inflammatory responses

Compelling evidence has been recently provided that thymic stromal lymphopoietin (TSLP) represents a key initiator of allergic inflammation at the interface of epithelial and dendritic cells, and TSLP may have a determinant role in the initiation and maintenance of the allergic immune response in atopic dermatitis and asthma [27-31]. Skin-derived TSLP was found to trigger progression from epidermal-barrier defects to asthma, the atopic march, in mice [31, 32].

TSLP is a 140-amino acid IL-7-like 4-helix bundle cytokine that was first isolated from a murine thymic stromal cell line and shown to support B-cell development in the absence of IL-7 [33]. Mouse and human TSLP share a poor homology of 43% amino acid identity. The human TSLP gene is localized in chromosome 5q22, not far from the gene cluster encoding for all the Th2 cytokines, IL-4, IL-5 and IL-13 [34]. The TSLP receptor (TSLPR) complex consists of a TSLP binding chain and the IL-7 receptor α chain (IL-7Rα). Like TSLP, human and mouse TSLPR share approximately 40% amino acid identity. By interacting with the heterodimeric receptor TSLPR/IL-7Rα, TSLP appears to initiate phosphorylation of signal transducer and activator of transcription (STAT) 3 and STAT-5 [27, 35].

It was demonstrated that epithelial cell-derived TSLP could strongly activate human myeloid dendritic cells to mature dendritic cells that produce OX40 ligand (OX40L) in the absence of IL-12 to induce an inflammatory Th2 response characterized by high level of pro-inflammatory cytokine TNF-α with low level of anti-inflammatory cytokine IL-10, distinct from the regulatory Th2 responses characterized by low TNF-α and high IL-10 production [27, 28]. This suggests that TSLP represents a key initiator of allergic inflammation at the interface of epithelial cells and dendritic cells. TSLP was also demonstrated to direct the innate phase of allergic immune responses through activating mast cells. Therefore, TSLP and OX40L may represent important targets for intervention in the initiation of allergic inflammatory responses.

Epithelial cells appear to be the major potential producer of TSLP in both mice and humans, although fibroblasts, smooth muscle cells, and mast cells all have the potential to produce TSLP [35, 36]. The expression of TSLP by epithelial cells has been recently shown to be stimulated by microbial ligands, inflammatory and Th2 cytokines [37-39]. Using ocular mucosal epithelium as a model, Li and associates [40] have evaluated the expression and production of TSLP by primary human corneal epithelial cells in response to 11 extracted or synthetic microbial components that are ligands of TLRs 1-9 (Table 1). As shown in Figure 1A, TSLP expression and production were found to be largely induced by the ligands to TLRs 3, 5 and 6, which were polyinosinic-polycytidylic acid (polyI:C), flagellin and FSL-1, respectively, representing viral dsRNA and the bacterial components flagellin and lipopeptides. PolyI:C and flagellin, the major TSLP inducers, stimulated TSLP production to 67- and 19-fold, respectively. The TSLP mRNA reached the peak levels rapidly in 4 hours in response to these ligands. The specificity of this response was confirmed when respective antibody against TLR3 or TLR5 significantly blocked TSLP expression induced by polyI:C and flagellin, respectively. The pattern of TLR-dependant TSLP induction indicates that human corneal epithelial cells are able to rapidly initiate an innate immune response to virus or bacteria through TLR-mediated pathways. TSLP was also moderately induced by pro-inflammatory cytokines at both mRNA and protein levels. TNF-α or IL-1β induced a concentration dependent increase in the TSLP mRNA and protein, but their stimulatory effects were much weaker than that of polyI:C and flagellin, which stimulated TSLP protein production over 15- and 4-fold higher, respectively, than TNF-α. These data suggest that TSLP induction is mainly through a TLR-dependant innate immune response to microbes in human ocular epithelium.

IL-4 and IL-13, the major cytokines secreted by Th2 cells, not only moderately induced TSLP mRNA and protein, but also strongly synergized with microbial ligands, such as polyI:C, or pro-inflammatory cytokine TNF-α to promote TSLP expression and production (Figure 1B). This synergized induction of TSLP was further confirmed in an ex vivo experiment model

using fresh human corneal epithelial tissues (Figure 1C). These findings demonstrate that adaptive immunity-derived Th2 cytokines are capable of amplifying the TSLP expression and production by the corneal epithelium, which in turn has the capability of priming Th2 cell differentiation through dendritic cell activation [27, 28]. These findings suggest that blocking TSLP could be a novel strategy for treatment of allergic diseases or other TSLP-driven conditions.

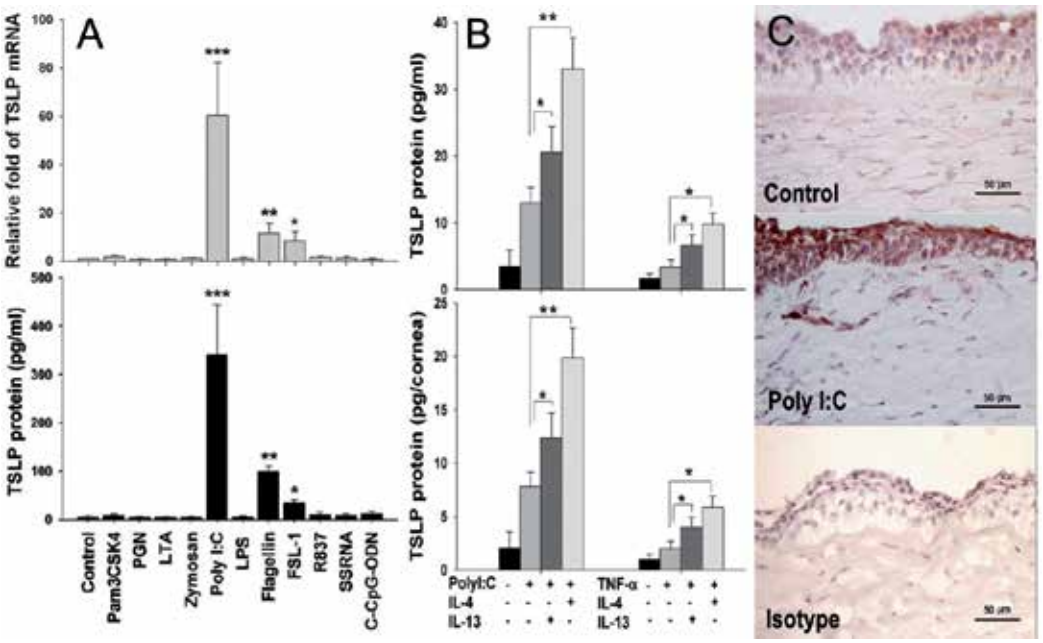

Fig. 1. TLR-mediated induction of TSLP by microbial ligands, TNF-α and Th2 cytokines. **A**. TSLP induction in HCECs. The confluent primary HCECs were incubated with 50μg/ml polyI:C or 10μg/ml of Pam_3CSK_4, peptidoglycan (PGN), LTA, Zymosan, LPS, flagellin, FSL-1, R837, single stranded RNA (ssRNA40) or C-CpG-ODN for 4 hours for TSLP mRNA expression by RT-qPCR, or for 48 hours for TSLP protein in the culture supernatants by ELISA; **B.** TSLP induction in an ex vivo model of human corneal tissues. A fresh corneoscleral tissue was cut into 4 equal size pieces. Each quarter of corneal tissue was placed into a well of 8-chamber slides in 150 μl of serum-free SHEM medium without or with polyI:C (50 μg/ml) or TNF-α (20 ng/ml) in the presence of IL-4 or IL-13 (100 ng/ml) for 24 hours. The culture supernatants were used for TSLP ELISA. Results shown are mean ± SD of 3 independent experiments. * $p < 0.05$; ** $p < 0.01$; *** $P < 0.001$. **C.** The corneal tissues were prepared for cryosections for TSLP immunohistochemical staining with isotype IgG as negative control.

Although the recognition of different ligands by specific TLRs leads to activation of an intracellular signaling cascade in a myeloid differentiation primary response gene 88 (MyD88)-dependent or independent fashion, all TLRs share NF-κB signal transduction pathways for activation of the transcription factors [20]. TNF-α is also well known to promote activation of the NF-κB signaling pathway [41]. TSLP induction has been observed through NF-κB activation in airway epithelial cells [30] and synovial fibroblasts [42]. As evaluated by Western blot analysis and immunofluorescent staining, NF-κB was found to be

dramatically activated in corneal epithelial cells exposed to polyI:C, flagellin or TNF-α for 4 hours. This activation was evidenced by nuclear translocation of p65 protein, one of the two proteins in NF-κB heterodimer. This p65 nuclear translocation and TSLP induction, stimulated by polyI:C, flagellin or TNF-α were markedly blocked by TLR3, TLR5 or TNF-α specific antibody, respectively, and also by quinazoline, a NF-κB activation inhibitor [40]. These findings confirm that TSLP is mainly induced by microbial components, proinflammatory cytokines and Th2 cytokines in human corneal epithelial cells via TLR and NF-κB signaling pathways, suggesting that epithelium-derived TSLP links the innate and adaptive immune responses,

4. TSLP/OX40L/OX40 signaling initiates Th2-dominant allergic conjunctivitis

Allergic diseases like seasonal allergy, asthma, atopic dermatitis, affect up to 20-30% of the population in industrialized countries, and up to 50% of these individuals reporting ocular allergic manifestations [43-45]. The incidence of allergies has increased steadily over the past 30 years. Th2-dominant hypersensitivity is a major contributor to allergic inflammatory diseases, but the underlining mechanism for initiation of this adaptive immune disorder by mucosal epithelia remains a relative mystery. The molecular triggers for Th2 allergic inflammation were not clear until studies identified a novel epithelium-derived pro-allergic cytokine TSLP, which activates myeloid dendritic cells (DCs) to produce OX40 ligand (OX40L) that triggers a Th2 inflammatory response. TSLP has been identified as a key initiator in the development of human allergic disease [31, 46, 47], including asthma, atopic dermatitis and allergic conjunctivitis, a triad of common atopic IgE-dependent allergic diseases [48]. The direct link between TSLP expression and the pathogenesis of atopic dermatitis and asthma in vivo has been demonstrated [29]. TSLP was found to be highly expressed by keratinocytes in skin lesions of atopic dermatitis and was associated with dendritic cell activation in situ [49]. Evidence associating TSLP with human asthma has also been reported [29, 32]. Patients suffering from one member of the triad often show symptoms of one or both of the other members, suggesting a common genetic or initiating element in these diseases [31].

Using a well characterized murine model of experimental allergic conjunctivitis (EAC) induced by short ragweed (SRW) pollen [50, 51], Li and colleagues observed that the repeated topical challenges with ragweed pollen allergen generated typical signs of allergic conjunctivitis in the pollen-sensitized BALB/c mice, which developed lid edema, conjunctival redness, chemosis, and tearing, as well as frequent scratching of the eye lids [52]. They found that TSLP mRNA expression was significantly upregulated in the corneal and conjunctival epithelia from mice sensitized and challenged with pollen when compared with phosphate buffered saline (PBS) alone and untreated normal controls. Immunohistochemical staining confirmed an increase in TSLP production in the eyes challenged with SRW pollen. As shown in Figure 2A, the corneal and conjunctival epithelia in EAC BALB/c mice displayed much stronger TSLP staining throughout the entire epithelium, especially the superficial epithelial layers of the conjunctiva, than the PBS-treated control. These data indicate the stimulated TSLP mRNA expression and protein production by ocular surface epithelia in the SRW-induced EAC murine model.

The accumulation of CD11c positive ($CD11c^+$) dendritic cells on the ocular surface was detected in this EAC model by reverse transcription and quantitative real-time polymerase

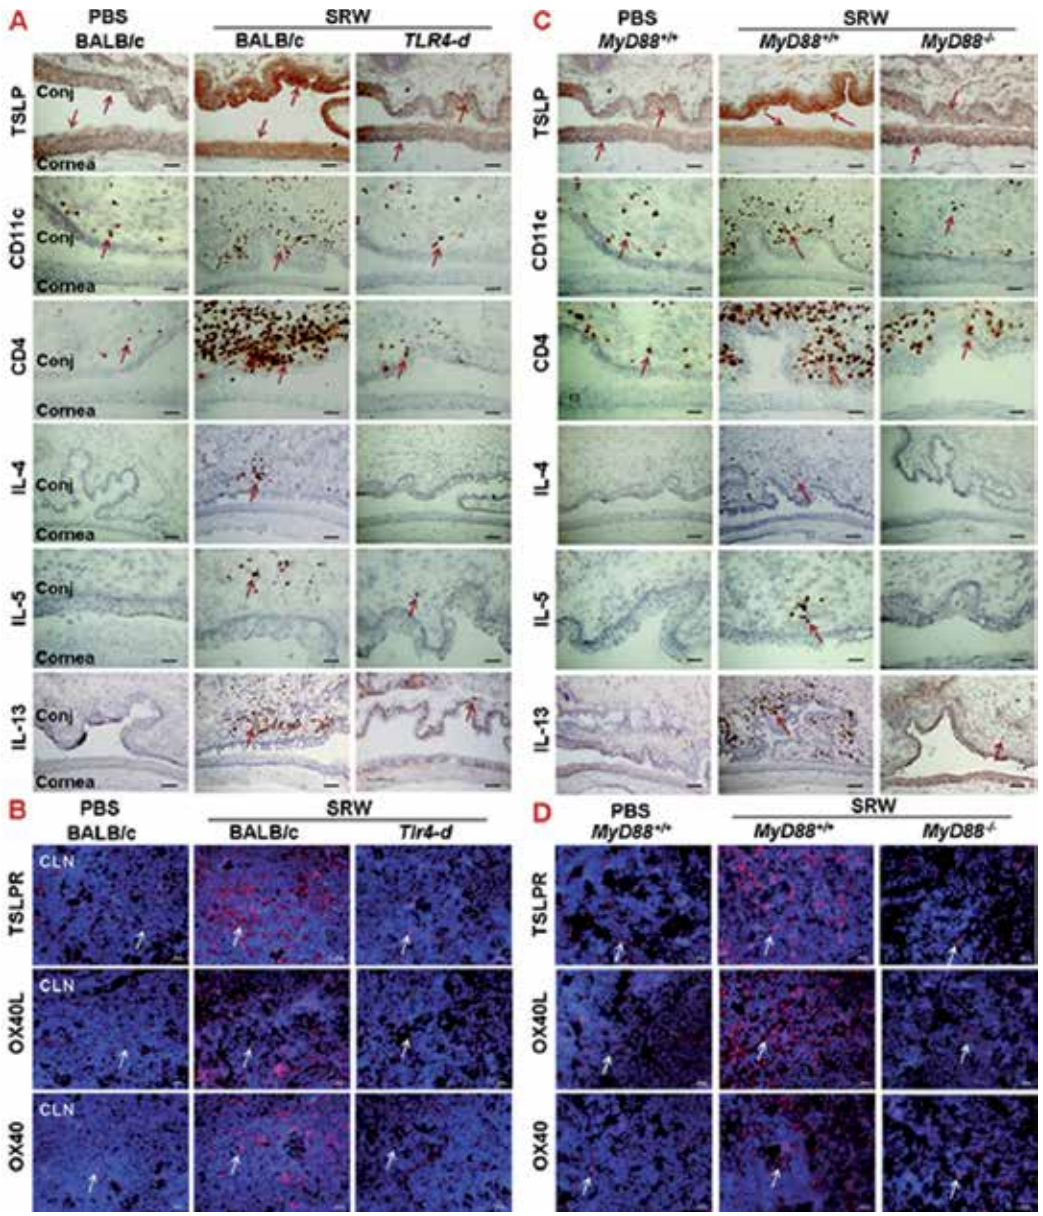

Fig. 2. The stimulated production of TSLP signaling proteins and Th2-dominant inflammation in SRW-induced EAC model requires TLR4 and MyD88. **Top panel**: The representative images showing immunohistochemical staining of epithelial TSLP, markers for dendritic (CD11c) and T cells (CD4), and Th2 cytokines (IL-4, IL-5 and IL-13) on cornea and conjunctiva (Conj) of wild type and *Tlr4* deficient BALB/c mice challenged by SRW pollen, with PBS-treated mice as controls (**A**), and of C57BL/6 based wild type *MyD88*$^{+/+}$ and knockout *MyD88*$^{-/-}$ mice challenged by SRW pollen, with PBS-treated mice as controls (**C**). **Bottom panel**: The representative images showing immunofluorescent staining of TSLP activated signals, TSLPR, OX40L and OX40 on cervical lymph nodes (CLN) of wild type and

Tlr4 deficient BALB/c mice challenged by SRW pollen with PBS-treated mice as controls (**B**), and of C57BL/6 based wild type *MyD88*$^{+/+}$ and knockout *MyD88*$^{-/-}$ mice challenged by SRW pollen, with PBS-treated mice as controls (**D**). Bar: 20μm; Arrows: red or red brown positive staining signals.

chain reaction (RT-qPCR) and immunostaining. The increased mRNA levels of CD11c, TSLPR and OX40L were observed in ocular surface, especially in conjunctival tissues, where their transcripts increased to 4-10 fold, respectively ($P< 0.05$ or <0.01), from SRW pollen-challenged mice, compared with PBS controls. The large amount of CD11c$^+$ dendritic cells was accumulated in the ocular surface of the pollen challenged eyes, primarily in the stroma subjacent to the conjunctival epithelia, in EAC mice, but not in the control mice treated with PBS (Figure 2A). These results suggest that ocular surface was infiltrated with TSLP activated dendritic cells that express TSLPR and produce OX40L in the EAC mice.

Th2-dominant inflammatory response was clearly observed on ocular surface in the mice challenged by pollen. The infiltration of T lymphocytes was evidenced by the increased CD4 mRNA expression and a markedly increased number of CD4 immunopositive (CD4$^+$) cells in the ocular surface, especially in the conjunctiva, of EAC mice (Figure 2A), when compared with PBS control mice. These CD4$^+$ T cells appear to be Th2 lineage because the transcripts of three key Th2 cytokines, IL-4, IL-5 and IL-13, were all found to be expressed at significantly higher levels in corneal and conjunctival tissues from the EAC mice than the PBS controls. Immunostaining data confirmed that the IL-4, IL-5 and IL-13-producing Th2 cells were largely infiltrated in conjunctival stroma (Figure 2A).

To confirm the TSLP signaling in SRW pollen-induced EAC mice, the ocular surface draining cervical lymph nodes (CLN) were collected for evaluation (Figure 3A). Compared with PBS controls, the mRNA levels of TSLPR and OX40L were significantly stimulated to 7.5 and 4.1 fold respectively (both $P<0.01$) while CD11c expression only slightly increased in CLN from EAC mice, indicating CD11c$^+$ DCs were markedly activated by ocular surface epithelia-derived TSLP. The mRNA levels of OX40 (3.4 fold, $P<0.05$) and Th2 cytokines, IL-4, IL-5 and IL-13 (13.2, 12.8 and 5.5 fold, respectively, all $P<0.01$), significantly increased while CD4 expression was not changed in the CLN from EAC mice, indicating naive CD4$^+$ T cells were largely differentiated to Th2 cells that might be primed by OX40L produced by TSLP activated dendritic cells [28]. The increased TSLPR$^+$, OX40L$^+$ and OX40$^+$ cells in the draining CLN of the pollen challenged EAC mice were further confirmed by immunofluorescent staining that showed dramatically increased immunoreactivity of these 3 signaling proteins at cell membrane and cytoplasm in CLN (Figure 2B). All these results demonstrate that TSLP/OX40L/OX40 signaling plays a critical role in the development of Th2-dominant allergic inflammation in pollen induced EAC model in BALB/c mice, suggesting that TSLP signaling molecules could be novel therapeutic targets to treat allergic inflammatory disease.

5. Cutting edge breakthrough: Short ragweed pollen triggers ocular allergic inflammation through TLR4-dependent innate immune response

Although there have been numerous studies on the development of allergen-induced inflammation, the mechanisms leading to resolution of allergic inflammation remain poorly understood. This represents an important knowledge gap and potential challenge because

failure to resolve allergen driven inflammation potentially leads to recurrent or chronic allergic diseases. Pollen, a ubiquitous allergen, affects a large population of allergic patients. Pollen is the trigger of seasonal rhinitis, conjunctivitis and asthma, as well as an exacerbating factor of atopic dermatitis. However, the underlying molecular mechanism by which pollen induces Th2-dominant allergic inflammation via epithelial innate immunity pathways is largely unknown. Substantial evidence now indicates that epithelial cells are central participants in innate and adaptive immune responses [4, 5, 7]. Based on the observation that we and other groups have made [40, 53, 54] that TSLP is mainly induced via TLR mediated innate response in epithelia exposed to microbial products, we hypothesized that pollen, such as Ambrosia artemisiifolia short ragweed (SRW), the most widespread plant in North America, may serve as a functional TLR4 agonist that induces production of a proallergic cytokine TSLP via innate immune response to trigger Th2-dominant allergic inflammation. To uncover the novel phenomenon and molecular signaling pathways involved in pollen induced allergic inflammation, a comprehensive set of experiments has been conducted using a well-characterized murine model of allergic conjunctivitis induced by SRW pollen in BALB/c, TLR4 deficient and MyD88 knockout mice, as well as a murine topical ocular surface challenge model and a culture model of primary human corneal epithelial cells exposed to an aqueous extract of defatted SRW pollen.

TLR-mediated TSLP induction has been recognized [39, 53, 54]. We have demonstrated that TSLP was largely induced by specific TLR ligands in human corneal epithelial cells [40]. MyD88 is a universal adapter protein necessary for response to all TLRs except TLR3 [55, 56]. *Tlr4*-deficient (*Tlr4*-d, C.C3-Tlr4Lps-d/J) and MyD88 knockout ($MyD88^{-/-}$) mice have been used to identify TLR4 mediated signaling [57, 58]. To explore whether SRW pollen stimulates TSLP through TLR4-dependent innate response, we sensitized and topically challenged the wild-type BALB/c, *Tlr4*-d (Jackson Laboratory, Bar Harbor, ME) and $MyD88^{-/-}$ mice (gifts from Dr. Shizuo Akira, Research Institute for Microbial Disease, Osaka University, Japan) with SRW pollen.

Compared with wild-type BALB/c mice, the ocular allergic signs, stimulated TSLP/OX40L/OX40 signaling and Th2-dominant inflammatory response by ocular mucosa, especially conjunctival tissues, were dramatically reduced or eliminated in BALB/c based *Tlr4*-d mice. As shown in Figure 3A, the mRNA levels of TSLP, OX40L, OX40 and Th2 cytokines (IL-4, IL-5 and IL-13) were significantly stimulated in cornea, conjunctiva and draining CLN from wild-type BALB/c, but not in those from *Tlr4*-d mice. The immunostaining results confirmed that SRW pollen did not stimulate TSLP and its downstream molecules or a Th2 response in ocular mucosal tissues (Figure. 2A) and draining CLN (Figure. 2B) of *Tlr4*-d mice. These findings suggest that TLR4-dependent TSLP signaling was involved in the SRW pollen induced allergic inflammation.

The SRW topical challenges triggered the typical allergic signs and scratching behavior in wild type $MyD88^{+/+}$ mice, although less severe than BALB/c mice. The expression of TSLP and its signaling molecules, TSLPR, OX40L and OX40, as well as Th2 cytokines IL-4, IL-5 and IL-13 was significantly stimulated in the cornea, conjunctiva and CLN from SRW challenged wild type $MyD88^{+/+}$ mice at both mRNA (Figure. 3B) and protein levels (Figure 2C, 2D). Clinical allergic signs and stimulated production of TSLP signaling molecules (TSLPR, OX40L and OX40) and Th2 cytokines (IL-4, IL-5 and IL-13) were dramatically reduced or eliminated in SRW challenged $MyD88^{-/-}$ mice as evaluated by RT-qPCR (Figure

3B) and immunostaining (Figure 2C, 2D). These findings suggest that MyD88 pathway is involved in the TLR4-dependent TSLP signaling induced by SRW pollen.

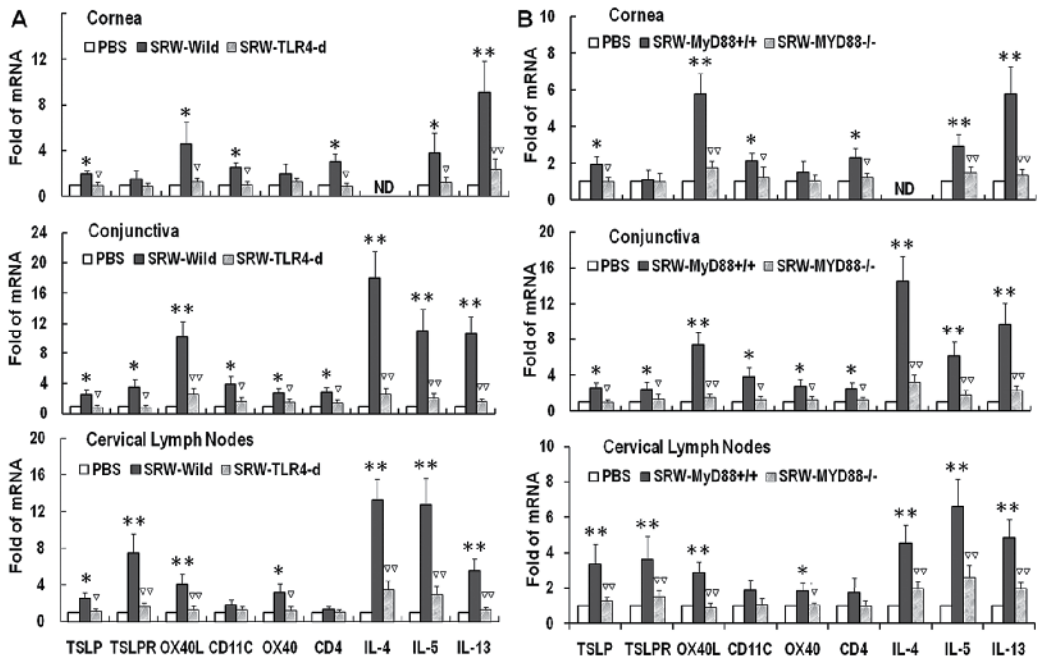

Fig. 3. The stimulated expression of TSLP signaling molecules and Th2 cytokines in SRW-induced EAC model requires TLR4 and MyD88. The mRNA expression of proallergic cytokine TSLP, its downstream signals in dendritic (TSLPR, OX40L, & CD11c) and T cells (OX40 & CD4), as well as Th2 cytokines (IL-4, IL-5 and IL-13) by corneal epithelium, conjunctiva and cervical lymph nodes in wild type and *Tlr4* deficient BALB/c mice sensitized and topically challenged by SRW with PBS-treated mice as controls (**A**), and in C57BL/6 based wild type *MyD88*$^{+/+}$ and knockout *MyD88*$^{-/-}$ mice, sensitized and topically challenged by SRW pollen, with PBS-treated mice as controls (**B**). The mRNA levels are presented as relative fold in EAC mice over the controls, which were evaluated by RT and real-time qPCR using TaqMan gene expression assay system with GAPDH as an internal control. Results shown are the Mean ± SD of four independent experiments. **P*<0.05, ***P*<0.01; *n*=4, compared with PBS controls; ▽P<0.05, ▽▽P<0.01, n=4, compared with wild type mice.

To confirm that SRW pollen directly stimulates TSLP production by ocular mucosal epithelia through TLR4-dependent innate immunity pathway, we created a topical challenge murine model using an aqueous extract of defatted SRW pollen (SRWe) at 150μg/5μl/eye for 4-24 hours. TSLP mRNA was induced as early as 4 hours and reached peak levels at 8 hours, and TSLP protein levels increased in 24 hours in ocular epithelia exposed to SRWe. As shown in Figure 4 A & B, SRWe significantly stimulated TSLP mRNA by 2 fold in corneal and conjunctival epithelia (Both *P*<0.05), and its protein levels by 3.2 fold (from 150.2±37.6 pg/mg cellular protein to 480.00±89.6 pg/mg) in cornea epithelia and 2.2 fold (from 128.6±29.8 pg/mg to 281.6±19.3 pg/mg) in conjunctiva in BALB/c mice when

compared with untreated or PBS-treated controls. The SRWe-stimulated TSLP were significantly decreased at both mRNA and protein levels by TLR4 blocker, a rat anti-mouse TLR4 antibody, but not by its isotype rat IgG2a.

The SRWe topical challenge did not increase TSLP mRNA (Figure 4C) and protein levels (Figure 4D) in corneal and conjunctival epithelia of *Tlr4-d* mice. Similarly, a TLR4 agonist lipopolysaccharides (LPS, 5μg/5μl/eye) stimulated TSLP production by corneal and conjunctival epithelia in BALB/c mice, but not in *Tlr4-d* mice. Furthermore, we applied this topical challenge model to MyD88 knockout mice and their wild type controls. SRWe

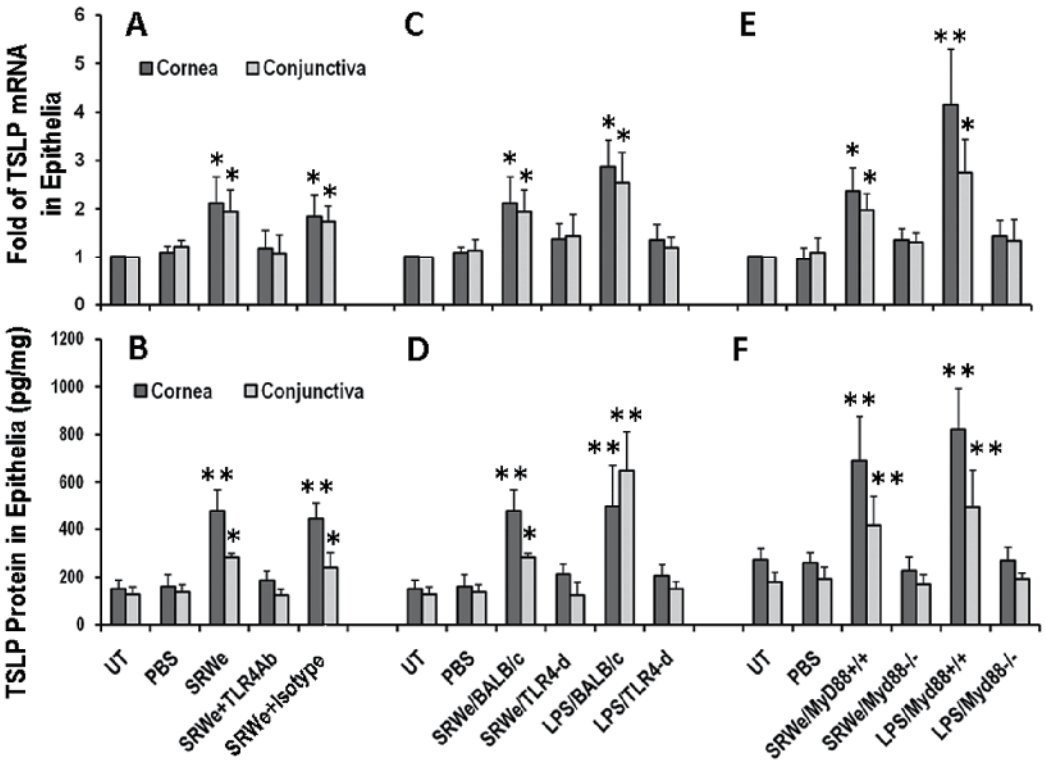

Fig. 4. Aqueous extract of defatted SRW pollen (SRWe) induces TSLP expression and production by murine ocular surface epithelia through TLR4- and MyD88-dependent innate immunity pathway. **A, B**. BALB/c mice were topically instilled with SRWe at 150μg/5μl/eye for 6 or 24 hours for TSLP mRNA (A) or protein (B) respectively, without or with pre-instilled rat anti-mouse TLR4 antibody (1μg/5μl/eye) or its isotype rat IgG2a. Untreated (UT) and PBS-treated mice were used as controls. Corneal epithelium and conjunctiva were harvested for TSLP mRNA and protein by RT-qPCR and ELISA respectively. **C, D**. TSLP mRNA (C) and protein (D) induction by topically challenged SRWe or LPS (5μg/5μl/eye) in wild type and *Tlr4-d* BALB/C mice, with untreated or PBS-treated mice as controls. **E, F.** TSLP mRNA (E) and protein (F) induction by topically challenged SRWe or LPS in wild type *MyD88*$^{+/+}$ and knockout *MyD88*$^{-/-}$ mice, with untreated or PBS-treated mice as controls. Results shown are the Mean ± SD of four independent experiments. **P*<0.05, ***P*<0.01; n=4, compared with PBS controls.

promoted TSLP production by ocular epithelia at both mRNA (Figure 4E) and protein levels (Figure 4F) only in *MyD88*$^{+/+}$ mice, but not in *MyD88*$^{-/-}$ mice, a similar pattern to that observed following LPS topical challenge. Taken together, these data demonstrated that SRWe directly stimulates TSLP production by ocular mucosal epithelia via a TLR4-dependent innate pathway.

To explore whether this phenomenon occurs in humans, we investigated TSLP expression in human corneal epithelium. TSLP mRNA was upregulated at 4 hours and its protein was detected at 24 hours in human corneal epithelial cells (HCECs) exposed to SRWe, which is consistent with our previous report [40]. TSLP induction at mRNA (Figure 5A) and protein levels (Figure 5B) was concentration-dependently stimulated by SRWe in primary HCECs. TSLP protein was barely detectable (4.83±1.60 pg/ml) in the supernatant of normal HCEC cultures. SRWe at 10μg/ml increased the TSLP protein to 48.92±4.23 pg/ml (P<0.01), the levels comparable to that stimulated by 10ng/ml of TNF-α in HCECs [40]. The SRWe (10μg/ml)-stimulated TSLP mRNA was significantly blocked by pre-incubation of cells with 10μg/ml of neutralizing monoclonal antibody against human TLR4, but not by its isotype mouse IgG2a k (Figure 5C). Furthermore, SRWe stimulated TSLP expression was also significantly inhibited by quinazoline, a NF-κB Activation Inhibitor (Figure 5C). These findings were confirmed by detection of increased TSLP protein levels as shown in Figure 5D. These data demonstrate that SRW induces TSLP production in human corneal epithelial cells through TLR4 and NF-κB innate signaling pathways.

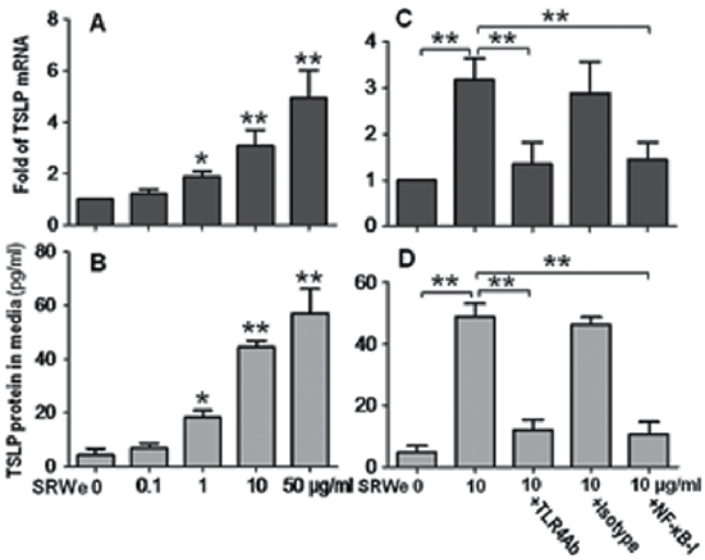

Fig. 5. SRWe induces TSLP expression and production by human corneal epithelial cells (HCECs) through TLR4 and NF-κB signaling pathways. **A, B**. Confluent cultures of primary HCECs were treated with 0.1 to 50 μg/ml of SRWe for 4 hours for TSLP mRNA or 48 hours for TSLP protein in the supernatants. **C, D.** HCECs were pre-incubated with mouse TLR4 antibody (10μg/ml), isotype mouse IgG2a k, or NF-κB activation inhibitor quinazoline (NFkB-I, 10μM) for 1 hour before adding 10μg/ml SRWe for 4 hours for TSLP mRNA or 48 hours for TSLP protein in the supernatants. Results shown are the Mean ± SD of four independent experiments. *P<0.05, **P<0.01; n=4.

Traditionally, TLRs recognize conserved microbial components as ligands or agonists. Recent studies have revealed that TLR4 recognizes a wider variety of ligands than previous thought. In addition to its first identified ligand, bacterial LPS, TLR4 was found to recognize certain viral proteins such as the F protein from respiratory syncytial virus and mouse mammary tumor virus. Not limited to pathogen-associated molecular patterns (PAMP), TLR4 responds to human endogenous structural proteins derived from tissue injury or during inflammation, the damage-associated molecular patterns (DAMP), such as type III repeat extra domain A of fibronectin, oligosaccharides of hyaluronic acid, human heat-shock protein Hsp60 and Hsp70 (see review [59]). A few reports have revealed the potential for protein extracts from plants and herbs to activate TLR4, such as taxol, an antitumor agent derived from the Yew plant [60], and aqueous extract of Rhodiola imbricata rhizome, a medicinal plant [61].

In conclusion, we have for the first time uncovered a novel phenomenon and a unknown mechanism that short ragweed pollen, serving as a functional TLR4 agonist, induces TSLP/OX40L/OX40 signaling to trigger Th2-dominant allergic inflammation via TLR4-dependent innate immunity pathways [62]. These novel findings shed light on the understanding of innate mucosal epithelial immunity involved in allergic inflammation, and may create new therapeutic targets to cure allergic disease.

6. Epithelium-derived interleukin 33 initiates allergic inflammation

The IL-1 receptor family has several members, including the classical IL-1 receptor (IL-1R) and the IL-18 receptor (IL-18R). In 1989, one member of the family, ST2, a protein encoded by IL-1 receptor-like 1 (IL-1RL1) gene, was identified as an orphan receptor [63]. Investigation into the function of ST2 revealed its participation in inflammatory processes, particularly regarding mast cells, type 2 $CD4^+$ T helper cells and the production of Th2-associated cytokines. In fact, ST2 was characterized as a specific cellular marker that differentiated Th2 from Th1 T cells. Clinical and experimental observations led to the association of ST2 with disease entities such as asthma, pulmonary fibrosis, rheumatoid arthritis, collagen vascular diseases and septic shock [64]. In 2005, the discovery of IL‑33 as a ST2 ligand provided new insights into ST2 signaling [65]. By binding to ST2 receptor, IL-33 can activate Th2 cells and mast cells to secrete the proinflammatory and Th2 cytokines and chemokines that lead to severe pathological changes in mucosal organs [66].

IL-33 is produced mainly by epithelial and endothelial cells, fibroblast, and others [66-68]. IL-33 expression has been found to be up-regulated by stimulation with inflammatory cytokines, TNF-α and IL-1β [69]. However, the expression and regulation of IL-33 by mucosal surface epithelia has not been well elucidated. Using fresh donor corneal tissues and primary HCECs, we recently observed that IL-33 is mainly expressed by epithelium and largely induced by microbial products through TLR and NF-κB signaling pathways [70]. The findings suggest that the mucosal epithelial cell-derived cytokine IL-33 may play an important role in allergic inflammatory diseases through innate immune responses.

As shown in Figure 6A, IL-33 expression and production were largely induced by polyI:C, lipopolysaccharides (LPS), flagellin, FSL-1 and R837, the ligands for TLR3, -4, -5, -6 and -7, representing viral dsRNA and the bacterial components flagellin and lipopeptides, respectively. PolyI:C and flagellin were major IL-33 inducers, stimulating IL-33 production by 7- and 4-fold, respectively, with the peak mRNA levels at 8 hours by HCECs. The IL-33 induction by these 2 ligands was further confirmed using an ex vivo donor corneal tissue

model (Figure 6B). The specificity of TLR-dependent response by HCECs was also confirmed when an antibody against TLR3 or TLR5 significantly inhibited IL-33 expression by polyI:C or flagellin respectively (Figure 6C). The pattern of TLR-dependent IL-33 induction indicates that HCECs are able to rapidly initiate an innate immune response to virus or bacteria, and play an important role in allergic inflammatory disease.

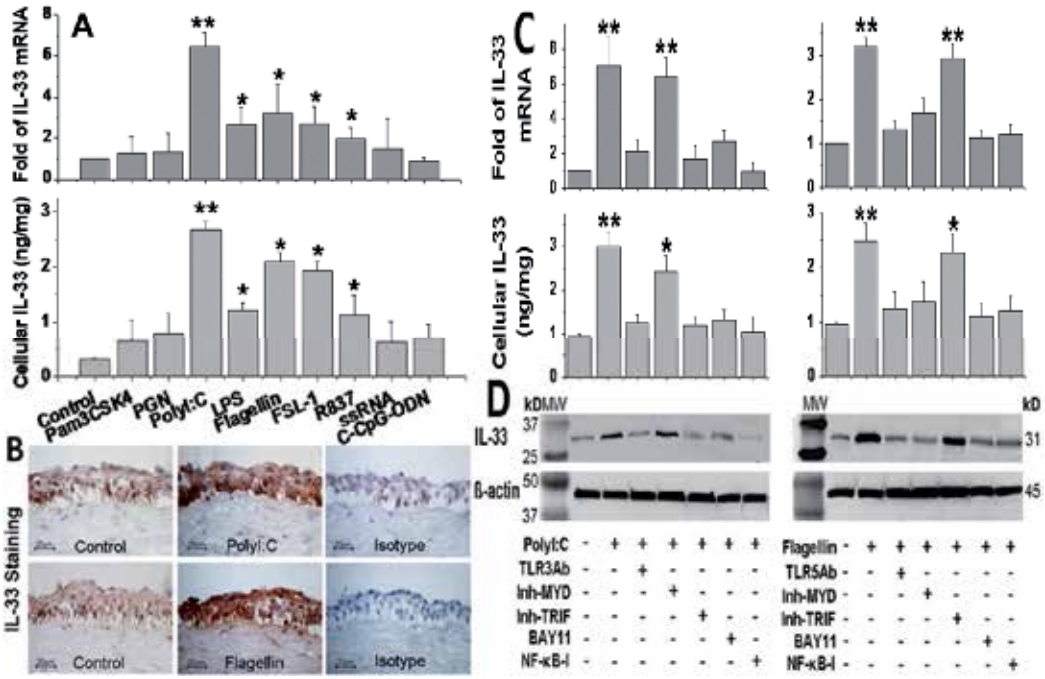

Fig. 6. TLR-dependent induction of IL-33 by microbial ligands in human corneal epithelium. **A.** IL-33 mRNA and protein levels induced by primary human corneal epithelial cells (HCECs) exposed to 50μg/ml polyI:C or 10μg/ml of Pam3CSK4, peptidoglycan (PGN), polyI:C, LPS, flagellin, FSL-1, R-837, ssRNA40 or C-CpG-ODN for 8 or 48 hours, evaluated by quantitative real-time PCR or ELISA, respectively. Results shown are the mean ± SD of four independent experiments. *P< 0.05; **P < 0.01. **B.** The immunohistochemical staining showing IL-33 induction in an ex vivo human corneal tissues by polyI:C (50μg/ml) or flagellin (10μg/ml) for 24 hours with isotype IgG as a negative control. **C.** TLR and NF-κB signaling pathways involved in IL-33 induction by polyI:C or flagellin in HCECs exposed to polyI:C (50μg/mL) or flagellin (10μg/mL) in the absence or presence of preincubated rabbit TLR3Ab (10μg/mL), TLR5Ab (10μg/mL), BAY11-7082 (10μM) or quinazoline (10μM) for 1 hour, and Pepinh-MYD (40μM) or Pepinh-TRIF (40μM) for 6 hours. The cultures treated by ligands for 8 hours for IL-33 mRNA, or for 48 hours for IL-33 protein by ELISA and by Western blot with β-actin as control (**D**). Results shown are the mean ± SD of four independent experiments. *P< 0.05; **P < 0.01.

IL-33 is an extracellular inflammatory cytokine while it also acts as a nuclear transcription factor [71]. It has been shown that IL-33 is mainly localized to the nucleus of endothelial cells and bound to chromatin. IL-33 mRNA is primarily translated and synthesized in vivo as a 30-kDa precursor, a pro-IL-33 protein. As a member of IL-1 super family and like IL-1 and

IL-18, pro-IL-33 protein sequence does not have a signal peptide that directs it for secretion via the ER–Golgi pathway [66, 72]. Like pro-IL-1β, human pro-IL-33 was reported to be cleaved by caspase-1 to generate active form, an 18-kDa fragment (mature IL-33), which is sufficient to activate signaling via the IL-33 receptor ST2. Recombinant mature IL-33 has been known to induce Th2-associated cytokines and inflammatory cytokines via its receptor, ST2 [72, 73]. However, processing of pro-IL-33 in vivo has not been clarified yet. It is not clear whether caspase-1 cleavage of pro-IL-33 occurs in vivo and whether, as for IL-1β, this cleavage is a prerequisite for IL-33 secretion and bioactivity.

Our data have showed that no significantly changes of IL-33 protein levels can be detected by ELISA in the culture supernatants, other than in cell lysate, of the HCECs. IL-33 protein levels significantly increased in the cell lysate, but not in the culture supernatants, of HCECs exposed to polyI:C or flagellin for 24-48 hours, when compared with the untreated control. However, the stimulated cellular IL-33 protein was released outside the cells into culture supernatant after co-incubation with ATP for additional 30 minutes, as evaluated by ELISA and Western blot analysis [70]. The finding supports a notion that caspase 1-dependant activation may involved in the release and secretion of IL-33 protein since ATP has been known to activate caspase-1 through triggering the P2X7 receptor [74]. Further studies are necessary to clarify the underlining mechanism.

As shown in Figure 6C evaluated by RT-qPCR and ELISA, as well as in Figure 6D by Western blotting, synthetic dsRNA polyI:C-induced IL-33 mRNA expression and protein production were markedly blocked by TLR3 antibody and TIR-domain-containing adaptor inducing interferon (TRIF) inhibitory peptide (Pepinh-TRIF), but not by TLR5 antibody or MyD88 inhibitory peptide (Pepinh-MYD), while extracted bacterial component flagellin-induced IL-33 production was dramatically suppressed by TLR5 antibody and Pepinh-MYD, but not by TLR3 antibody or Pepinh-TRIF, in corneal epithelial cells. The stimulated IL-33 induction by polyI:C or flagellin were also significantly blocked by IκB-α inhibitor BAY11-7082 or NF-κB activation inhibitor quinazoline. Further study has shown that NF-κB was dramatically activated with p65 protein nuclear translocation in corneal epithelial cells exposed to polyI:C or flagellin for 4 hours, as evaluated by Western blot analysis and immunofluorescent staining. BAY 11 selectively inhibits the phosphorylation and degradation of IκB-α, blocked the nuclear translocation of NF-κB p65 protein. NF-κB activation inhibitor quinazoline also blocked the p65 nuclear translocation. These findings demonstrate a novel phenomenon that a newly defined pro-allergic cytokine IL-33 is largely induced by microbial components through TLR and NF-κB signaling pathways in human corneal epithelium. This suggests that human ocular mucosal epithelium plays an important role in initiating Th2-dominant allergic inflammation via innate immune responses.

In a clinical study, we have tested conjunctival impression cytology specimens obtained from 8 patients with active atopic conjunctivitis and 8 normal subjects by RT-qPCR (Figure 7). The mRNA levels of TSLP, TSLPR, OX40L, OX40, IL-33 and ST2 were found to be significantly elevated in the atopic group compared with the normal control subjects, suggesting a potential role of TSLP/TSLPR/OX40L/OX40 and IL-33/ST2 signaling pathways in allergic conjunctivitis (Figure 7A). In SRW pollen induced EAC mice, the transcripts and proteins of IL-33, ST2, and IL-1 receptor accessory protein (IL1RAP) were also found to be significantly increased in the corneal epithelium, conjunctiva and CLN, as evaluated by RT-qPCR (Figure 7B) and immunostaining (Figure 7C). IL-33, ST2 and TLRs could become novel biomarkers and molecular targets for the intervention to treat allergic inflammatory diseases.

The role of IL-33 in allergic disease. **A.** Elevated mRNA levels of TSLP and IL-33 signaling molecules in conjunctiva of atopic patients compared with normal subjects by RT-qPCR. * $P<0.05$, ** $P<0.01$, n=8. **B.** The mRNA levels of IL-33, ST2 and IL1RAP in corneal epithelium (Cornea), conjunctiva (Conj) and cervical lymph nodes (CLN) of in BALB/c mice with PBS-treated mice as controls. * $P<0.05$, n=3. **C.** Immunostaining images showing the stimulated IL-33 in ocular surface of EAC BALB/c mice with untreated mouse control and isotype IgG negative control.

7. Th17 pathway links innate and adaptive immunity

Th17 has been recently identified as a new T helper cell subset. $CD4^+$ T helper (Th) cells now include three different types based on their cytokine signatures: interferon-γ (IFN-γ)-secreting Th1, IL-4, -5, and -13-secreting Th2 [75], and IL-17-producing Th17 cells [76]. Th17 cells have been recognized to be key effector T cells in a variety of human inflammatory and autoimmune diseases as well as experimental animal models [77, 78]. The IL-17 family includes 6 members (IL17A-F). IL-17A (also known as IL-17) and IL-17F are the founding members of the IL-17 cytokine family. The genes encoding IL-17A and IL-17F are localized in the same chromosomal region in mice and in humans. But IL-17F has significantly weaker biological activity than IL-17A [79, 80]. IL-17E, also known as IL-25, is produced by Th2 cells and mast cells. In contrast, IL-17B, IL-17C and IL-17D have not been well investigated [81, 82]. The receptor for IL-17A (IL-17R or IL-17RA) is a single-pass transmembrane protein of approximately 130 kDa. Four additional receptors (IL-17RB-RE) have been identified, but are not well characterized. IL-17RC was recently identified to be a receptor for IL-17F [83]. It has been reported that Th17 cells also produce IL-22 [84, 85] and CC-chemokine attractant ligand 20 (CCL20) [86] in mice and humans. Therefore, distinct from Th1 and Th2 cells, Th17 cells produce a unique and expanding array of pro-inflammatory cytokines.

Compelling evidence has demonstrated that the differentiation of Th17 cells from naïve $CD4^+$ T cells is initiated by cytokines IL-6 or TGF-β, and expanded by cytokines IL-23, IL-1β and IL-21. IL-6 or TGF-β was proposed as a major initiator necessary for Th17 differentiation [87-89]. IL-23 was the first cytokine shown to selectively regulate IL-17 expression [90, 91], but it might not be required for the initial differentiation of Th17 cells in vivo [92]. Recently, IL-1β was found to promote Th17 cell development and proliferation in the presence of TGF-β and IL-6 [88]. IL-21, produced by activated T cells and natural killer (NK) cells [93], may be required for full commitment of Th17 cells [94, 95]. Hence IL-23, IL-1β and IL-21 may possibly maintain and expand the differentiated Th17 cells in the presence of IL-6 and TGF-β [88]. Furthermore, STAT3 has been found to mediate the initiation of Th17 cell differentiation by these inducing cytokines [87]. Activation of STAT3 induces the expression of retinoic-acid-receptor-related orphan receptor-α (RORα) and RORγt [96], two transcription factors that promote the Th17-cell-associated gene-expression program, leading to the production of IL-17, IL-17F, IL-22 and CCL20.

Using peripheral $CD4^+$ T cell isolated from mouse spleen and cervical lymph nodes, our team evaluated the differential effects of these inducing cytokines in promoting Th17 differentiation [97]. The results showed that IL-6 and TGF-β1, only minimally induced IL-17 production at both mRNA and protein levels. In the presence of IL-6 and TGF-β1, IL-23 was the strongest stimulator of the Th17 signature cytokines IL-17A and IL-17F, IL-22, and chemokine CCL20, as well as STAT3 among the 3 expanding cytokines IL-23, IL-1β and IL-21. In the 4 cytokine system, IL-1β stimulated much higher levels of IL-17 family cytokines, 1.5-2 fold greater than IL-21 in the presence of TGF-β1, IL-6 and IL-23. These findings suggest that TGF-β1 and IL-6 initiate low level differentiation of Th17 cells; and their maintenance and development need other expanding factors, among which IL-23 plays a potent role and IL-1β amplifies this expansion further in Th17 differentiation [97].

A variety of mucosal epithelia have been found to produce Th17 inducing cytokines, including TGF-β1, IL-6, IL-23, and IL-1β [98, 99]. IL-1β is a well recognized proinflammatory

cytokine produced by mucosal epithelia in response to stress, infection or wounding. In an attempt to mimic known stressors of the ocular surface, we measured production of Th17 inducing cytokines in cultured HCECs in response to hyperosmotic stress, microbial components and inflammatory cytokines.

The ocular surface epithelium is subjected to hyperosmotic stress in dry eye conditions. Exposure of human epithelial cells to hyperosmotic stress has been noted to activate mitogen-activated protein kinase pathways and stimulate production of pro-inflammatory cytokines, such as IL-1β, TNF-α, and IL-8 [100]. We have also observed that TGF-β1, IL-6 and IL-23 were highly induced in the corneal epithelium in response to hyperosmotic stress.

We evaluated the expression and production of Th17-inducing cytokines by HCECs in response to 9 extracted or synthetic microbial components that are ligands of TLRs 1-9, respectively. TGF-β1, IL-6, IL-23, and IL-1β expression and production were found to be largely induced by polyI: C, flagellin, and R837, the respective ligands for TLRs3, 5 and 7, representing viral or bacterial infections. Among these TLR agonists, polyI:C was the strongest stimulator of Th17 inducing cytokines by HCECs.

Hyperosmotic stress and microbial components also promoted production of pro-inflammatory cytokines including TNF-α, which plays an important role in ocular surface disease [100, 101]. Consequently, TNF-α stimulus was found to markedly induce TGF-β1, IL-6, IL-23, and IL-1β.

Based on our findings that among TLR ligands, polyI:C is the potent stimulator of Th17 inducing cytokines, and that TNF-α is a representative pro-inflammatory factor, we evaluated the Th17 inducing capacity of conditioned media (CM) of HCECs treated with polyI:C and TNF-α [97]. It has been observed that Th17 cell differentiation was significantly stimulated in $CD4^+$ T cells exposed to the 50% conditioned media of HCECs challenged by polyI:C (CM-polyI:C) or TNF-α (CM-TNF-α) when compared with media from untreated cultures.

As shown in Figure 8A-E, the mRNA levels of IL-17A, IL-17F, IL-22, CCL-20 and STAT3 were significantly higher in $CD4^+$ T cells treated with CM-polyI:C or CM-TNF-α for 4 days compared with the control medium or conditioned media of HCEC culture without any stressors (CM-Control, all $P<0.05$, n=3). IL-17 protein levels in the supernatants of $CD4^+$ T cells exposed to CM-polyI:C or CM-TNF-α for 4 days (Figure 8F) were also significantly higher than the media (both $P<0.01$, n=3) and CM ($P<0.05$, n=3) controls. Furthermore, the number of IL-17-producing cells differentiated from $CD4^+$ T cells, determined by ELISPOT bioassay (Figure 8G, 8H), displayed the same pattern to the induction of IL-17 mRNA and protein. The numbers of IL-17-producing cells were stimulated by CM-polyI:C or CM-TNF-α, to the levels similar to that seen in the 3-cytokine system (TGF-β1+IL-6+IL-23), suggesting that cytokines in the conditioned media of HCECs exposed to polyI:C or TNF-α were capable to promote Th17 cell expansion to levels induced by IL-6+TGF-β1+IL-23. It suggests that the Th17 cells can be indeed promoted by factors produced by corneal epithelium in response to a variety of inflammatory stimuli [97].

8. Th17-mediated inflammation in dry eye

Dry eye is the second most common problem of patients seeking eye care, and is characterized by eye irritation symptoms and blurred vision. The prevalence of dry eye

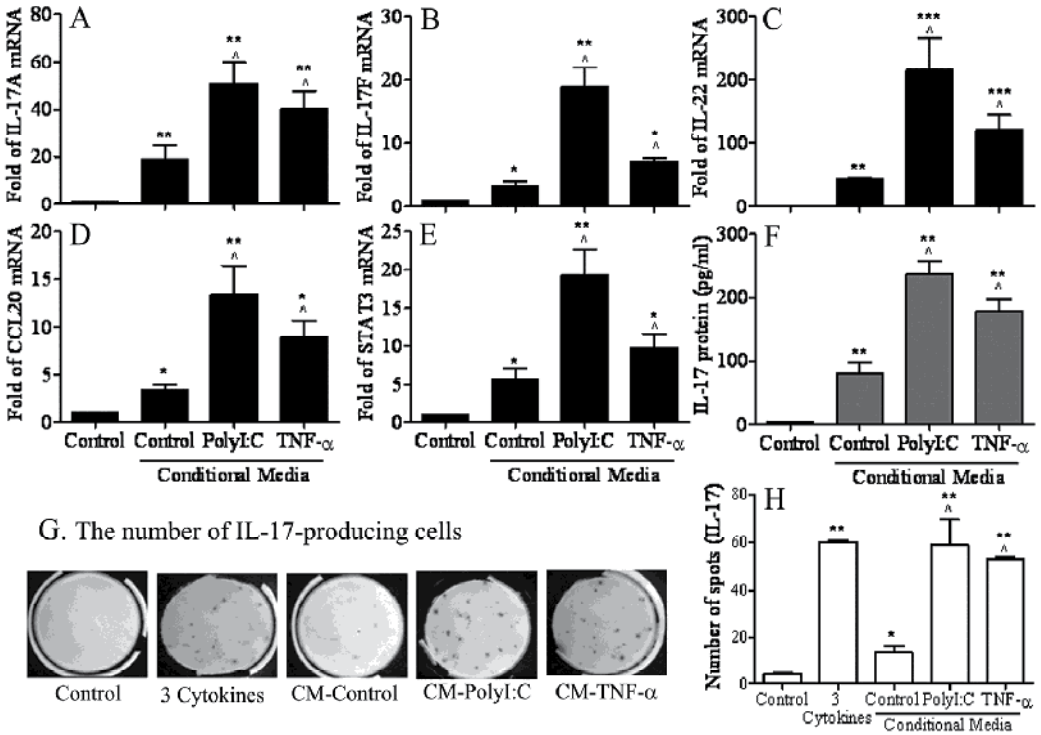

Fig. 8. Induction of Th17 differentiation of murine CD4+ T cells cultured in RPMI media containing 50% conditioned media (CM) of HCECs. **A-E.** Real-time PCR data showing the relative fold of mRNA of Th17 associated cytokines (IL-17A, IL-17F, IL-22, CCL-20) and regulator STAT3 in CD4+ T cells incubated for 4 days with 50% of conditioned media of HCECs irritated by polyI:C (CM-PolyI:C) or TNF-α (CM-TNF-α) for 48 hrs. **F.** Luminex immunobead assay showing IL-17 concentration in the supernatant of CD4+ T cells receiving the same treatment for 4 days. **G & H.** ELISPOT bioassay showing the spots/3x10^5 cells/well, representing the numbers of IL-17-producing T cells, in CD4+ T cells treated with CM-PolyI:C, CM-TNF-α, or 3 cytokines (TGF-β1+IL-6+IL-23) for 7 days. increases with age, 6% at the age of 40, and 15-25% in the population over the age of 65. Among dry eye patients, 11% have been estimated to have the systemic autoimmune condition Sjögren's syndrome, a severe and potentially blinding condition. Dry eye is a potent stimulus of both innate and adaptive immune systems. At the nexus of the dry eye inflammatory/immune response is the dynamic interplay between the ocular surface epithelia and bone marrow derived immune cells. On the one hand, the ocular surface epithelial cells play a key initiating role in this inflammatory reaction, while on the other hand they are targets of cytokines that are produced by activated T cells that are recruited to the ocular surface in response to dry eye.

Dry eye has been demonstrated to cause inflammation of the ocular surface, evidenced by increased levels of inflammatory cytokines (IL-1, IL-6, and TNF-α) in the tear fluid, corneal and conjunctival epithelium, and an increased infiltration of dendritic cells and T lymphocytes in the conjunctiva [102-105]. Recently, increased levels of IL-17, IL-23 and IL-6 were found in saliva and salivary glands biopsies obtained from patients with the severe autoimmune dry eye condition, Sjögren's syndrome [106]. The increased matrix metalloproteinase (MMP) 9 and disrupted barrier function were observed in human [107] and murine dry eye [108]. Recently, our group has found increased expression of Th17 associated cytokines and IL-17-producing cells in human and experimental murine dry eye [108, 109]. Increased expression of Th17 cytokine IL-17A was observed in corneal and conjunctival epithelia of the dry eye mice. Since IL-17A is produced by T cells, not by epithelial cells, the Th17 reaction of the ocular surface is likely due to $CD4^+$ T cells, which have previously been found to infiltrate ocular surface tissues following experimental desiccating stress [110, 111]. Antibody neutralization of IL-17 ameliorated experimental dry eye-induced corneal epithelial barrier dysfunction and decreased the expression of MMP-3 and -9 [108]. These findings provide clear evidence that changes in the ocular surface environment, such as Th17-inducing cytokines, following desiccating stress are capable of inducing Th17 differentiation [112], which plays an important role in dry eye disease.

Th17 differentiation was also found to be mediated through a dendritic cell-mediated pathway. DCs have an important function in Th17 cell differentiation. They are antigen-presenting cells specialized to activate $CD4^+$ T cells and through their interaction with $CD4^+$ T cells to initiate primary immune responses. Furthermore, when primed, certain DCs express a high-level of Th17 inducing cytokines, including IL-6, TGF-β, IL-23 and IL-1 [113].

We found that efficient differentiation of $CD4^+$ T cells to IL-17 producers required the combination of ocular surface epithelium from dry eye mice and dendritic cells. $CD4^+$ T cells that were co-cultured with ocular epithelial explants from desiccating stress-induced dry eye mice and dendritic cells were found to express increased mRNA levels of Th17 cytokines (IL-17A, IL-17F, IL-22) and chemokine (C-C motif) ligand 20 (CCL20) (Figure 9A), as well as to produce and release IL-17A (Figure 9B & 9D), but not Th1 cytokine IFN-γ (Figure 9C). Exposure of dendritic cells to conditioned media from ocular surface explants of dry eye mice did not sufficiently activate these cells to promote T cell differentiation. The possible explanations for these findings include the need for direct contact between these cells, more efficient activation of cytokines such as TGF-β1 produced by the ocular surface epithelial cells or insufficient concentrations of Th17 inducing factors in the explants conditioned media.

The transcription factor RORγt was identified as a candidate master regulator that drives Th17 cell lineage differentiation [96]. Expression of RORγt is induced by TGF-β or IL-6, and overexpression of γt was found to promote Th17-cell differentiation when both Th1- and Th2-cell differentiations were blocked. In a model of experimental autoimmune encephalomyelitis, mice with RORγt-deficient T cells were found to have attenuated autoimmune disease and lacked tissue-infiltrating Th17 cells [96]. We found robust up-regulation (up to 100 fold) of the level of Th17 cell transcription factor-RORγt in T cells co-cultured with desiccated ocular surface tissues and dendritic cells (Figure 9E). This provides further evidence of the potent Th17 prone environment induced by desiccation.

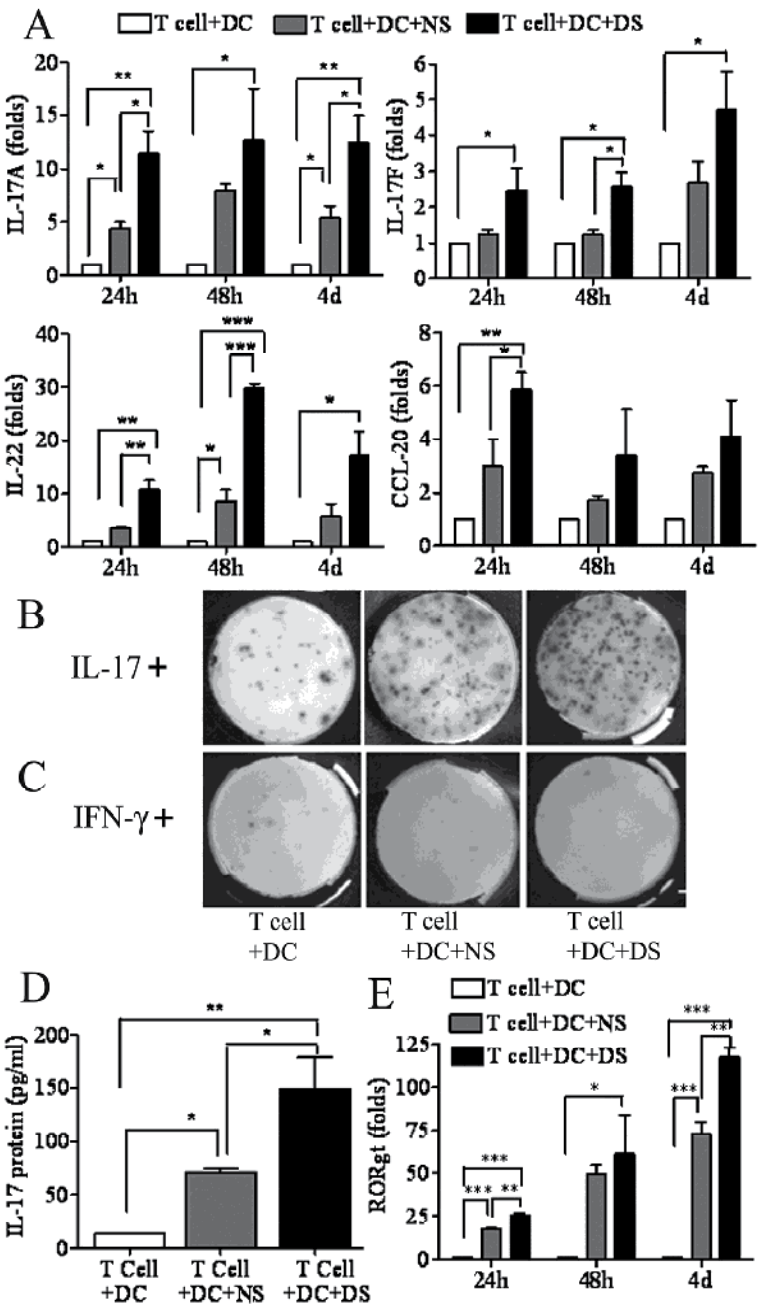

Fig. 9. Th17 differentiation of CD4+ T cells induced by the co-culture with dendritic cells (DCs) in the presence of cornea and conjunctival tissues of C57BL/6 mice subjected to desiccating stress. A. Real-time PCR data showing the relative mRNA expression (*x*-fold) of Th17 cytokines (IL-17A, IL-17F, IL-22, CCL-20) in CD4+ T cells ($3x10^5$ cells/ well) co-cultured for 1, 2, 4 days with DCs (T cell+DC), or with DCs and cornea and conjunctival explants from non-stressed control mice (T cell+DC+NS) or from mice desiccating stressed for 10-day (T

cell+DC+DS), (n=4). B & C. ELISPOT bioassay showing the numbers of IL-17 or IFN-γ-producing cells in these 3 groups. D. IL-17 concentration in the supernatant of $CD4^+$ T cells co-cultured with DCs for 4 days in absence or presence of corneal and conjunctival explants from non-stressed and 10 day desiccating stressed mice. E. Real-time PCR showing the relative mRNA expression of RORγt in $CD4^+$ T cells co-cultured for 1, 2, 4 days in 3 conditions. Data are presented as mean ± SD of 3 or 4 independent experiments. *P<0.05, **P<0.01, ***P<0.001.

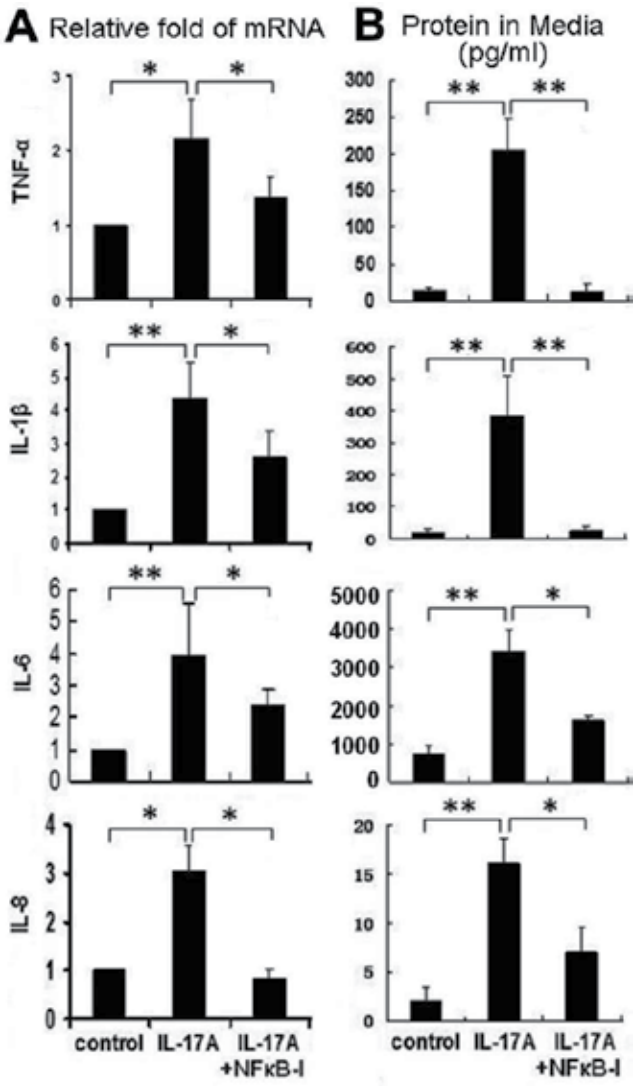

Fig. 10. The inflammatory effects of IL-17 on HCECs. Primary HCECs (5×10^5 cells/well) were treated with recombinant human IL-17A at 10 ng/ml for 4-48 hours with or without NF-κB activation inhibitor quinazoline (NFκB-I, 5μM). The pro-inflammatory cytokines (TNF-α, IL-1β and IL-6) and chemokine IL-8 were measured by RT-qPCR for mRNA (**A**) and by ELISA or Luminex immunobead assays in culture supernatants (**B**). Results shown are mean ± SD of 4 independent experiments. * $P < 0.05$, ** $P< 0.01$.

IL-17 producing T cells are distinct from Th1 cells. Analysis of the expression of transcription factors showed clearly that IL-17-producing T cells expressed neither GATA-3 nor T-bet and its target Hlx, which were typically expressed by IFN-γ-producing Th1 cells [88]. In the T cells co-cultured with desiccated ocular surface tissues and dendritic cells, we observed the lower expression of Th1 associated factors (IL-2, T-bet) and Th2 associated factors (IL-4, IL-13, GATA-3). There was no change in production of IFN-γ and IL-12 transcripts as well as in the number of IFN-γ-producing $CD4^+$T cells in this co-culture system. Taken together, these findings indicate that desiccating stress may selectively promote the Th17 pathway, a finding that is consistent with the increased level of IL-17 in dry eye disease [108].

IL-17 initiates pro-inflammatory effects by binding to the IL-17 receptor (IL-17R), which is expressed by a variety of cell types including epithelial, endothelial, and fibroblastic stromal cells [81, 114]. As shown in Figure 10, recombinant human IL-17A (10 ng/ml) significantly increased mRNA levels (2-4 fold) of proinflammatory cytokines (TNF-α, IL-1β and IL-6) and chemokine IL-8 expressed by HCECs. These stimulatory responses to IL-17A were confirmed by 4-7 fold increases at protein levels. The stimulated production of these inflammatory cytokines and chemokine was significantly suppressed at both mRNA (all $P<0.05$, n=4) and protein levels ($P<0.05$ or 0.01) by NF-κB activation inhibitor quinazoline [115], indicating NF-κB pathway is involved in the inflammatory effect of IL-17 on mucosal epithelium.

These findings demonstrate that desiccating stress stimulates the expression and production of Th17 inducing cytokines by corneal and conjunctival epithelia, and that desiccation creates an environment promoting Th17 differentiation through a dendritic cell-mediated pathway. We hypothesize that Th17 inducing cytokines produced by the ocular epithelium may participate in Th17 differentiation in three ways: (1) activation of immature dendritic cells on the ocular surface; (2) direct transfer to the lymph node in lymphatic liquid; or (3) direct promotion of differentiated Th17 cells that infiltrate the ocular surface.

9. Conclusion

This chapter focused on recent breakthroughs in ocular mucosal immunology, including the discoveries of TLR signaling in innate immunity, novel epithelium-derived pro-allergic cytokines TSLP and IL-33, and a new Th17 cell population in adaptive immunity. One of important breakthroughs is a discovery of a novel mechanism by which short ragweed pollen, serving as a functional TLR4 agonist, induces TSLP/OX40L/OX40 signaling to trigger Th2-dominant allergic inflammation via TLR4-dependent innate immunity pathways. All these advances provide compelling evidence that mucosal epithelium actively participate, as initiators, mediators and regulators, in innate and adaptive immune responses for host defense, in addition to physical barrier function. These novel signaling molecules may be critical for allergic, inflammatory and autoimmune diseases on mucosal ocular surface, and may become potential molecular targets for new therapies to treat these ocular diseases.

10. Abbreviations used in this chapter

CLN: cervical lymph nodes; **DAMP**: damage-associated molecular patterns; **DC**: dendritic cell; **dsRNA**: double stranded RNA; **EAC**: experimental allergic conjunctivitis; **HCECs**:

Department of Ophthalmology, Harvard Medical School
USA

1. Introduction

The role of immuno-inflammatory responses in the cornea and ocular surface has continuously been evolving over the past decades and has been becoming the center stage for therapeutic approaches for many diseases. In fact, the relevance of inflammation as a significant component in the pathophysiology of most acute and chronic forms of corneal and ocular surface diseases (e.g., microbial keratitis, allergy, and dry eye syndrome) has become evident. Both local and systemic immunomodulation with anti-inflammatory agents have been used successfully in improving these conditions or bringing these conditions under control. Thus, understanding the cellular and molecular mechanisms by which the ocular surface participates in immuno-inflammatory disorders is crucial for a more rational clinical approach to treating these diseases.

There are several unique anatomical and physiological features of the cornea and ocular surface as compared to other tissues in the body, which translate into specific mechanisms by which they are involved in both inciting and expressing immunity, as well as preventing unnecessary inflammation. There are a very large number of immune and inflammatory disorders that involve the cornea and ocular surface. Control of leukocyte entry and migration within the cornea and ocular surface is thus vital to regulate protective and pathological responses. While local control of pathogens is dependent on the ability of immune cells to access and operate within these sites, too much inflammation can be deleterious and lead to loss of vision. In this chapter, the current knowledge on the coordinated migratory events that regulate leukocyte trafficking in the cornea and ocular surface are discussed. The aim is to first provide an overview of the contribution of resident bone marrow (BM)-derived cells of the cornea and ocular surface. Second, the role of infiltrating leucocytes in some of the innate defense mechanisms will be discussed. Third, we will provide a summary of the mechanisms that dictate immune cell trafficking to the cornea and ocular surface in response to inflammation. Finally, we will discuss trafficking mechanisms of antigen presenting cells from the cornea and ocular surface to draining lymph nodes where the immune responses are initiated.

2. Role of leukocytes in disease

2.1 Overview of resident leukocytes

The cornea and ocular surface have constant and direct contact with the external world. This necessitates a powerful and intrinsic immune surveillance system involved in their natural defense. Resident ocular tissue elements together with circulating bone marrow-derived cells are important components of this system, delicately balancing defense and tolerance under steady sate conditions. The ocular surface consists of three distinct anatomical regions: the cornea, limbus, and the conjunctiva. These regions function both in concert and independently against microbial, immunogenic and traumatic insults.

Antigen presenting cells (APCs) and in particular dendritic cells (DCs) orchestrate the immune response through their capacity to capture, process and subsequently present antigens. APCs serve as the principal immune sentinels to the foreign world. They can be divided into 'professional' and 'nonprofessional' types. While the latter are found among nonlymphoid tissues (e.g., vascular endothelial or some tissue epithelial cells), professional APC are BM-derived, and form an integral part of the immune system. Professional APCs include DCs (including epithelial Langerhans cells; LCs), macrophages, and B cells, although DCs are the most potent APCs. Expression of major histocompatibility class II (MHC-II) antigens on DCs, whose primary function is to distinguish between self and non-self, plays an integral role in antigen recognition and presentation. DCs have a dual function as key regulators of T cell immunity and tolerance induction to both self and foreign antigens. Precursor and progenitor DCs constitutively repopulate normal tissues from the bloodstream, and are recruited in elevated numbers to sites of inflammation. A second type of DC precursors is constituted by peripheral blood monocytes that are recruited during an inflammation.

DCs originate from bone marrow hematopoietic stem cells. (Traver et al., 2000; Wu et al., 2001) DC progenitors are not restricted to the BM and can be found in multiple locations. These progenitors can differentiate into DC upon challenge in peripheral tissues. Fully differentiated DC are found in healthy tissues as immunologically immature cells, being able to sample foreign antigens, but not able activate T cells. Although rare in numbers in the circulation, one fully mature DC is capable to interact with ten thousand T cells per day.(O'Keeffe et al., 2003) DC consist of several distinct populations that can be differentiated by surface and intracellular phenotypic markers, immunological function, and anatomic location. Irrespective of their phenotype and immunological role, DC exert their activity in the eye remote from their place of origin, where they utilize their advanced migratory skills for navigation. Currently, factors leading to the development from precursor DC to differentiated mature DC are still largely unknown. It has been shown that depending on the environmental cues, different forms of DC may be generated.(Naik et al., 2006) Further, while in lymphoid as well as in some non-lymphoid organs,(Kabashima et al., 2005; Merad et al., 2002) DC have been shown to proliferate locally, it is yet unclear whether resident corneal DC have the same proliferative potential, or are alternatively replenished through circulating DC. The diverse functions of DC in immune regulation depend on the diversity of DC subsets and lineages and on the functional plasticity of DCs at their immature stage.

Over the last several decades, the search for corneal APC, largely reliant on their presumed and universal MHC-II expression, had led to the dogma that APC are essentially absent in the central corneal. This absence of corneal APC was assumed to be a critical component of corneal immune privilege. However, this paradigm has now shifted with the demonstration of a diverse population of resident APC over the last years.(Hamrah et al., 2003a; Hamrah et al., 2003b, c) Dendritic cells, the sentinels of the immune system, were recently discovered to reside not only in the peripheral cornea, but also in the centreal cornea (**Fig 1**).(Hamrah et al., 2003c; Hamrah et al., 2002b; Liu et al., 2002) While a large number of DC are MHC class II^+ in the periphery, a large population of MHC class II-*negative* immature/precursor DC are present both in the central epithelium and stroma.(Hamrah et al., 2003c; Hamrah et al., 2002b) Immature DC do neither express major histocompatibility complex (MHC)-II nor costimulatory molecules unless they are incited by cytokines. Thus, in contrast to other organs, where terminally differentiated populations of resident DC and/or macrophages outnumber colonizing precursors, large numbers of DCs within the cornea remain in an undifferentiated state.

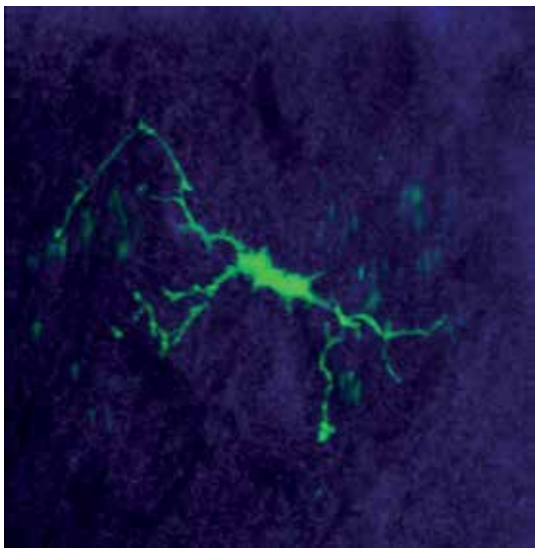

Fig. 1. Dendritic Cell in central corneal epithelium in CD11c-Yellow fluorescent protein (YFP) transgenic mouse

The constitutive presence of these DCs in the cornea focuses now attention on the cornea as a participant in immune and inflammatory responses, rather than the cornea being essentially a collagenous tissue that simply responds to the activity of infiltrating cells. Other immune cells that populate the cornea and ocular surface are T cells, B cells, macrophages, plasma cells, and neutrophils (PMN). Further, macrophages and neutrophils together with natural killer (NK) cells, initially constitute the primary innate immune response, while DCs, T cells and B cells largely play a role in the secondary, adaptive response.(Janeway C, 2004) While the primary innate immune response is non-specific, rapid, and lacks memory, the secondary adaptive immune response is slower, but highly specific. Further, T and B cell responses maintain immunological memory, such that any following encounters with the same antigen will lead to rapid and robust immune responses.

2.2 Microbial keratitis

2.2.1 Herpes simplex virus type-1 (HSV-1)

HSV-1, is a member of the α-herpesviridae family of double-stranded DNA (dsDNA) viruses.(Shukla & Spear, 2001) HSV-1 infections are prevalent both in the developed and developing countries with a higher and earlier onset of seroconversion in population groups of lower socioeconomic status.(Whitley & Roizman, 2001) 60% to 90% of the global adult population is infected with this pathogen, with a remarkably high prevalence of approximately 90% in the United States.(Carr et al., 2001; Whitley & Roizman, 2001) The two main forms of ocular HSV-1 infections are epithelial keratitis, and immune stromal keratitis.(Thomas, J. & Rouse, 1997) In the West, HSV-1 is also the leading cause of blindness secondary to recurrent infection, corneal stromal inflammation (herpes stromal keratitis; HSK), stromal thinning, neovascularisation and scarring.(Dana, M. R. et al., 2000)

The ocular surface, through several means, is able retard host invasion by external pathogens. The tear film which forms the outermost layer of the ocular surface presents the first barrier to viral invasion.(Farris, 1998) Some of the anti-viral factors in the tear film include, but are not limited to, tear film proteins such as lysozyme, immunoglobulin A (IgA), lactate dehydrogenase (LDH), complement proteins, amylase, peroxidase, as well as interferons alpha (IFNα) and beta (IFNβ). (Babu et al., 1995; Chatterjee et al., 1984; Chen et al., 1994) Since herpes viruses rely on replication and dissemination in metabolically active cells (Schang et al., 1998; Schang et al., 2000), the terminally differentiated outer layers of the corneal epithelium act as both a physical and metabolic barrier against viral entry. In the event of a breach in the integrity of the corneal epithelium, the virion attaches to epithelial cells via interaction of its surface glycoproteins with cognate receptors, (Campadelli-Fiume et al., 2007; Shukla et al., 1999; Spear, 2004) leading to either attachment, surfing and fusion of the virion envelope to the host cell plasma membrane, or, via endocytosis of the nucleocapsid into the host cell cytoplasm. Having intercepted the barriers to entry, HSV-1 inhibits its host's programmed cell death, assembles its immune-defying, host-crippling machinery to invade, replicate and infect the cornea, nerves and eventually the trigeminal ganglion where the virus maintains lifelong latency, leading to recurrent infections and potentially irreversible damage to the corneal tissue.(Akhtar & Shukla, 2009; Whitley & Roizman, 2001) Transmission may occur through cell lysis and shedding of viral progeny or cell-to-cell spread of the virion. Once the host corneal epithelial layers are penetrated, HSV replicates in the corneal epithelial cells. Following host infection, the outcome of viral latency or resolution has been shown to be dependent on the initial viral load.(Kintner & Brandt, 1995).

Cytokines are low molecular weight proteins produced by various resident corneal cells such as epithelial cells, stromal cells, and APCs.(Torres & Kijlstra, 2001) They are responsible for recruiting inflammatory and immune cells via cell-to-cell signalling through autocrine, paracrine and endocrine pathways, thus promoting tissue damage.(Balkwill & Burke, 1989) As the disease course changes, expression profiles of cytokines follow suit. During the early phase of HSK, the cornea expresses interleukin (IL)-1α, interferon (IFN)-γ and IL-2, whereas IL-4 is expressed later, indicating that the Th1 T cell response is required for induction of HSK. (Babu et al., 1995; Niemialtowski & Rouse, 1992b) (Heiligenhaus et al., 1999) While IL-2 may be responsible for incurring destructive effects on the stroma, IL-2 knockout mice

are more prone to severe HSV infection, which is ameliorated by providing recombinant IL-2 treatment, hence indicating that the Th1 T cell response not only plays a role in tissue destruction, but also plays a protective role against HSV-1 invasion.(Ghiasi et al., 1999) Paradoxically, IFN-γ has also been implicated in the clearance of virus from the cells thus reducing latency, (Bouley et al., 1995; Smith et al., 1994) (Hendricks et al., 1991) yet driving immunopathogenesis as exemplified by the reduction in HSK severity following neutralisation of IFN-γ titres beforehand. (Hendricks et al., 1992b; Niemialtowski & Rouse, 1992a, b) Among the array of cytokines produced, IL-1 is particularly pertinent to corneal melting by induction of LC migration into the cornea thereby priming the tissue for further destruction. In order to combat the effects of IL-1, human corneal epithelium and stroma constitutively express interleukin-1 receptor antagonist (IL-1 RA), which helps maintain corneal immune privilege.(Dana, M. R. et al., 1998; Kennedy et al., 1995) Finally, while proinflammatory cytokines contribute to the augmentation of the immune response, vascular endothelial growth factor (VEGF) secreted by polymorphonuclear (PMN) cells, and local epithelial cells, contributes to corneal neovascularization in HSK.(Lee, S. et al., 2002; Zheng, M. et al., 2001)

Chemokines are specific, small cytokines of 8-10 kDa and can be classified according to their structure and function. Structurally, they fall into four families, the two most important of which are the CXC (alpha) and CC (beta) families. The CC and CXC chemokines are named based on intervening residues between their amino (N)-terminal cysteine amino acids. Hence, the CC family of chemokines have two adjacent cysteine amino acids near the N-terminus without an intervening residue. However, in the CXC family of chemokines, these N-terminal cysteine residues are separated by an amino acid "X", thus their "CXC" salutation. Chemokine receptors (CCR) CCR1, CCR2, CCR5, CXC chemokine receptor (CXCR) CXCR2 and their ligands (CCL/CXCL) have a well-defined role in HSV. Viral replication leads to expression of chemokines such as macrophage inflammatory protein (MIP)-1α/CCL3, KC/CXCL1, MIP-1β/CCL4, MIP-2/CXCL2, monocyte chemotactic protein (MCP)-1/CCL2 and lymphotactin/XCL1. (Thomas, J. et al., 1998) (Wolpe et al., 1989) Of these, MIP-1 α /CCL3 plays the most pivotal role in causing stromal inflammation, possibly by recruiting neutrophils and T cells as seen in experimental studies on murine corneas.(Tumpey et al., 1998; Wolpe et al., 1988) Furthermore, CXCR3 and its ligands, namely, monokine induced by gamma interferon (MIG)/CXCL9, interferon gamma-induced protein 10 (IP-10)/CXCL10 and interferon-inducible T-cell alpha chemoattractant (I-TAC)/ CXCL11 may also contribute to the development of a protective, anti-viral immune response seen in the cornea following HSV-1 infection. (Carr et al., 2008; Wuest & Carr, 2008) These chemokines may form potential targets for therapy in HSK.

It is well established that primary infection with HSV-1 incites both a localized innate immune response, and systemic immunity through the adaptive arm of the immune cascade. The localized innate immune response involves PMNs, natural killer (NK) cells, and macrophages, with the adaptive immune response involving DCs and T cells.(Brandt & Salkowski, 1992; Ghiasi et al., 2000; Hendricks & Tumpey, 1990; Meyers-Elliott & Chitjian, 1981; Niemialtowski & Rouse, 1992a; Pepose, 1991; Tullo et al., 1983; Tumpey et al., 1996) Clinically, the collection of these cells is seen as infiltrates in the corneal stroma. Within 48 hours following infection, PMN cells, which constitute the first line of defense, are recruited to the cornea by means of the limbus vasculature, following a multi-step adhesion cascade,

including selectins, integrins, and chemokines.(Thomas, J. et al., 1997) A cytokine and chemokine response by recruited PMN cells, including tumor necrosis factor (TNF-α),(Daheshia et al., 1998) then quickly translates into recruitment of other cells to the site of infection. Additionally, toll-like receptors (TLRs) expressed on the corneal epithelium and stroma, recognise pathogens and their activation leads to generation of both an innate and acquired adaptive immune responses. Of particular note are TLRs 3, 4, 7, and 9 which mediate an anti-viral response to corneal epithelial infection with HSV-1 (Redfern & McDermott) Binding of the pathogen to TLRs causes release of cytokines and chemokines which provide alert signals to draw in inflammatory cells such as neutrophils and lymphocytes. TLR activation also induces resident corneal APCs to express MHC-II and costimulatory molecules thus engaging the acquired immune response.(Hamrah & Dana, 2007) The anti-viral immune response of TLR7 has been successfully tested in clinical trials treating HSV following the success of Imiquimod, an FDA-approved TLR7 agonist used in the treatment of infection with the human papilloma virus (HPV).(Miller, R. L. et al., 2008) Despite encouraging results of TLR agonist therapy for HSV, one must exercise caution in their use since excessive TLR stimulation can lead to an unfavourably strong immune response with much damage to bystander cells and tissues of the eye.

Langerhans cells have been found in abundance near the limbus and are recruited to the site of inflammation within a few days in the wake of HSV-1 infection.(Streilein et al., 1979) (Asbell & Kamenar, 1987; Hendricks et al., 1992a) There they process the viral antigens for presentation to naïve T-helper (Th0) cells in draining lymph nodes. These Th0 cells mature into Th1 or Th2 cells depending upon the type of cytokines, prostaglandins and costimulatory molecules released by LCs and cells of the innate immune system.(Torres & Kijlstra, 2001) The extent of stromal damage in HSK is affected by the density of LCs in the cornea.(Asbell & Kamenar, 1987; Hendricks et al., 1992a; Jager et al., 1991; Jager et al., 1992; Miller, J. K. et al., 1993) Virally-induced migration or maturation of LCs in the cornea precedes the development of HSK. Induction of LC migration into the central cornea before HSV-1 infection results in an accelerated and enhanced delayed type hypersensitivity (DTH) response to HSV-1 antigens, and an increased severity of HSK. On the contrary, depletion of DCs reduces the incidence and severity of HSK, suggesting a role for DCs in the induction of a T cell response. These findings have led to the conclusion that HSV-1 infection results in *de novo* migration of LCs from the limbus, which in turn might play a role in the immunopathology of HSK through presentation of antigens to T cells in the infected cornea. Thus, patients that have a higher density of corneal LCs are likely to get more severe forms of HSK, which highlights the role of LCs as a potential therapeutic target in HSK.

HSK has been studied extensively using mouse models of disease and $CD4^+$ T helper 1 (Th1) cells have been purported to be key mediators in the immunopathogenesis of corneal HSV-1 infection. (Hendricks, 1997; Streilein et al., 1997) In mice depleted of CD4+ cells, HSK development and progression was prevented or retarded, whereas depletion of CD8+ cells either made no difference or made the severity of HSK worse. (Newell et al., 1989a; Newell et al., 1989b) Corticosteroids, which are commonly prescribed in addition to antiviral therapy in HSK, work partially via inhibition of CD4+ T-cell response and are thus effective in controlling inflammatory damage to the eye. Among other local tissue factors, the kind of T-helper response generated is orchestrated by a fine balance between cytokines IL-12 and IFN-α, and IL-4 and IL-10, which mature Th0 cells into Th1 or Th2 respectively. (Torres &

Kijlstra, 2001) The predominant expression of cytokines IL-2 and IFN- α in HSK further corroborates the role of CD4+ Th1 immune response in HSK pathogenesis.(Hendricks et al., 1992b; Niemialtowski & Rouse, 1992b) The role of Th2 cells in HSK is far more controversial and inconclusive. While some groups state that Th2 cells have negligible involvement in HSK, (Niemialtowski & Rouse, 1992a, b) others either ascribe Th2 cells as inducers of HSK, (Foster et al., 1993; Jayaraman et al., 1993) or ascribe their role to convalescent phase of HSK.(Jayaraman et al., 1993) There is however one caveat; the kind of response generated is also driven by the strain of HSV-1. Corneal infections with the reticuloendotheliosis (RE) strain of HSV-1 are predominantly CD4+ driven, whereas the relatively less neuroinvasive (KOS) strain recruits and activates CD8+ T cells. (Hendricks & Tumpey, 1990; Newell et al., 1989a; Russell et al., 1984) T cell mediated delayed type hypersensitivity eventually is critical for the elimination of the virus. After this point circulating memory T and B lymphocytes continuously scan the cornea.

The suggested T-cell mediated immune response in HSK, is supported by the fact that specific HSV epitopes have been shown to mount an immune response by generation of autoreactive T cells. (Zhao et al., 1998) Murine studies of chronic HSK further demonstrated that despite clinical signs of active disease and lesions, 10-15 days post viral inoculation, viral antigens and messenger RNA (mRNA) were undetectable in the corneas of these mice.(Babu et al., 1996) Furthermore, Avery and colleagues performed elegant experiments, demonstrating that transfer of autoreactive $CD4^+$ T cells to into athymic mice infected with HSV-1, results in the development of HSK.(Avery et al., 1995) However, there is ongoing debate regarding the source of antigenic response elicited in HSK. Verjans et al. have shown that T cells harvested and cultured from HSK donor corneas failed to show reactivity against human corneal antigens.(Verjans et al., 2000) Moreover, human studies to date have been inconclusive and it has been hypothesised that a variable clinical spectrum of disease in patients with recurrent HSK may either be due to a heterogeneous immune response to the HSV epitopes, or, to heterogeneity in the expression of corneal autoantigens in the host.(Ellison et al., 2003)

Based on the ability of HSV-1 to circumvent the immune response and maintain latency, along with the complexity of immune players that orchestrate signalling cascades leading to a spectrum of disease seen clinically, it is challenging for clinicians to treat HSK effectively. Attempts towards immunomodulation of HSK have been made, ranging from induction of apoptosis in T cells by amniotic membrane transfer,(Bauer et al., 2009) to suppression of chemotaxis and activation of CD4+T cells by targeting chemokine receptors.(Komatsu et al., 2008; Lee, S. K. et al., 2008). However, with an evolving and deeper understanding of the molecular mediators of HSV-1 infection, new molecular targets may provide platforms for emerging therapies.

2.2.2 Pseudomonas keratitis

One of the most important organisms in the group of bacterial keratitides is the Gram-negative bacterium *Pseudomonas aeruginosa. P. aeruginosa* is an opportunistic pathogen, which like other microbes, requires a breach in the corneal surface for infection.(Hazlett et al., 1978) Such infections are typically seen in individuals who wear contact lenses for extended periods of time, and in nosocomial or tropical settings stemming from the ability of the bacterium to grow in any niche without much nutritional support.(Hazlett, 2004)

Pseudomonal keratitis is highly invasive and can lead to corneal perforation within 24-48 hours post-infection.(Jones, 1973) Pseudomonal infections of the cornea are marked by inflammation and necrosis; there is a suppurative stromal infiltrate, coagulative necrosis, epithelial edema, a mucopurulent exudate, and in some cases a paracentral corneal ring infiltrate that can be seen in addition to a hypopyon.(Hazlett, 2004) One of the main host factors that is the culprit for a stromal meltdown is the massive recruitment of neutrophils, which release lysosomal enzymes and oxidative compounds, digesting collagen of the stromal extracellular matrix. (Carubelli et al., 1990; Nicas & Iglewski, 1985; Trinkaus-Randall et al., 1991; Van Horn et al., 1978; Weiss, 1989) IL-6, one of the cytokines expressed within 24 hours of *P.aeruginosa* invasion, may be involved in recruitment of PMNs to the site of inflammation by upregulating the expression intercellular adhesion molecule-1 (ICAM-1), a key molecule involved in migration of neutrophils.(Cole et al., 1999; Youker et al., 1992) Integrin-mediated neutrophil migration is a critical phenomenon that occurs not only within the proteoglycan matrix, but also among stromal keratocytes which express adhesion molecules.(Burns et al., 2005)

The rapid spread of infection in the early stages of disease has been attributed in part to a delayed response from the responsible TLRs, TLR-2, -4 and -5, which are expressed at a later stage in the disease thus leading to a delay in activation of both the innate and adaptive arms of the immune response. (Jin et al.) Using a murine model of pseudomonal keratitis, Sun and colleagues demonstrated that *P.aeruginosa* activates expression of TLR-4/5 on resident corneal bone marrow-derived macrophages, inducing transcription of chemokines and cytokines such as KC/CXCL1, as well as IL-1α and IL-1β. Subsequent recruitment of neutrophils into the corneal stroma leads to destruction of *P.aeruginosa*. The produced IL-1 has a positive feedback effect by activating the IL-1 receptor in macrophages and other cells of the cornea, thus ensuring a sustained response against the bacteria.(Sun et al.) While a sustained immune response favours reducing bacterial load, it is also associated with bystander local tissue damage from dysregulation of cytokines and chemokines as seen by elevated expression of TNF- α , MIP-2/CXCL2, IL-1α but low levels of IL-10.(Zhou et al.) It is evident that the role of a prompt and efficient immune response is critical in curtailing the spread and severity of pseudomonal keratitis, and eventually in preventing loss of vision. However, the caveat to a robust immune response remains the collateral damage incurred to surrounding cells and tissues.

From a therapeutic standpoint, TLRs make interesting molecular targets. Particularly, TLR-9 is one of the first in its class to be expressed when the cornea is invaded by *P. aeruginosa.* Huang and colleagues used RNA interference (RNAi) to knockdown TLR-9 in mice which resulted in decreased corneal opacity, fewer corneal perforations, with decreases in PMNs, inductors of the Th1 pathway IFN-γ and IL-12, and mediators of chemotaxis IL-1 β and MIP-2/CXCL2, but higher bacterial titers than controls.(Huang et al., 2005) Further, when mice were either depleted of $CD4^+$ T cells or received IFN- γ neutralising antibodies prior to inoculation, they were spared corneal perforation and had a reduced DTH response, corroborating the role of a CD4+ T-cell mediated immunopathogenesis of this disease.(Kwon & Hazlett, 1997) Cytokines released by CD4+ T cell and LC result in infiltration of higher numbers of PMN, eventually leading to increased corneal.(Hazlett et al., 2001; Hazlett et al., 2002) While some propose that in order to minimise this collateral damage to ocular tissues, therapies should consider directing the immune response from

CD4+/Th1 mediated towards a Th2 pathway, (Kijlstra, 1994) others are of the opinion that it is the balance between pro-and anti-inflammatory mediators that is of greater significance in pseudomonal keratitis. (Hazlett, 2004) (O'Callaghan et al., 1996)

2.2.3 Fungal keratitis

Fungal keratitis is a vision-threatening infection and has seen a recent continual rise in incidence, with a spike during 2005-2006, following *Fusarium* contamination of a commercial contact lens solution. The three most common risk factors for fungal keratitis are contact lens use, trauma and penetrating keratoplasty. (Yildiz et al.) (Iyer et al., 2006) Filamentous fungi form the majority of causative organisms with *Fusarium* (41%), *Candida* (14%), *Aspergillus* (12%) and *Curvularia* (12%) being among the top contenders.(Iyer et al., 2006; Jurkunas et al., 2009) Fungal infections of the cornea, if not treated immediately and managed appropriately, can rapidly lead to corneal ulceration, perforation, corneal neovascularisation, loss of vision and possibly, loss of the eye. (Yuan & Wilhelmus, 2009) (Thomas, P. A. & Geraldine, 2007) It is thus imperative to understand the molecular underpinnings of fungal keratitis, especially the involvement of immune players, for a more thorough understanding towards devising novel and efficacious treatment modalities.

Contact lens wear can compromise the integrity of the corneal epithelium, making it susceptible to fungal invasion. It is known that contact lens wear can induce a subclinical host immune response with recruitment of LCs into the cornea. (Sankaridurg et al., 2000) TLRs on APCs, such as LCs or macrophages, recognize fungi, thereby activating the innate and adaptive immune response to clear the infection.(Barton & Medzhitov, 2003; Johnson et al., 2005) Hu et al. demonstrated the importance of macrophages through depletion of these cells, showing the contribution of macrophages in two different fungal infection models 5 and 7 days following infection. In this study development of more severe keratomycosis in mice depleted of macrophages points the contribution of macrophages in limiting fungal disease. (Hu et al., 2009) *In vitro* studies have shown that inactivated hyphae of *Fusarium solani* upregulate gene expression of TLRs-2, 3, 4 and 6, along with protein expression of TLRs 2 and 4 with resultant increases in cytokine expression of IL-6 and IL-8. The importance of TLR-4 in modulating the host defense mechanisms to fungi, especially *Fusarium* keratitis, has been demonstrated by several groups. In an experimental model of infectious keratitis, it was observed that resolution of *Fusarium* keratitis involved activation of both the innate immune response along with the adaptive arm through TLR-4.(Sun et al.) In another murine study, inoculation in knockout models of TLR-4, lead to impaired host anti-fungal defense mechanisms, decreased production of CXCL1 with subsequent decreased recruitment of neutrophils into the cornea, as well as uncontrolled fungal growth and eventually corneal perforation (Tarabishy et al., 2008) On the contrary, hydrocortisone treatment *in vitro* leads to a TLR-mediated increase in resistance to *Fusarium solani* with a concomitant increase in IL-6 expression by human corneal endothelial cells (HCEC).(Jin et al., 2007)

Similarly, in humans, fungal keratitis secondary to *Aspergillus* and *Candida* species also rely on human corneal TLRs 2 and 4 for hosting an immune response.(Mambula et al., 2002; Netea et al., 2002; Netea et al., 2003) TLRs 2 and 4 recognise fungal zymosan and mannan, leading to an expected increase in the production of IL-6 and IL-1β when challenged with *Aspergillus*, which is diminished by knocking down these innate receptors, confirming the

putative role of TLRs 2 and 4 in Aspergillus keratitis.(Guo & Wu, 2009) In a recent study from the same group investigated the effect of targeting TLR2 by a small interfering RNA (siRNA) construct applied subconjunctively and topically to the cornea, showed that suppressing TLR2 expression in the cornea results in a decrease in neutrophil infiltration, allowing the cornea to preserve its morphological integrity. Suppressing TLR2 expression also caused a decrease in TNF-α, IL-1β, IL-6, IL-12, monocyte chemoattractant protein (MCP-1)/CCL2 and macrophage inflammatory protein (MIP-2)/CXCL2 expression. Immunomodulation by targeting TLR2 might be a treatment approach in fungal keratitis to avoid damage to the cornea by an immune response.(Guo et al.) *Aspergillus fumigatus* also induces IL-10 expression, and taken together, these cytokines attract and direct PMNs into the cornea, inciting innate immunity.(Redfern & McDermott) Thus, in addition to anti-fungal therapy, modulating fungus-specific TLR responses and controlling the host's immune response to the patient's advantage, is an exciting avenue to explore in the field of molecular anti-fungal therapy towards quicker resolution of infection with minimal residual damage.

2.2.4 *Acanthamoeba* keratitis

Acanthamoeba keratitis (AK) is a resilient, vision-threatening infection of the cornea. *Acanthamoeba* is an ubiquitous protozoa, which is exceptionally difficult to treat. Infection with *Acanthamoeba* either resolves spontaneously, or, as often seen, results in progressive infection and eventual corneal melting, suggesting a role of the immune system in its pathophysiology. Corneal transplantation is indicated in cases of severe infection, however, reinfection can commonly occur due to the presence of *Acanthamoeba* cysts within the host graft bed. Reinfection and recrudescence indicates the absence of memory against this parasite, and hence a poor activation of the adaptive arm of the immune response. *Acanthamoeba species* exist freely in the environment and on certain mucosal surfaces of healthy individuals.(Alizadeh et al. 1996; Niederkorn et al. 1999) Two of the most critical risk factors for AK include contact lens use and corneal trauma.(Niederkorn et al. 1999) Trophozoites attach to the surface of the contact lens which are then introduced to the ocular surface. Integrity of the host immune machinery predicts the severity of infection and incidence of disease as patients with AK have lower tear levels of IgA against *Acanthamoeba* antigens as compared to healthy controls, implicating the role of mucosa-mediated immunity in AK. (Alizadeh et al. 2001) The unique resilience of the double-layered cellulose wall of *Acanthamoeba* cysts, which are resistant to extreme temperatures, UV and gamma irradiation, underlies the challenges of treating AK. Systemic immunization to *Acanthamoeba* antigens does not confer immunity unlike mucosa-induced immunity.

Once the trophozoites invade the corneal epithelium through dislodgement of the epithelial cells caused by contact-lens induced microabrasions, there is a TLR-4-mediated immune response in corneal epithelial cells with release of cytokines IL-8 and TNF-α as shown in rats (Ren and Wu 2011). The innate immune response is activated with recruitment of neutrophils and macrophages. Macrophages are believed to be pivotal to the resolution of AK. They have a chemotactic response to the pathogen, and bear an inherent ability to kill the trophozoites *in vivo.* This phenomenon can be demonstrated by the depletion of macrophages in Clodronate treated animals which develop severe, chronic AK. (Stewart et al. 1992; van Klink et al. 1996) Although cysts are more difficult to eradicate, macrophages

forming the first line of defence in AK may also attack *Acanthamoeba* cysts by direct phagocytosis as seen *in vitro* (Hurt et al. 2003). Like macrophages, neutrophils also form the first-line defence against both *Acanthamoeba* cysts and trophozoites, but demonstrate a more robust and efficient response. They are found in large numbers in corneas with AK, where they clear the protozoan using myeloperoxidase-dependent killing. Neutrophils are important both in the prevention and resolution of AK.(Hurt et al. 2003; Clarke et al. 2005).

The most convincing and potent response from the adaptive arm of the immune system is the secretion of IgA antibody. IgA antibody promotes neutrophil-mediated killing of trophozoites hence preventing adhesion of the trophozoites to the corneal epithelium. Furthermore, it shuts down the corneal melt-down plant of the trophozoites by inhibiting mannose-induced cytopathic protein 133 (MIP-133)-induced digestion of the corneal epithelium and stroma. The role of corticosteroids in the treatment of AK remains controversial. This issue arises from the contrary effects of dexamethasone on the eye; on the one hand they help in the resolution of AK-associated ocular inflammation, but on the other hand, they induce excystment of dormant cysts leading to recrudescence. Thus, targeting MIP-133 offers an attractive target in the therapy of AK. Earlier detection of disease by visualization of cysts in the cornea using *in vivo* confocal microscopy (IVCM) may offer an advantage in the management of AK.(Kumar et al. 2010) Through a more sensitive approach in the detection and consequent treatment of AK, the prognosis may be improved leading to fewer cases of corneal melting and associated complications.

2.3 Corneal transplantation

Corneal transplantation is the most common form of solid tissue transplantation with approximately 45,000 cases being performed annually in the United States alone.(CCTS, 1992; Niederkorn, 1999; Streilein, 1999) Unlike other solid tissue transplants, corneal allotransplants enjoy immune privilege, and neither require standard human leukocyte antigen (HLA) matching, nor permanent systemic immunosuppression. First time recipients of corneal allografts enjoy a 2-year graft survival rate of greater than 90% if the recipient corneal bed is avascular and free of inflammation.(Niederkorn, 1990) Corneal immune privilege is attributed to: (a) an avascular corneal bed which prevents recruitment of immune cells and leukocytes to the graft site, thus preventing recognition of non-self HLA antigens; (b) lack of lymphatic vessels, which eliminates transport and presentation of non-self HLA antigens and egress of APCs to T cells in draining lymph nodes, thus decreasing sensitisation (c) paucity of mature MHC-II$^+$/HLA-DR$^+$ resident corneal dendritic cells, including LC, thus decreasing direct presentation of unmatched HLA antigens to T cells; (d) constitutive expression of Fas ligand (CD95; FasL), which programs cell death of activated Fas$^+$ T cells; (e) local ocular production of immunomodulatory neuropeptides and factors in aqueous humour such as transforming growth factor beta (TGF)-β_2 and alpha-melanocyte stimulating hormone (α -MSH), which inhibits alloantigen-driven T cell activation and DTH.(Dana, M. R. et al., 2000; Dua & Azuara-Blanco, 1999; Griffith et al., 1995; Jager et al., 1995; Niederkorn, 1990; Niederkorn et al., 1989; Streilein, 1993, 1995; Stuart et al., 1997; Thiel et al., 2009)

Neovascularization of the corneal graft greatly increases the rate of rejection.(Alldredge & Krachmer, 1981; Maguire et al., 1994) As per guidelines of the Collaborative Corneal Transplantation Studies, the recipient cornea is considered “high-risk” if there is stromal

vascularisation in two or more quadrants preoperatively.(1992) The other factors which lead to graft rejection include growth of lymphatic vessels into the cornea, thereby establishing drainage to the cervical lymph nodes;(Hamrah et al., 2002a) migration of LCs into the cornea; maturation of resident LCs and DCs of the cornea, which can then serve as APCs;(Dekaris et al., 1999; Hamrah & Dana, 2007; Hamrah et al., 2002b; Liu et al., 2002) increased expression of cytokines IL-1 and TNF- α , which lead to recruitment of neutrophils, suppression of anterior chamber-associated immune deviation (ACAID), maturation of corneal APCs, upregulation of vascular adhesion molecules, and recruitment of leukocytes.(Dana, M. R. & Streilein, 1996; Dana, R., 2007; Hamrah et al., 2007; Pepose et al., 1985; Streilein et al., 1996; Yamagami et al., 1999; Zhu, S. et al., 1999; Zhu, S. N. & Dana, 1999)

The process of corneal transplant rejection includes an induction phase, called the "afferent" arm, and an expression phase, called the "efferent" arm. In the afferent arm, the host becomes sensitized to the donor antigens by APCs (e.g., MHC class II-positive DC, LC, macrophages, etc.) that present antigens to T cells in draining lymph nodes. This sensitization process involves two different pathways. The *direct* pathway, which involves *donor* APCs that sensitize the host *directly* when T cells recognize the donor class II MHC, thus generating direct alloreactive T cells, and the *indirect* pathway, which involves *host* APCs that migrate to the graft, take up donor antigens, process it, migrate to draining lymph nodes, and then present their antigens to T cells. Host sensitization to donor antigens of corneal grafts occurs through both pathways of sensitization, especially in high-risk corneal grafting. Further, the critical role of draining cervical lymph nodes in the process of allosensitization has been clearly demonstrated by recent studies. Upon arrival in the lymph nodes, APCs upregulate surface expression of co-stimulatory molecules, secrete cytokines, leading to activation of T cells. The subsequent efferent phase is then responsible for the actual rejection of the graft. This phase consists of the proliferation of alloreactive T cells in lymphoid organs, migration of these cells to the cornea, and the development of "memory" that can assist the alloimmune response in case of repeated exposure to the same antigens. Both $CD8^+$ cytotoxic T lymphocyte (CTL) and $CD4^+$ T helper (Th) cells have been implicated in the rejection process. Th1 cells uniquely secrete IL-2, IFN-γ, and lymphotoxin, and have the purpose of eradicating offending pathogens by promoting inflammation. Th2 cells secrete IL-4 and IL-10, suppress Th1 cells, and promote B cell differentiation, leading to the production of antibodies. $CD4^+$ Th1 cells are the primary mediators of the efferent arm and act directly as effector cells and not as helper cells in corneal graft rejection. IL-2, secreted by these cells, stimulates the activation and proliferation of other T and B cells, whereas IFN-γ activates macrophages and induces expression of class II antigens in the donor tissue. The role of $CD8^+$ T cells in the rejection of allogeneic corneal grafts remains controversial. While $CD8^+$ T cells can contribute to graft rejection, corneal grafts can still be rejected in their absence, hence making $CD8^+$ T cells sufficient but not necessary for graft rejection.

A major factor directing the recruitment of T cells and other leukocytes into grafts are chemokines. Surgical trauma induces release of early cytokines such as TNF-α and IL-1 by corneal epithelial cells. These cytokines in turn stimulate the production of early neutrophil- and macrophage-attractant chemokines, including MIP-2/CXCL2, MCP-1/CCL2, regulated upon activation normal T-cell expressed and secreted protein (RANTES)/CCL5, MIP-1α/CCL3, MIP-1β/CCL4 and eotaxin/CCL11, especially after high-risk corneal

transplantation.(Flynn et al., 2008; Yamagami et al., 2005; Yamagami et al., 2000; Yamagami et al., 1999) While early chemokines direct non-antigen-specific leukocytes to the graft, late chemokines as stated above produced by the graft and infiltrating leukocytes recruit alloantigen-primed T cells into the graft. In addition, recipients of high-risk transplants express very high levels of the IP-10/CXCL10 chemokine. Chemokines function together with other molecular mediators including integrins and adhesion molecules to direct the immune response toward the graft. Therapeutic endeavours seek to inhibit either or both arms of the immune response to prolong graft survival. Regulatory T cells ($Foxp3^{+}T_{regs}$) have been shown to promote graft survival by inhibiting alloimmunity in draining lymph nodes as opposed to altering to the effector arm of the immune response.(Chauhan et al., 2009; Cunnusamy et al.; Tang & Bluestone, 2008) Measures devised to enhance graft survival should essentially revolve around three main goals: (a) to prevent induction of alloimmune response, (b) to inhibit or deplete immune effector cells, and, (c) to induce tolerance to specific alloantigens.(Niederkorn, 2002)

2.4 Dry Eye Disease

Dry eye disease (DED) is one of the most common diagnoses made in ophthalmic practice. DED affects millions of people around the world. It is more prevalent in women than men and is of inflammatory etiology.(Calonge et al.; 2007b) In epidemiologic studies conducted by Schaumberg and colleagues, they found a prevalence of 5.7% in women aged 50 years or younger, and 9.8% in women aged 75 years or above.(Schaumberg et al., 2003) Patients usually present with ocular irritation and in severe cases, there may be accompanying ocular pain, punctate keratopathy and filamentary keratitis.(Pflugfelder, 1998) The definition of DED has been modified over the years to integrate evolving concepts of the involvement of tear film hyperosmolarity, inflammation of the ocular surface, and the effects of DED on vision. In 2007, the International Dry Eye Workshop (DEWS) defined DED as: "a multifactorial disease of the tears and ocular surface that results in symptoms of discomfort, visual disturbance, and tear film instability with potential damage to the ocular surface. It is accompanied by increased osmolarity of the tear film and inflammation of the ocular surface."(DEWS, 2007a)

Clinically, DED can be categorised into (a) aqueous deficient and, (b) evaporative dry eye. (Lemp, 1995) Aqueous deficient DED consists of disorders that affect the lacrimal functional unit (LFU). The term "lacrimal functional unit" was coined in 1998 by Stern and group, comprising the ocular surface, lacrimal glands, associated innervation, and neuroendocrine factors.(Stern et al., 1998; Stern et al., 2004) The clinical diagnosis of DED is made using a combination of examination techniques, including Schirmer's test, tear film osmolarity, and fluorescein tear break-up time (fTBUT). A reading of less than 15mm on the Schirmer's strip in conjunction with elevated tear film osmolarity (>315 mOsm) is indicative of decreased tear production, hence, suggestive of aqueous-deficient DED. When fTBUT is less than 10 seconds, there is increased suspicion of evaporative DED. Diseases that lead to aqueous deficient dry eye disease include Sjögren's syndrome and non-Sjögren's autoimmune conditions. Whereas, evaporative dry eye is due to diseases that affect the production, quality and distribution of the tear film lipid layer, namely, meibomian gland dysfunction (MGD) and chronic blepharitis.(Barabino & Dana, 2007; Calonge et al.) It has been demonstrated that regardless of the etiology of dry eye, inflammation of the ocular surface and homing of immune cells to the target tissue, are hallmarks of DED. These immuno-

inflammatory processes are culprits of corneal and conjunctival damage leading to the presenting symptoms.(Barabino & Dana, 2007; Dana, M. R. & Hamrah, 2002)

Recent evidence suggests a role for chemokines in the pathogenesis of dry eye syndromes. Increased RNA levels of IL-8, which is chemotactic for neutrophils, are found in the conjunctival epithelium of Sjogren's syndrome patients compared to controls. Furthermore, increased levels of select chemokines in the lacrimal glands of nonobese diabetic (NOD) mice, an animal model of Sjogren's syndrome, have been detected. NOD mice are a murine model for type-1 insulin-dependent diabetes with an autoimmune component. They represent a murine model of Sjogren's syndrome based on the similar histopathological picture of sialoadenitis. These mice have lymphocytic infiltration of not just the pancreas but also the submandibular and lacrimal glands. Both RANTES/CCL5 and IP-10/CXCL10 gene transcripts are detected in lacrimal glands at 8 weeks of age increased markedly during the course of active disease, concomitant with induction of their receptors CCR1, CCR5 and CXCR3. The examination of lacrimal glands indicated that lymphocytes in the inflammatory infiltrates are responsible for the production of these chemokines. Moreover, anti-RANTES treatment significantly reduced inflammation in the lacrimal glands of these mice. Further, patients with DED have a significant increase in the number of ocular surface cells that express CCR5, the receptor for RANTES/CCL5 and MIP-1β/CCL4. These data suggest that a better understanding of the role of chemokines and chemokine receptors in DES could open new doors for development of molecular strategies for immune modulation in this common disorder.

Numerous studies have demonstrated the enhanced expression of pro-inflammatory cytokines (e.g., IL-1, IL-6, IL-8, TNF-α) mRNA and protein by the ocular surface epithelium or tear film. The increase of these proinflammatory cytokines can lead to epithelial cell proliferation, keratinization, and angiogenesis, and thereby could link ocular surface disease with a number of lid margin disorders, such as rosacea, characterized by inflammation. In addition, IL-1 may lead to upregulation of matrix proteases, including collagenases, and thereby exacerbate stromal pathology as well as alter the paracrine effect of other cytokines on resident DCs, macrophages, fibroblasts, and epithelial cells by altering the matrix milieu in which these cytokines bind their respective receptors. Corneal epithelial cells respond to stress signals by producing cytokine mediators of inflammation such as TNF- α , IL-1β, IL- 8 and MMPs.(Li et al., 2006; Luo et al., 2004) Subsequently, maturing resident and recruited DC carry antigen to the draining lymph nodes to present and activate T cells. T cell-mediated responses have recently been shown to play a center stage in DED. Th1 cells recognize antigenic peptides in association with MHC class II molecules on the surface of APC, and release pro-inflammatory cytokines that increase vascular permeability and recruit further inflammatory cells to the site of injury. Due to the nonspecific nature of cell recruitment employed by CD4+ Th1 cells, inflammation can be severe with damage to bystander tissue. More recently, Th 17 associated cytokines and IL 17 producing cells have been found in the ocular surface epithelium of dry eye patients and it has been hypothesized that epithelial cells subjected to desiccating conditions promote DC to secrete IL-6, IL-23 and TGF-β, which in turn induce Th17 cells.(Zheng, X. et al.)

3. Leukocyte trafficking

Trafficking signals finely control the movement of distinct subsets of immune cells into and out of specific tissues. Leukocyte extravasation from blood to tissue, including that of APC

and T cells, usually occurs through a multistep process, involving adhesion molecules and chemokines. Because the accumulation of leukocytes in tissues contributes to a wide variety of diseases, these 'molecular codes' provide new targets for inhibiting tissue-specific inflammation. However, immune cell migration is also critically important for the delivery of protective immune responses to tissues. Therefore, the challenge lies in identifying trafficking molecules that will specifically inhibit key cell subsets that drive disease processes without affecting the migration of leukocytes required for protective immunity.

Adhesion molecules can be categorized according to their structure or function. Four major families are distinguished structurally: the selectins, the sialomucins, the integrins, and the Ig superfamily. Leukocyte tethering and rolling, mediated typically by three selectins, L-selectin, E-selectin and P-selectin, are the first steps in the process of leukocyte binding to vascular endothelium. Two selectins, P- and E-selectin, are expressed on activated endothelium, whereas L-selectin is found on leukocytes. L-selectin is involved in the homing of T cells to lymphoid tissues but is also expressed on other leukocytes, where it participates in inflammation. E-selectin is expressed on corneal vascular endothelium, whereas P-selectin is expressed on inflamed vascular endothelium and by certain leukocytes. P-selectin glycoprotein ligand-1 (PSGL-1) binds all three selectins and is expressed on peripheral blood DC.

In the cornea, studies in both human and animal models of disease have confirmed that cell adhesion molecules are closely associated with the development of herpetic keratitis, and corneal allograft rejection. P- and E-selectin have been shown to mediate neutrophil recruitment to the cornea in studies using P/E-selectin knockout mice. Integrins are found on most cell types. Two subfamilies are most important for leukocyte migration: the α4 (CD49) and the β2 (CD11/CD18) integrins. Four distinct members of β2 integrins exist, three of which are expressed by DC. Vascular endothelial ligands for these molecules are members of the immunoglobulin superfamily. Leukocyte arrest in venules requires *in situ* activation of at least one of the four main integrins: VLA-4 (binds to VCAM-1), α4β7 (binds to MadCAM-1), Mac-1(binds to ICAM-1) and LFA-1 (binds to ICAM-1 and 2). VCAM-1 has been shown to be present on monocytes and vascular endothelial cells during corneal inflammation. Arguably the most important ligand for β2 integrins is ICAM-1, which is expressed on many cell types and is strongly upregulated upon exposure to inflammatory cytokines in the cornea and on limbal endothelial cells, deletion of which has been shown to suppress corneal graft rejection.

Chemokine receptors regulate leukocyte retention within tissues. The migration of leukocytes to inflammatory sites depends on a cascade of discrete events mediated, in part, by chemokines and their receptors. Numerous chemokines have now been described during inflammation, including CCL3/MIP-1α, CCL4/MIP-1β, and CCL5/RANTES, ligands for CCR1 and CCR5; CCL2/MCP-1, a ligand for CCR2; CCL22/MDC and CCL17/TARC, ligands for CCR4; CCL20/MIP-3α, the ligand for CCR6; CXCL8/IL-8, a ligand for CXCR1 and CXCR2; CXCL1/KC, CXCL2/MIP-2, and CXCL5/ENA-78, ligands for CXCR2; CXCL9 /MIG, CXCL10/IP10 and CXCL11/ITAC, ligands for CXCR3. In addition, constitutively expression of CCLs 2-5,CXCL10, and CCL27/CTACK, a ligand for CCR10 have been described in the normal cornea. Which of these chemokines is relevant in recruitment, retention and egrees of corneal APC, is unclear. Little is known about the constitutive recruitment of DC and macrophage precursors into peripheral tissues in the absence of

inflammation. APC function and migratory behavior are related to rapid and coordinated *switching* in chemokine receptor expression by these cells, allowing them to coordinate migratory routes and biological function. During inflammation, CCL2, CCL5, and CXCL8 are produced to attract immature DC that express CXCR4 and CCR4 respectively. In addition, these DC are ideally suited for recruitment to inflammatory sites by their expression of functional receptors for inflammation-induced chemokines, such as CCR1, CCR2, CCR3, CCR5 and CXCR1.

Inflammatory signals induce resident corneal DCs to undergo maturation. Upon maturation, DCs downregulate pattern recognition receptors necessary for surveillance of antigens and upregulate CCR7, a receptor important in the homing of DCs to the lymph nodes. Maturing CCR7+ DCs then enter CCL21-expressing lymphatic vessels and travel to the draining lymph nodes where CCR7 ligands, namely, CCL19/EBI1 ligand chemokine (ELC) and CCL21/secondary lymphoid tissue chemokine (SLC), are produced. In addition, after fluorescein isothiocyanate (FITC) painting (dendritic cell migration assay), CXCR4 inhibition has been shown to impair LC and dermal DC migration to draining LNs, indicating that both CCR7 and CXCR4 make independent contributions to the egress of DCs from resident tissue to the lymph nodes. DC migration into and along afferent lymphatics occurs through a series of steps, including (1) mobilization, (2) detachment, (3) interstitial migration, (4) entry into the afferent lymphatics, and (5) transit via lymph. Recent data have shown that lymphatic endothelial cells upregulate E-selectin, chemokines (CCL5, CCL20, and CXCL5), and adhesion molecules (ICAM-1 and VCAM-1) after cytokine stimulation *in vitro* or *in vivo*. Once in the draining lymph nodes, antigen-loaded mature DCs activate naive T cells, which then proliferate and enter the blood and migrate back to the site of inflammation. In the cornea, CCR5 and CX3CR1, but not CCR1 are partially involved in the recruitment of MHC-II$^+$ LCs. How the central immature LC or stromal APC populations are recruited is not known, although the recently demonstrated constitutive expression of CCR2 on stromal BM-derived cell subsets, implicates a role for this chemokine. Further, both vascular endothelial growth factor (VEGFR)-3 and CCR7 are partially implicated in the egress of stromal DCs. APC recruitment to the cornea is likely complex, highly regulated and dependent on recruitment signals that are either tissue-specific or inflammation-induced, or both.

4. Conclusion

The cornea and ocular surface are constantly exposed to environmental pollutants and irritants, microbes, and other potentially noxious agents. Since from an evolutionary standpoint the scope of the host defense mechanisms against these stimuli should be narrow, that is to say adequately effective to protect the eye against the potential harm from these agents and yet tempered enough not to lead to unwanted damage, the eye has developed many mechanisms to effect and regulate its response to environmental challenges. Identification of the critical pathways of cell migration to and from the cornea will provide new molecular targets for pharmacological intervention in inflammatory, infectious, alloimmune and autoimmune diseases and may lead to novel highly specific strategies for immunotherapy, through modulation of APC and T cell migration and function. Few effective anti-inflammatory drugs have emerged over the last decades in the ophthalmic field and an urgent need for new drugs exists, as many inflammatory diseases are inadequately responsive to current medications.

Keratoconus Layer by Layer – Pathology and Matrix Metalloproteinases

Dasha Nelidova and Trevor Sherwin
Department of Ophthalmology, Faculty of Medical and Health Sciences, University of Auckland, Auckland New Zealand

1. Introduction

Keratoconus is an ectatic disease in which the cornea develops a conical shape due to thinning of the collagenous corneal stroma. Characteristic morphological features seen on slit lamp examination are well described. This overview describes the recent advances in our understanding of keratoconic pathology, focussing particularly on the matrix metalloproteinase hypothesis of keratoconus disease progression.

2. The diversity and complexity of keratoconus

Keratoconus is a corneal ectatic disease where the cornea assumes a conical shape due to thinning of the corneal stroma, inducing irregular astigmatism and myopia and leading to marked impairment of vision[1]. Keratoconus typically starts at puberty and progresses until the third or fourth decade of life; alternatively it may commence later and arrest at any age. This disease is associated with several conditions, particularly those which encourage eye rubbing.

The mechanism of disease progression has long been the subject of intense research; however, research is complicated by the large degree of variation in clinical features between patients. *Forme fruste* or sub-clinical forms of the disease, likely contribute to the differences in reported incidence are estimated to occur between 50 and 230 per 100,000 of the general population[1]. There are also significant geographical variations. New Zealand, for example, has an unusually high prevalence of keratoconus. 50% of corneal transplants performed in New Zealand are due to this debilitating disease, compared with 30% in Australia[2] and 20% in the UK[3].

3. Clinical signs of keratoconus

The first adequate description of keratoconus, setting it aside from other ectatic conditions, was advanced by Nottingham in 1854 in his treatise 'Practical observations on conical cornea: and on the short sight, and other defects of vision connected with it'[4].

In 1943 Berliner[5] listed the seven distinct features of keratoconus as classified by Von der Heydt and Appelbaum:

1. Thinning of the cornea at the apex of the cone
2. Reflex from the endothelial cup
3. Striae
4. Irregular superficial opacities or scars
5. Ruptures in Descemet's membrane
6. Increased visibility of the nerve fibres and
7. Fleischer's ring.

These morphological features became incorporated by Duke-Elder[6] into the 1965 text 'System of Ophthalmology', which went on to describe keratoconus as a disease which can be recognised by:

1. A thinning of the cornea at the apex of the cone from one half to one fifth of its normal dimensions
2. An endothelial reflex in the central portion of the cornea at the peak of the cone
3. Vertical lines in the deeper layers of the stroma
4. An increased visibility of the nerve fibres which form a network of grey lines interspersed with small dots
5. Fleischer's ring, a line running round the base of the cone
6. Ruptures of Descemet's membrane of characteristic appearance
7. Ruptures in Bowman's membrane in advanced cases producing superficial linear scars.

Rabinowitz[1] lists the following clinical signs which may be present individually or in combination in moderate to advanced keratoconus:

'Stromal thinning (centrally or paracentrally, most commonly inferiorly or inferotemporally); conical protrusion; an iron line partially or completely surrounding the cone (Fleischer's ring); and fine vertical lines in the deep stroma and Descemet's membrane (Vogt's striae)... Other accompanying signs might include epithelial nebulae, anterior stromal scars, enlarged corneal nerves and increased intensity of the corneal endothelial reflex and subepithelial fibrillary lines.'

Since then advances in corneal topographical assessment have greatly aided the diagnosis of early disease. Prior to topography, forme fruste keratoconus was harder to recognise as patients do not necessarily have symptoms or observable clinical signs in these early stages.

4. Antero-posterior review of morphological changes in keratoconus

Pathological and histopathological abnormalities have been documented in every layer of the keratoconic cornea and this has previously been reviewed by our laboratory[7]. The following represents a layer by layer summary of keratoconic morphological variations reported.

4.1 Epithelium

Ex vivo histological analysis of keratoconic corneas has demonstrated significant thinning of the central epithelium[8]. Central epithelial thinning was significantly greater in those corneas which also had breaks in the Bowman's layer, however, the authors thought it likely that differences in the integrity of Bowman's layer could nevertheless be considered to be manifestations of the same disease process. Subsequent studies report thickened epithelia in

keratoconus[9,10] or else no difference in epithelial thickness between keratoconus and normal controls[11].

In vivo confocal microscopy studies of the epithelium demonstrate morphological alterations in the area of the keratoconic corneal apex. Elongated superficial epithelial cells, arranged in a whorl-like fashion, can be observed. Near Bowman's membrane highly reflective changes and fold-like structures are visible[12]. These *in vivo* pathological features may well reflect the oedematous disruptions of basal epithelial integrity in keratoconus.

Apoptotic changes have also been detected in epithelia of keratoconic samples. TUNEL positive epithelial cells were confined to the superficial epithelium of normal corneas while extending further down in keratoconic corneas[9].This is supported by the work which reported that intense TUNEL labelling was present in the basal epithelia of fifteen out of sixteen keratoconic corneas examined[13].

The keratoconic basement membrane assumes an irregular appearance and breaks in places[14]. It also undergoes a change in composition[15,16] that cannot be explained by scarring alone. Laminin-1 and laminin-5 staining was shown to be irregular and thickened at defect sites, however monoclonal antibodies against the α2 and β2 chains did not react[15]. Type IV collagen α1 and α2 reactivity was also only found in the defect regions of keratoconic or scarred corneas[15]. Immunostaining for type VII collagen was patchily localised to the basement membrane defects[15]. Integrin β4 staining which was positive in the basement membrane and the lateral and apical cell membranes of the epithelial cells, was found to be discontinuous in keratoconic corneas[15]. It has been suggested that a process similar to wound healing might account for such differences in structure. Basement membrane alterations may affect critical interactions of the corneal epithelium with the underlying basement membrane, as well as cell-matrix interactions and matrix organization in the stroma[16].

4.2 Nerve fibres

Increased visibility of nerve fibres by slit lamp biomicroscopy has been demonstrated in keratoconus. Corneal nerves pass between the stroma and epithelium at sites of early degradative change[17]. Keratocytes wrap around the nerves as they pass through an otherwise acellular Bowman's layer[17]. Localised nerve thickenings develop in the epithelium and stress epithelial architecture[17].

4.3 Bowman's layer

Scanning electron microscopy has found defects and ruptures in Bowman's layer to varying degrees in all keratoconic corneas examined[18]. Discontinuities in Bowman's layer are sometimes accompanied by distortion of the stroma beneath the defect[15] or alternatively, direct contact between epithelial and stromal cells[19]. Rather than being seen throughout the affected cornea, such abnormalities of the extracellular matrix are usually confined to several loci, suggesting a localised focus of disease progression.

4.4 Stroma – Collagen lamellae and keratocytes

The thickness of collagen lamellae in keratoconus is unaltered, but the number of lamellae appears to be significantly reduced compared to normal tissue[20]. There is no difference in

interfibrillar spacing between keratoconus and control corneas, conclusively demonstrating that stromal thinning in keratoconus is not due to closer packing of the fibrils in the stroma.

There is some evidence for a progressive loss of lamellae from the stroma, for example, a reduction in the volume of proteoglycan along the collagen fibrils has been found in keratoconus[21]. Low angle x-ray scattering has shown that the orientation of collagen fibrils within lamellae is also altered in the disease[22]. It is likely that these changes reflect the presence of a degradative process or alternatively, insufficient repair mechanisms. Biochemical analyses of stromal matrix components are inconclusive: Critchfield and co-workers[23] described decreased collagen and total protein levels in keratoconic tissue by western blotting. Radda et al.[24] found a 5% increase in type I collagen in keratoconus; while Zimmermann et al.[25] found no differences in collagen composition.

Keratoconus is also associated with changes in keratocyte morphology as well as loss of keratocyte density[11, 12]. Keratocytes may be lost though apoptosis[9,13], however, as apoptosis was not seen in all keratoconic samples analysed it was proposed that such cells might not be detected if at the time of analysis the tissue was in a period of keratoconic remission. An alternative explanation suggests that because keratoconus is diagnosed on the basis of clinical findings, there may be several diseases with differing pathophysiological mechanisms that produce the phenotypic change that is referred to as keratoconus.

Keratocyte density was lowest in the anterior-most part of the stroma[12]. Whilst there may be a significant decrease in the density of keratocytes in the stroma immediately underneath Bowmans' membrane, the remaining keratocytes are far from quiet. Such keratocytes and their pseudopodia are oriented apically towards the overlying epithelium and their activated state is reflected by the abundance of rough endoplasmic reticulum within the cells[26].

Studies of the peripheral keratoconic cornea also show discrete incursions of fine keratocytic processes into Bowman's membrane[10]. These processes were often observed in conjunction with posterior collapse of epithelial cells into the Bowman's layer[10].

4.5 Descemet's membrane

Ruptures and folds in Descemet's membrane are common in keratoconus[14]. The origin of these ruptures is unclear as several studies of extracellular matrix proteins have revealed no differences in the levels of collagens, laminin, entactin or perlecan between keratoconus and normal tissue[19,25]. The appearance of the defects in Descemet's membrane may well be associated with environmental factors such as eye rubbing and may lead to the development of hydrops[1].

4.6 Endothelium

The endothelium may be normal in keratoconus or may demonstrate intracellular dark structures, pleomorphisms or elongation of cells[1]. Scanning slit confocal microscopy and ultrasound biomicroscopy in living patients with keratoconus revealed central detachment of Descemet's membrane and endothelium from the posterior part of the stroma[27]. Ruptures in Descemet's membrane may directly lead to endothelial cell loss by triggering cell membrane perforation, loss of cell contents and edema[28]. Alternatively apoptosis may account for decreased endothelial cell density[13].

4.7 Evidence from recurrence of keratoconus

The recurrences of keratoconus in patients after penetrating keratoplasty[29] suggest either a recurrence of the host disease in the graft or else represent transmission of undiagnosed keratoconus from the donor cornea[30]. Histological examination of corneal buttons from patients undergoing repeated penetrating keratoplasty revealed structural changes compatible with a diagnosis of keratoconus in all the examined corneas[31]. Recurrence of keratoconus characteristics may be attributed to graft repopulation by the recipient cells, ageing of the grafted tissue, or both. However a recent study from our own laboratory failed to find evidence of recurrence of keratoconus in patients undergoing regraft surgery[32].

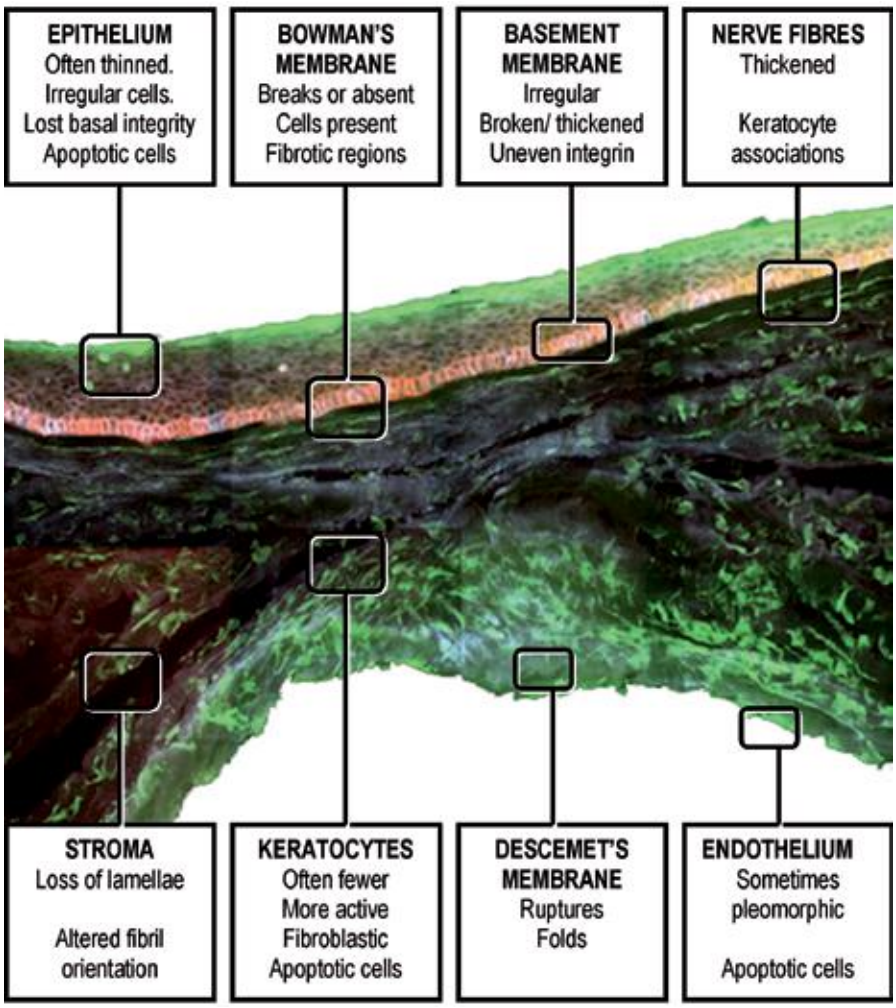

Fig. 1. A diverse range of morphological changes have been described in every layer of the keratoconic cornea. An antero-posterior section of a keratoconic cornea labelled with CellTracker green to highlight cellular morphology and integrin α3β1 labelling the basal epithelium in red helps to summarise characteristic histopathological abnormalities by corneal layer.

5. Pathology to pathogenesis

The diversity of pathologies described for keratoconus are likely to represent temporal differences in the progression of the disease, positional differences relative to the apical centre of maximum damage and reflect a variety of pathophysiological diseases which make up the clinical pigeonhole of keratoconus.

Matrix metalloproteinases (MMPs) have long been suspected of mediating the pathological progression of keratoconus. The cornea is 70% collagen by weight and the reduced collagen content of the keratoconic cornea suggests a degraded extracellular matrix[23]. Extracellular matrix breakdown is, however, only a small component of the MMP repertoire of activity. Nevertheless, this function is essential for normal remodeling, leading to the constitutive expression of MMPs in healthy tissues.

Various models emphasise the role of MMPs in disease, for example, as mediators of connective tissue destruction in arthritis[33]. Consistent with such an involvement is the MMP hypothesis of keratoconus which proposes that MMPs are over-expressed in the disease while MMP inhibitors may be down-regulated, shifting the balance towards excessive tissue destruction. Over the last decade many studies have set out to measure the levels of MMPs and their inhibitors by a variety of techniques yet over-expression of MMPs or presence of active forms has not been found consistently[34].

It is important to consider that the relative balance between various MMPs could be more significant than absolute concentrations. This is relevant given that MMPs often undergo intermolecular interactions with each other to achieve activation from the latent form or to target MMP action to a particular site such as the cell surface. Paradoxically, tissue inhibitors of matrix metalloproteinases (TIMPs) can associate with pro form MMPs to trigger proteolytic activity[33]. Tissue degradation in thinning disorders, such as keratoconus, also involves the expression of inflammatory mediators, including proinflammatory cytokines and cell adhesion molecules[35], which modulate MMP activity and are themselves modulated by it.

The MMP family includes more than 25 members that make up five families based on their substrate preference: collagenases (MMP-1, MMP-8, and MMP-13), stromelysins (MMP-3, MMP-10), matrilysins (MMP-7, MMP-26), gelatinases (MMP-2, MMP-9), membrane type MMPs (MPP-14 to MMP-17, MMP-24) and others[36]. Most are synthesised by resident cells, some are brought in by invading leukocytes. Specific MMPs appear in specific locations within the cornea[36], likely due to cellular and soluble factors particular to the layer.

MMP changes have been described in every layer of the cornea in keratoconus. The following is a layer by layer summary of MMP changes reported within the last 15 years.

5.1 Tear film and increased MMP-9

Tear film composition reflects ocular surface events and tears may therefore be considered a vehicle for some of the pathogenic protagonists of keratoconus. Unfortunately, the cellular origin of any such molecules cannot be determined conclusively as both corneal and non-corneal secretions will be represented in the tear fluid.

In 2000 the presence of collagen degradation products was reported in the tears of patients with keratoconus[37]. The detected telopeptides were presumed to be of corneal origin but the authors conceded that serum and conjunctiva were also potential sources. The conjunctival

epithelium is indeed altered in keratoconus. Elevation of lysosomal enzyme levels has been found in corneal and conjunctival epithelium[38] though such enzymes are mostly involved with lipid metabolism, rather than turnover of proteins or connective tissues. Lipids, however, are crucial to the integrity of the tear film and indeed, chronic ocular desiccation and aqueous tear deficiency can produce inferior corneal steepening and high astigmatism resembling keratoconus[39].

More recently, the levels of interleukin-6 (IL-6), tumour nectosis factor-α (TNF-α), and MMP-9 in the tear fluid of keratoconic patients were measured by enzyme linked immunoadsorbent assay and were found to be significantly higher than in normal subjects[40]. Increases in the levels of these molecules may be intermittent, but sufficient to provoke slowly progressive ectasia[40]. No significant differences in the concentrations of adhesion molecules inter cellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion protein-1 (VCAM-1) were detected and other proteinases were not measured[40].

In most cases, keratoconus initially affects only one eye and later the ectasia may progress to include both eyes. Lema et al. followed up their initial work by measuring the concentrations of IL-6, TNF-α and MMP-9 in thirty patients with unilateral keratoconus - one eye diagnosed with keratoconus and the other eye having subclinical disease. IL-6 and TNF-α levels were found to be raised in both eyes in patients with asymmetric keratoconus, however, only TNF-α was significantly higher in the keratoconic eye, with respect to the subclinical one. Increased MMP-9 levels were found in keratoconic eyes only[35].

TNF-α has been shown to upregulate MMP-9 expression in human corneal epithelial cells[41] and such proinflammatory cytokines are present at the ocular surface even in the absence of inflammation[42]. Interestingly, increased concentrations of cytokines are found in tears from various ocular allergic disease states[43]. While atopy is associated with keratoconus[44], multivariate analysis has shown that the contribution to pathogenesis likely occurs from the eye rubbing encouraged by the itch of atopy rather than from chemical mediators associated with atopy itself[45].

The keratoconic ocular surface is characterised by a disorder of tear quality, decreased corneal sensitivity, conjunctival squamous metaplasia and higher fluorescein and rose bengal staining scores, all of which seem to relate to the extent of keratoconus progression[46]. In that respect the ocular surface is not unlike that of dry eye. It has been shown that inflammation plays an important role in both of these conditions and MMP-9 is found in the tears of both[40,47].

In fact MMP-9 accumulation has been demonstrated in several other disorders with an inflammatory basis, for example, in tears of patients with peripheral ulcerative keratitis, herpetic keratitis and Sjogren's syndrome[48].

Among the MMPs, MMP-9 is of central importance in cleaving epithelial basement membrane components and tight junction proteins that maintain corneal epithelial barrier function[47]. MMP-9 belongs to the gelatinase group of metalloproteinases that degrade denatured collagen; native collagens type IV, V, and VII; and elastin[47]. Expression of MMP-9 by ocular surface epithelia in normal healthy eyes is low. Indeed, MMP-9 knockout mice show significantly less alteration of epithelial barrier function in response to experimental desiccating stress than do wild-type mice, an effect abrogated by topical application of MMP-9 to the ocular surface[49].

5.2 Whole cornea studies and decreased TIMP-1

Studies have also assessed levels of various degradative enzymes in whole processed keratoconic corneas. This research was triggered by observations that cultured human dermal fibroblasts exposed to reactive oxygen species go on to upregulate MMP-1 and MMP-2 mRNA while downregulating TIMP-2 mRNA[50,51]. Thus oxidative stress was thought to be a contributing factor to the pathogenesis of keratoconus by promoting, amongst others, degradative activity.

Kenney et al. measured RNA levels by semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR) and Southern blot. MMP-1, -2, -7, -9, -14, TIMP-2 and TIMP-3 mRNA levels did not differ between normal and keratoconic corneas[52]. There was, however, a 1.8 fold decrease in TIMP-1 mRNA and 2.8 fold decrease in TIMP-1 protein in keratoconus[52].

Decreased TIMP-1 may account for the high gelatinase activity and increased apoptosis of keratoconus. It has been proposed that TIMP-1 curtails the activity of MMP-2, the major protease of the corneal stroma. Unlike the constitutively expressed TIMP-2, TIMP-1 is an inducible inhibitor generally confined to the corneal epithelium[53]. Its synthesis seems to be upregulated in stromal cell cultures from scarred keratoconic corneas[53]. Apart from its anti-proteinase role TIMP-1 prevents TIMP-3 mediated stromal cell apoptosis[53]. Dysequilibrium in the TIMP-1/TIMP-3 system can thus, at least partially, account for the keratoconic condition.

It is likely that changes in MMP and TIMP systems are also present in several other eye diseases. For example, diabetic retinopathy corneas contain higher levels of MMP-3 and MMP-10 mRNA as measured by RT-PCR compared with keratoconic corneas[54]. This is thought to account for the various basement membrane and extracellular matrix alterations in the cornea of diabetic retinopathy.

5.3 Epithelium and increased MMP-1

Collier et al. performed peroxidase immunohistochemistry and determined that MMP-14 (MT1-MMP) was significantly elevated in the epithelium of keratoconic corneas compared to eye bank controls, while MMP-2 was not[55]. This was surprising given that MMP-14 was previously shown to activate latent MMP-2 as well as being able to degrade matrix molecules directly. MMP-14 forms a tri-molecular complex on the cell surface with MMP-2 and TIMP-2 in a complex sequence[55]. The timing of this interaction and concentrations of component molecules determine whether the MMP-14 active site is exposed and available for MMP-2 activation and matrix degradation[55].

It was also noted that the expression of MMP-14 in control corneas varied considerably from virtually none to pronounced levels, raising the possibility that the enzyme is expressed in response to any minor inflammatory or other pathological event.

Subsequent work failed to detect a significant difference in either MMP-2 or MMP-14 between keratoconic and normal epithelium[56], instead reporting higher levels of MMP-13 in the keratoconic epithelium compared to healthy specimens[56]. TNF-α and IL-1β increase corneal epithelial MMP-13 synthesis[57] while MMP-13 has been shown to activate MMP-9 *in vitro*[58]. The temporal and spatial correlation between MMP-13, MMP-9 and corneal re-epithelialisation suggests that MMP-13 plays a role in corneal reepithelialisation after injury[59]. MMP-13 activation seems to be much more prominent in bullous keratopathy than keratoconus[60].

Several studies report increased MMP-1 expression in keratoconus. The epithelia of healthy corneas and corneas with post LASIK keratectasia display nearly absent immunolabelling for MMP-1, whereas strong labelling occurs in the epithelium and stroma of keratoconic specimens[56,61,62]. MMP-1 is able to degrade many non-collagenous components of the extracellular matrix, including fibronectin, laminin, and basement membrane glycoproteins, but first and foremost, it cleaves native interstitial collagens types I and III[62].

MMP-1 can be effectively induced by the extracellular matrix metalloproteinase inducer (EMMPRIN), which is a member of the immunoglobulin superfamily of adhesion molecules[62]. In keratoconus, EMMPRIN expression was found in all layers of the cornea, especially in histopathologically altered areas, however, the distribution of MMP-1 did not totally overlap with histologically apparent corneal damage and EMMPRIN expression[62]. This may be because EMMPRIN upregulates other MMPs (MMP-2, MMP-3) in stromal fibroblasts. In areas of destruction EMMPRIN-inducible MMPs, other than MMP-1, may be participating in the local pathological process.

MMP-8 seems to be down-regulated in keratoconic epithelium compared to normal controls[56]. MMP-8 plays a paradoxical role in tissues, on the one hand being able to cleave collagens despite the presence of TIMPs and on the other controlling the inflammatory load in tissues by downregulating the polymorphonuclear (PMN) burden[63]. Unlike other MMPs epithelial MMP-8 is not upregulated by TNF-α and IL-1β[57]. Such MMPs may contribute to the pathogenesis of keratoconus by proteolytic modulation of proinflammatory cytokines or chemokines or the generation of apoptotic signals for inflammatory and corneal cells.

5.4 Stroma

Despite much research, contradictory reports preclude any conclusive statement on the contribution of specific MMPs to histopathological hallmarks found in the keratoconic corneal stroma.

In one study MMP-1, -2 and -13 immunolabelling was noted to be greater in keratoconic samples compared to normal controls while no difference in MMP-8 or MMP-14 immunolabelling was observed[56]. In another study, keratoconic immunolabelling for MMP-1, -2 and -3 resembled that of the normal cornea and post LASIK keratectasia[61] while peroxidase immunohistochemistry performed by Collier's group showed that MMP-14 was significantly elevated in the keratoconic stroma[55].

Stromal tissue layer supernatant showed no significant difference in MMP-2, MMP-9, pro MMP-13 and TIMP-1 concentrations between bullous keratopathy and keratoconus[60]. Keratocyte cultures from normal and keratoconic corneas also showed no significant changes in mRNA levels for MMP-1, -2, -3, TIMP-1, or TIMP-2[64]. Only TIMP-1 protein was decreased, prompting a three-fold increase in the MMP-2/TIMP-1 ratio in keratoconus[64].

Yet stromal cell cultures performed by Smith et al. found MMP-2 to be over-expressed in clear keratoconic and scarred keratoconic corneas[65]. The quantities of TIMP-1 and TIMP-2 in normal and clear keratoconic cultures were similar. Scarred keratoconic cultures over-expressed TIMP-1[65]. In these cultures the cells remained healthy and the extent of stress induced MMP-2 activation was low[65]. For this reason, in addition to inhibiting MMP activity, upregulated TIMP-1 production may be a feature of corneal scar tissue cells that are refractory to dying. Alternatively, TIMP-1 may prevent cell death that is conceivably initiated by upregulated TIMP-3 production and sequestration in the extracellular matrix[65].

5.5 Endothelium with Descemet's

There are only a few studies assessing MMP changes specific to Descemet's membrane and endothelium. The endothelial monolayer often gets damaged or lost as the result of tissue handling making studies technically difficult. It was noted that endothelial cells and Descemet's membrane were pathologically altered in keratoconus and EMMPRIN was expressed next to areas of histological damage without, however, any evidence of MMP-1 expression in the area[62]. Mackiewicz et al. did not detect a difference in MMP-1, -13 and -14 between keratoconus and healthy controls but did report more MMP-2 in the endothelium and Descemet's of keratoconus and less MMP-8 in the same layers compared to normal controls[56]. Endothelial tissue supernatant showed no significant difference in MMP-2, MMP-9, pro MMP-13 and TIMP-1 concentrations between bullous keratopathy and keratoconus[60].

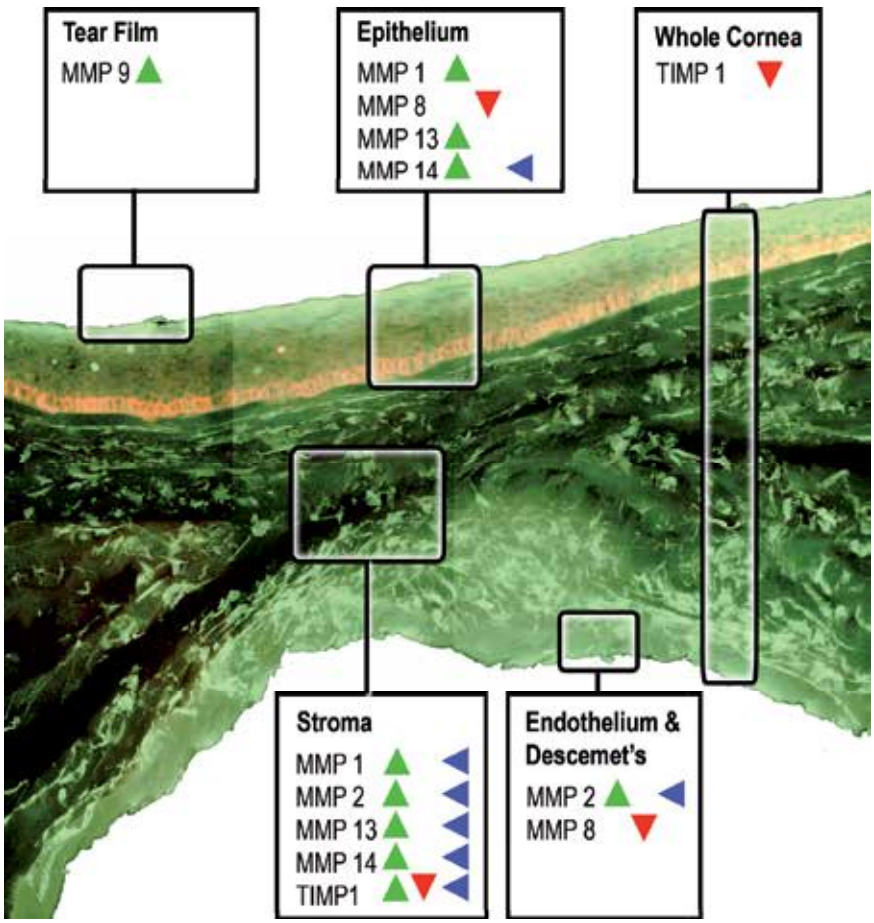

Fig. 2. Matrix metalloproteinase (MMP) and tissue inhibitor of matrix metalloproteinase (TIMP) changes have been described in every layer of the keratoconic cornea. Again, an antero-posterior section of a keratoconic cornea illustrated the MMP and TIMP molecules whose expression have been reported as altered in keratoconus. Green arrows represent increased expression, whilst red represents reported decreased expression and blue no change. It is evident in several cases that reported expression profiles are cotradictory.

6. Conclusion

MMPs are a group of proteolytic enzymes that are able to degrade the main components of the extracellular matrix and corneal membranes. Owing to these activities, MMPs are widely assumed to have a central role in the pathogenesis of keratoconus. However, studies have shown that MMPs can also handle substrates distinct from extracellular matrix proteins, influencing cell processes such as apoptosis. Proteolytic modulation of proinflammatory cytokines or chemokines or the generation of apoptotic signals for resident and inflammatory cells may prove to be as important in mediating keratoconus progression as purported extracellular matrix degradation.

The involvement of proteases in keratoconus has been the subject of much research; however, the exact nature of proteolytic phenomena that contribute to keratoconus progression remains unclear. Studies have described upregulation of MMP-1, MMP-2, MMP-9, MMP-13 and MMP-14 in keratoconus, yet this has not been seen consistently. Other authors report no change in MMP levels or else a downregulation of MMP-8 or TIMP-1. Increased activity of other proteinases such as cathepsins[66] likely contributes to the structural deterioration seen in keratoconus.

For MMP inhibition or TIMP upregulation to be considered a valid therapeutic target for amelioration of the disease process it is important to know exactly which MMPs are culpable. However, due to complex inter-molecular interactions between individual members of the MMP family, the ratios between various MMPs may turn out to be more significant to keratoconus pathogenesis than absolute concentrations of specific MMPs. The ability to measure multiple MMPs in a single corneal specimen is therefore necessary in order to understand the interplay of proteinases within the cornea. Tear fluid analysis affords the opportunity to investigate keratoconus protagonists in the earlier stages of the disease, a significant advantage over end-stage corneal tissue analysis. MMP changes are seen in many other corneal diseases, suggesting that MMP activation may be a nonspecific response to corneal insult. Indeed, the observed changes in inflammatory mediators or MMP levels within the cornea can in fact be epiphenomena of changes in corneal structure[35]. It is also possible that several diseases, with differing pathophysiology produce the phenotypic changes that are called keratoconus, accounting for the difference in proteinase profiles of examined keratoconic samples.

Corneal Surgical Techniques

Miroslav Vukosavljević, Milorad Milivojević and Mirko Resan
Eye Clinic, Military Medical Academy, Belgrade, Serbia

1. Introduction

1.1 History of corneal refractive surgery

There is a long history of corneal refractive surgery. Leonardo Da Vinci in 1508 said the theory of refractive errors. The first systematic analysis of the nature and results of refractive errors came from Francis Cornelius Donders. His classic treatise, "On the anomalies of accommodation and refraction of the eye", outlined the fundamental principles of physiological optics. Ironically, in this treatise, Donders railed against surgical attempts to correct refractive errors by altering the corneal shape. In 1885 Hjalmar Schiotz performed corneal incision to correct astigmatism. Modern refractive surgery extended corneal reshaping to treat myopia and astigmatism. Throughout the 1930s and 1940s, Sato published several reports, describing his attempts to refine incisional refractive surgery with anterior and posterior corneal incisions. The Russian ophthalmologist, Fyodorov later developed a systematic process of anterior radial keratotomy and treated thousands of myopic patients with greater predictability. Lamellar surgery was first introduced by Jose Barraquer. He invented keratoplasty procedures that involved the transplantation of corneal tissue of a size different from the host size to alter the curvature of cornea. He also invented a series of lamellar procedures and developed a formula that represented the relationship between the added corneal thickness and the change in refractive power, later called Barraquer's law of thickness. The transition from incisional to ablative laser refractive surgery arose with the development of Excimer laser technology. Excimer lasers use argon fluoride gases to emit ultraviolet laser pulses. Taboda and Archibald reported the use of the Excimer laser to reshape the corneal epithelium in 1981. In 1983, Trokel and colleagues showed how the Excimer laser could be used to ablate bovine corneal stroma. In 1985, Seiler did the first Excimer laser treatment in a blind eye. He later did the first Excimer laser astigmatic keratotomy. In 1989, McDonald and colleagues did the first photorefractive keratectomy on a seeing eye with myopia. Jose Barraquer's pioneering work, including the use of lamellar procedures to subtract corneal stromal tissue and the development of the first microkerotomes, set the stage for laser in situ keratomileusis (LASIK) surgery. Ruiz and Rowsey modified Barraquer's technique to perform keratomileusis in situ with a geared automated microkeratome. In the early 1990s, Pallikaris and colleagues and Buratto and colleagues independently described a technique that combined two existing technologies: the microkeratome and the Excimer laser. Pallikaris coined the term LASIK for this new technique, which has become a widely used refractive technique worldwide (1).

1.2 Introduction

Astigmatism is a unique refractive error that causes reduced visual acuity and produces symptoms of glare, monocular diplopia, asthenopia, and distortion. The control and correction of astigmatism has been a topic of great interest to cataract, refractive and corneal surgeons.

Corneal refractive surgical techniques that can correct astigmatism are: incisional surgical techniques, such as arcuate keratotomy and limbal relaxing incisions; laser-assisted *in situ* keratomileusis (LASIK); and surface ablation techniques, such as photorefractive keratectomy (PRK), *trans*-epithelial PRK (tPRK), laser-assisted subepithelial keratomileusis (LASEK), epi-LASIK and Intralase.

Arcuate keratotomy is an incisional surgical technique in which arcuate incisions of approximately 95% depth are made in the corneal midperipheral 7,0 mm zone placed in the steep meridian(s). Arcuate keratotomy was used to correct naturally occuring astigmatism, but it is now used primarily to correct postkeratoplasty astigmatism. Limbal relaxing incisions are incisions set at approximately 600 μm depth, or 50 μm less than the thinnest pachymetry at the limbus, and placed just anterior to the limbus. Limbal relaxing incisions are used to manage astigmatism during or after phacoemulsification and intraocular lens (IOL) implantation (2).

LASIK is a lamellar laser refractive surgical technique in which the Excimer laser ablation is done under a partial-thickness lamellar corneal flap. The lamellar flap could be made with a microkeratome or with a femtosecond laser. The microkeratome uses an oscillating blade to cut the flap after immobilization of the cornea with a suction ring. Microkeratomes from several companies cut the lamellar flaps with either superior or nasal hinges, and can cut to depths of 100–200 μm. A femtosecond laser has been developed that can etch lamellar flaps within the cornea stroma at a desired corneal depth. The femtosecond laser provides more accuracy in flap thickness than previous methods; the microkeratome cuts can vary widely in depth. The ablation might either correct sphere and cylinder error, or is wavefront-guided. After the ablation has been completed, the stromal bed is irrigated and the corneal flap is repositioned (3).

Surface ablation is a generic term referring to the application of Excimer laser directly on the anterior stromal surface. The epithelium is removed in order for the Excimer laser to be applied to the stroma. There are several ways in which the epithelium can be separated from Bowmans layer. The epithelium can be fashioned as a flap and replaced (as in LASEK and epi-LASIK) or removed (as in PRK). Surface ablation techniques are continuously evolving in order to achieve better results with faster visual recovery and less pain (4).

LASIK and PRK are the most commonly used refractive surgical methods worldwide.

2. Laser in situ keratomileusis (LASIK)

Laser in situ keratomileusis (LASIK) is the most commonly used refractive surgical method worldwide. This method employs two technologies: Excimer laser and microkeratome. Excimer (acronym for excited dimer) laser is an ultraviolet gas laser (argon-fluoride, ArF) with wavelength of 193 nm, which achieves photoablative effect on tissue of corneal stroma.

First, microkeratome cuts through the cornea and make intrastromal flap on hinge. Flap has a diameter from 8 to 10 mm and its thickness can be 100-180 μm, but usually 100-130 μm (about 15-35% of total corneal thickness). Then the flap is lifted and the corneal stroma exposed to the Excimer laser, and stroma is remodeled according to the type of ametropia and its values. On the end of Excimer laser the flap is repositioned and for a short time have stable position without of need for sutures (5). Postoperative visual rehabilitation is rapid. Sixteen hours after LASIK the majority of patients are reaching 97% of the preoperative best corrected visual acuity (6).

Fig. 1. Placing of suction ring and microkeratome on the eye (5).

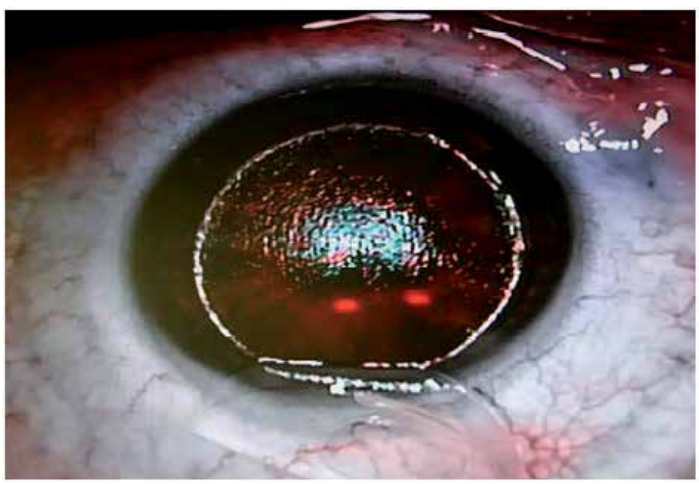

Fig. 2. Flap is created and corneal stroma prepared for Excimer laser ablation (5).

The American Academy of Ophthalmology (AAO) recommended the indications for LASIK: myopia up to - 10 Dsph, hyperopia up to + 4 Dsph, and astigmatism up to 4 Dcyl (7).

The contraindications for Excimer laser refractive surgery including LASIK and PRK are general and ophthalmic. General are: immunological diseases (autoimmune, collagen

vascular, immune deficiency); pregnancy or breast feeding; the tendency to form keloids; diabetes; and systemic administration of isotretionin or amiodarone. Ophthalmic are: dry eye; neurotrophic keratitis; herpes zoster ophthalmicus / keratitis herpetica; glaucoma; ectatic corneal dystrophy (keratoconus, keratoglobus); highly irregular astigmatism; uveitis, diabetic retinopathy; progressive retinal disease and previously performed radial keratotomy (8).

The complications of LASIK include: intraoperative and postoperative complications. The intraoperative complications or flap related complications (9) are: wrong ablation, flap loss, buttonhole flap (hole in the flap), thin flap, brief flap, free cap (flap amputation), corneal bleeding, epithelial defects and corneal perforation (very rare). The postoperative complications (10) are: infections, dislocation of the flap, flap folding (striae), diffuse lamellar keratitis (sands of the Sahara), epithelial ingrowth, corneal ectasia, regression, intraflap fluid accumulation and paradoxical hypotony.

Each candidate for LASIK should be at least 21 years of age and must have a stable refractive error in the period of two years. Preoperative evaluation of each candidate includes: general and ophthalmic history; autorefractokeratometry; uncorrected visual acuity (UCVA) and best corrected visual acuity (BCVA); Schirmer test; review of the eye anterior segment on slit-lamp; applanation tonometry; review of the eye fundus in a wide pupil; imaging of corneal topography and aberrometry. The following formula to evaluate whether a candidate can safely perform LASIK is:

Central pachymetry – flap thickness - ablation depth = residual stromal thickness of the cornea

As a limit value for residual stromal thickness of the cornea (residual stromal bed) after cutting and effects of Excimer laser 300 μm are taken; as a critical value for steep corneal meridian (steep K) <39 or > 47 D are taken; as a limit value for elevation of the posterior corneal surface 50 μm are taken (5).

Numerous studies confirm the effectiveness of LASIK for the correction of astigmatism. Stojanovic and Nitter evaluated safety, efficacy, predictability, and stability in the treatment of myopic astigmatism with LASIK and PRK using the 200 Hz flying-spot technology of the Excimer laser. This retrospective study included 110 eyes treated with LASIK and 87 eyes treated with PRK that were available for evaluation at 6 and 12 months. The mean preoperative spherical equivalent (SE) was −5.35 diopters (D) ± 2.50 (SD) (range −1.13 to −11.88 D) in the LASIK eyes and −4.72 ± 2.82 D (range −1.00 to −15.50 D) in the PRK eyes. The treated astigmatism was 4.00 D in both groups. None of the eyes lost 2 or more lines of best spectacle-corrected visual acuity. Seventy-seven percent of the LASIK eyes and 78% of the PRK eyes achieved an uncorrected visual acuity of 20/20 or better; 98% in both groups achieved 20/40 or better. In conclusion, Excimer laser was safe, effective, and predictable and with LASIK and PRK the results are stable when treating low to moderate myopia and astigmatism up to 4.0 D (11). Ditzen et al evaluated safety, predictability, efficacy, and stability of LASIK for spherical hyperopia and hyperopia with astigmatism. This retrospective study analyzed the results of 23 eyes of 23 patients who had LASIK for spherical hyperopia (preoperative astigmatism $\leq$0.75 D) and 44 eyes of 44 patients who had LASIK for hyperopia with astigmatism. In group 1 (spherical hyperopia), mean preoperative spherical equivalent refraction was +4.88 ± 2.13 D (range +2.13 to +9.63 D); in group 2

(hyperopic astigmatism), +4.33 ± 2.15 D (range +0.50 to +9.50 D). One year after LASIK, mean spherical equivalent refraction was +0.30 ± 0.90 D (range -0.75 to +2.50 D) in group 1 and +0.29 ± 1.27 D (range -3.25 to +3.25 D) in group 2. In group 1, no eyes lost two or more lines, and one eye (6%) lost one line of best spectacle-corrected visual acuity at 1 year. In group 2, one eye (4%) lost one line and one eye (4%) lost more than two lines at 1 year. Uncorrected visual acuity of 20/40 or better was achieved in 83% (group 1) vs. 62% (group 2) at 1 year. In conclusion, LASIK seemed to be safe and effective for hyperopia and hyperopia with astigmatism for corrections up to +6.00 D (12). Albarran-Diego et al evaluated bitoric LASIK for the correction of mixed astigmatism. This prospective study included 28 eyes of 21 patients with mixed astigmatism who had bitoric LASIK. Six months after bitoric LASIK, the mean UCVA was 0.70 ± 0.23 (SD). The percentage of eyes with a UCVA of 20/40 or better was 78.6% and of 20/20, 21.4%. There was a statistically significant increase in the mean BCVA from 0.71 ± 0.19 before surgery to 0.83 ± 0.15 at 6 months. Three eyes (10.7%) lost 1 line of BCVA. The mean preoperative astigmatism of −4.04 ± 1.13 diopters (D) was reduced to −0.67 ± 0.79 D after surgery (13).

3. Photorefractive keratectomy (PRK)

Photorefractive keratectomy (PRK) is still a successful method in certain indications and now is used worldwide as PRK or as its modification - LASEK and EpiLASIK. All methods for its performance require use of Excimer laser (14).

PRK is superficial ablative method because the Excimer laser thinner and reshapes the anterior part of the corneal stroma just below Bowman's membrane. This provides greater residual stromal thickness, and thus strengthens the biomechanical strength of the cornea. But, ablation of front stroma, especially through a layer of Bowman's membrane, causing aggressive response in wound healing, which may result in frequent appearance of subepithelial clouding (haze) and scarring compared with LASIK. Recovery after PRK is slower and more painful compared with LASIK. One to four days after the intervention most of the patients have a transient low-intensity pain. Postoperative visual rehabilitation is a little longer and lasts several weeks (1,15).

Certain situations may favor PRK over LASIK in particular safety issues due to the absence of flap related complications in PRK. These situations include: predisposition for contact injury (e.g. those involved in martial arts or boxing); anterior basement membrane (BM) dystrophy; epithelial sloughing during LASIK in the fellow eye; thin corneas in which the residual stromal bed would be less than 250–300 mm; deep set eyes or a small palpebral aperture (poor exposure for the microkeratome); previous surgery involving the conjunctiva (e.g. glaucoma drainage bleb, scleral buckle); and moderate dry eye before surgery. In addition, flat (< 41 D) or steep corneas (> 48 D), with the risk of free, thin, incomplete or buttonholed flaps, may be better suited to PRK. It is desirable to avoid suction and iatrogenically raising the IOP during LASIK, as in patients with glaucoma or a risk of poor optic nerve perfusion, PRK procedure would be preferred (15).

In PRK the first step is corneal epithelium removing (mechanically with knife-hockey or rotating brush; or by chemical abrasion with 20% ethanol), then the corneal stroma is exposed to the effects of Excimer laser which thins and reshapes it according to the type of ametropia and its values and after that therapeutic soft contact lens is applied for 5 days.

The American Academy of Ophthalmology (AAO) recommended the next indications for PRK: myopia up to – 8 Dsph, hyperopia up to + 4 Dsph, and astigmatism up to 4 Dcyl (7). Large corrections (ablation depth greater than 100 μm) are considered for adjunctive 0,02% mitomycin C (MMC) because of the increased risk of postoperative haze and regression (16).

Complications of PRK include: subepithelial haze, corneal scarring, ectasia and regression.

Each candidate for PRK should be at least 21 years of age and must have a stable refractive error in the period of two years. Preoperative evaluation of each candidate includes: general and ophthalmic history; autorefractokeratometry; uncorrected visual acuity (UCVA) and best corrected visual acuity (BCVA) in each eye; Schirmer test; examination of the eye anterior segment on slit-lamp; applanation tonometry; examination of the eye fundus in a wide pupil; imaging of corneal topography and aberrometry. As a limit value for residual stromal thickness of the cornea (residual stromal bed) is 300 μm. The critical value for steep corneal meridian (steep K) is <39 or > 47 D and the limit value for elevation of the posterior corneal surface is 50 μm (5).

Numerous studies have investigated the effectiveness of PRK in the correction of astigmatism. Haw and Manche evaluated the safety and efficacy of PRK for the treatment of primary compound myopic astigmatism. Ninety three eyes from 56 patients with a mean spherical equivalent of −4.98 ± 1.80 diopters (range, −1.75 to −8.5) underwent photoastigmatic refractive keratectomy and were followed for 2 years. Fifty-six eyes (94.9%) had an uncorrected visual acuity of 20/40 or greater, whereas 34 eyes (57.6 %) demonstrated an uncorrected visual acuity of 20/20 or greater. One eye (1.7%) lost 2 or more lines of best spectacle-corrected visual acuity (17). Nagy et al evaluated the results of PRK using Gaussian flying spot technology in the treatment of hyperopia and hyperopic astigmatism. Two hundred eyes were evaluated with 12-month follow-up. Eyes were divided into four groups: group 1 (spherical hyperopia up to +3.50 D and astigmatism less than 1.00 D, n=62); group 2 (hyperopia up to +3.50 D and astigmatism of 1.00 D or more, n=44); group 3 (hyperopia greater than +3.50 D and astigmatism less than 1.00 D, n=56); and group 4 (hyperopia greater than +3.50 D and astigmatism of 1.00 D or more, n=38). In group 1, 82.2% (51/62 eyes) were within ±0.50 D of target refraction; 88.7% (55/62 eyes) had 20/20 or better uncorrected visual acuity; 1.6% (1/62 eye) lost two or more lines. In group 2, 68.1% (30/44 eyes) were within ±0.50 D; 77.2% (34/44 eyes) had 20/20 or better uncorrected visual acuity; 9.1% (4/44 eyes) lost two or more lines of spectacle-corrected visual acuity. In group 3, 76.8% (43/56 eyes) were within ±0.50 D; 78.6% (44/56 eyes) had 20/20 or better uncorrected visual acuity; 5.4% (3/56 eyes) lost two or more lines of spectacle-corrected visual acuity. In group 4, 42% (16/38 eyes) were within ±0.50 D; 60.5% (23/38 eyes) had 20/20 or better uncorrected visual acuity; 15.8% (6/38 eyes) lost two or more Snellen lines. In conclusion PRK was most safe and effective for low hyperopia (18).

4. Trans-epithelial photorefractive keratectomy (tPRK)

In this method, the Excimer laser is used to ablate the epithelium in addition to then ablating the underlying stroma. The cornea undergoes an epithelial ablation within a fixed diameter. The operating room lights are turned off as blue fluorescent light is emitted whereas epithelium is ablated. Once the blue fluorescence disappears, this indicates that the epithelium has been removed. Accuracy with this method is dependent upon regular

epithelial thickness across the diameter treatment zone and also similar epithelial thicknesses between different eyes. This technique can produce variable results when laser surface enhancement is proposed after previous refractive surgery due to areas of epithelial hyperplasia causing variable epithelial thickness (15).

5. Laser-assisted subepithelial keratomileusis (LASEK)

LASEK is a surgical procedure that combines certain elements of both LASIK and PRK to improve the risk/benefit ratio. Diluted alcohol is used to loosen the epithelial adhesion to the corneal stroma. The loosened epithelium is moved aside from the treatment zone as a hinged sheet. Laser ablation of the subepithelial stroma is performed before the epithelial sheet is returned to its original position. The main rationale for combining elements of LASIK and PRK to LASEK is to avoid the flap-related LASIK complications and the slow visual recovery and haze risk of PRK. LASEK may avoid several of the inherent complications, including free caps, incomplete pass of the microkeratome, flap wrinkles, epithelial ingrowth, flap melt, interface debris, corneal ectasia, and diffuse lamellar keratitis, after LASIK and postoperative pain, subepithelial haze, and slow visual rehabilitation after PRK. Current ophthalmic literature does not provide the specific indications, visual outcomes, complications, and limitations of LASEK (19). Bilgihan et al. evaluated the efficacy, predictability, and safety of LASEK for treatment of high myopia with astigmatism. LASEK was performed in 61 eyes of 36 consecutive patients with myopic spherical equivalent refraction of -6.00 to -10.00 D using the Aesculap-Meditec MEL60 Excimer laser. Ninety-six percent of eyes achieved 20/40 or better uncorrected visual acuity (UCVA) at 1 month. At 12 months, 64% of eyes achieved 20/20 and 92% achieved 20/40 or better UCVA. Two eyes lost 2 lines of best spectacle-corrected visual acuity (BSCVA) at 6 or 12 months. Accuracy of correction was ±0.50 D from emmetropia in 82% of eyes, and ±1.00 D in 90% at 12 months (20). Taneri et al evaluated the visual outcomes and complications in low to moderate levels of myopia and astigmatism treated with LASEK. One hundred seventy-one eyes of 105 patients were studied. Preoperatively, the mean spherical equivalent was -2.99 diopters (D) ± 1.43 (SD) and the mean cylinder -0.78 ± 0.73 D. One week postoperatively, 96% of eyes had a UCVA of 20/40 or better but definitive visual recovery took more than 4 weeks in some eyes. Approximately 95% of eyes were within ±1.0 D of emmetropia after 4 to 52 weeks; the remaining 5% did not show major deviations. At 4 to 52 weeks, only 1 eye was overcorrected by more than 1.0 D of manifest refraction (21).

6. Epithelial laser in situ keratomileusis (Epi-LASIK)

Epi-LASIK has proved to be a suitable procedure, especially in patients with active lifestyles or occupations, eyes with thin corneas without ectatic disorders, and patients with moderate dry-eye syndrome. In epi-LASIK, an epithelial flap is created with the help of a special microkeratome. The epithelial flap is repositioned on the cornea after photoablation. It has been postulated that compared with conventional laser-assisted subepithelial keratectomy (LASEK), in which an epithelial flap is created after the epithelium is exposed to an alcohol solution, cell viability of the epithelial sheet is better in epi-LASIK surgery, in which mechanical separation is performed with a microkeratome. The quality of the epithelial separation is crucial for the success of the procedure because stromal lacerations or remaining islands of basal epithelial cells would reduce the optical quality of the cornea after photoablation (22).

Factor	PRK	LASEK	EPI-LASIK	LASIK
Range of correction	Low to moderately high			Low to moderately high
Postoperative pain	Mild to moderate 24–72 hours			Minimum 12 hours
Postoperative medications	1–3 months			1 week
Functional vision recovery	3 to 7 days			<24 hours
Refractive stability achieved	3 weeks to 3 months			1 week to 3 months
Specific complications	Haze formation, scarring	Haze formation, scarring	Haze formation, scarring, incomplete epithelial flap, stromal incursions	Free caps, incomplete pass of microkeratome, flap wrinkles, epithelial ingrowth, flap melt, interface debris, corneal ectasia, diffuse lamellar keratitis
Dry-eye sensitive	1 to 6 months			1 to 12 months
Thin corneas or wide pupils	Often not contraindicated			May be contraindicated depending on amount of intended correction
Special (relative) indications	Thin corneal pachymetry, wide scotopic pupil, LASIK complications in fellow eye, predisposition to trauma, keratoconus suspect (irregular astigmatism), glaucoma suspect, recurrent erosion syndrome, dry-eye syndrome, basement membrane disease			Concern about postoperative pain, requirement of rapid visual recovery
Special (relative) contraindications	Concern about postoperative pain, requirement of rapid visual recovery	Concern about postoperative pain, requirement of rapid visual recovery	Concern about postoperative pain, requirement of rapid visual recovery, glaucoma, scleral buckle, deep-set eyes, small palpebral fissure	Thin corneas, wide pupils, recurrent erosion syndrome, glaucoma, scleral buckle, deep-set eyes, small palpebral fissure

Fig. 3. Widely accepted relative differences between PRK, LASEK, epi-LASIK, and LASIK (23).

7. Femtosecond laser in laser in situ keratomileusis

In the early 1960s, Barraquer introduced the concept of lamellar refractive procedures. In the 1990s, Pallikaris et al. and Buratto et al. conceived of techniques combining lamellar procedures with Excimer laser ablation. These advances led to the development of modern laser in situ keratomileusis (LASIK) procedures. LASIK has several advantages over PRK when performed properly in appropriate eyes. These include faster visual recovery, less discomfort after surgery, and milder and more predictable wound healing with less risk for corneal stromal opacity (haze). Lamellar corneal flap formation is the critical step in successful LASIK surgery. Improper flap formation, including improper flap geometry, decentration, irregularity of the cut, and epithelial damage, can lead to myriad LASIK complications. Considerable progress has been made over the years in producing safer instruments for LASIK flap formation since the Automated Corneal Shaper was adapted to LASIK. Thus, more reliable and safer mechanical microkeratomes contributed to the explosive growth of refractive surgery over the past 15 years. Despite these advances, complications such as incomplete or partial flaps, free flaps, buttonholes, and small irregular flaps continue to plague refractive surgeons who perform LASIK with a microkeratome. There are also significant limitations to the eyes that can safely have lamellar flap formation

performed with a mechanical microkeratome, including corneas that are too steep (likely to have buttonhole flaps), too flat (likely to have small diameter flaps), or relatively thin (more likely to have low residual stromal bed) (Fig. 4).

Decentered flaps
Irregular-shaped flaps
Incomplete flaps
Button-hole flaps
Flap laceration
Epithelial defects
Limited hinge location, 1 or 2 sites per head (nasal or superior)
Poor flap thickness predictability, SD of flap thickness ±20 to 40 μm
Wide range of flap thickness for a given attempted thickness (up to 200 μm range)
Achieved mean thickness less than the labeled head
Sensitive to preoperative corneal curvature: steeper corneas create thinner flaps
Sensitive to preoperative corneal thickness: thicker corneas create thicker flaps[20,21]
Menicus-shaped flaps: thinner centrally than peripherally
Highly variable hinge length
Flap thickness dependent on translation speed: faster translation creates thinner flaps
Blade quality affects results: second eye use of same blade associated with thinner flaps
Gap width of microkeratome head variable affecting flap thickness predictability
Anterior chamber perforation (older models)

Fig. 4. Corneal complications reported with conventional microkeratomes (24).

The femtosecond laser became available for LASIK flap formation approximately 10 years ago. Since the early femtosecond laser models were introduced, considerable progress has been made in improving flap geometry and limiting complications of LASIK performed with the laser. This has led to increasing popularity of LASIK performed with the femtosecond laser, to the point that different sources estimate that 30% to 50% of LASIK procedures in the United States in 2008 were performed using a femtosecond laser. Recently, new femtosecond laser models were introduced. These include the Femtec (20/10 Perfect Vision AG), the Femto LDV (Zeimer Group), the Visu-Max (Carl Zeiss Meditec) and commonly used IntraLase 60 kHz femtosecond laser (Abbott Medical Optics, Inc.). All 4 commercially available femtosecond laser systems use ultrashort pulses of laser and produce corneal tissue cutting using a photodisruption process. To create the lamellar flap, the IntraLase laser generates pulses of femtosecond laser at a near-infrared (1053 nm) wavelength and delivers closely spaced 3 mm spots, which are focused at variable depths to photodisrupt stromal tissue. When a high peak power is reached, hot plasma is generated, initiating a process of tissue ionization that is commonly called laser-induced optical breakdown. The hot plasma expands in shock waves and creates an intrastromal cavitation bubble composed primarily of water and carbon dioxide. Multiple cavitation bubbles coalesce, and an intrastromal cleavage plane is created. The laser delivers a series of pulses

in a specified pattern to create the lamellar intrastromal cut and then extends the cleavage to the surface with a side cut to complete the flap (25). Stonecipher et al. reported the refractive results after LASIK for high myopia and cylinder at one center with one surgeon comparing two laser platforms. A total of 206 eyes of 121 patients were treated for –6.00 to –12.00 diopters (D) of spherical equivalent refractive error with up to 3.00 D of cylinder. All eyes underwent LASIK with the ALLEGRETTO WAVE 200-Hz (n=141) or 400-Hz (n=65) laser (Alcon Laboratories Inc). Corneal flaps were created with the IntraLase femtosecond laser (Abbott Medical Optics) at an intended thickness of 100 or 110 μm in all cases. At 3- and 6-month follow-up in the 200-Hz group, 77% (109/141) and 86% (121/141) of eyes, respectively, were within ±0.50 D of intended correction. In the 400-Hz group, 98.5% (64/65) and 100% (65/65) of eyes were within ±50 D of intended correction at 3 and 6 months postoperatively. At 3- and 6-month follow-up, 84% (119/141) and 77% (109/141) of eyes, respectively, in the 200-Hz group and 80% (52/65) and 92% (60/65) of eyes, respectively, in the 400-Hz group had 20/20 or better uncorrected distance visual acuity. At 6-month follow-up, refractive predictability and visual acuity were statistically superior in eyes in the 400-Hz group (chi square, $P<.01$). No eyes underwent retreatment as a secondary procedure during the time of analysis (26).

8. Refractive laser surgery in children

The use of Excimer laser vision correction in children is controversial because their eyes and refractive state continue to change. More studies on the growing eye and the effect of Excimer laser on the pediatric corneal endothelium are needed before the effect of refractive surgery in the pediatric age group can be fully understood (27).

Traditional methods of correcting and rehabilitating the refractive status of children with high myopia, myopic anisometropic amblyopia, hyperopia, hyperopic anisometropic amblyopia or significant astigmatism include glasses and contact lenses combined with some form of occlusion or optical penalization therapy. However, some children may not improve with these traditional forms of treatment because of aniseikonia, compliance issues, or both. This is especially true when children have concurrent medical diagnoses such as autism, cerebral palsy, developmental delay, Down syndrome, or other associated ocular disorders (eg, corneal, retinal, and optic nerve problems). So, in such children traditional optical refractive correction is often not successful (28, 29).

In the past ten years, refractive laser surgery techniques have been shown to be a good last-resort treatment in children who have failed with traditional treatment approaches. There are numerous reports of the successful performance of PRK, LASIK and LASEK in children when conventional therapy failed.

Autrata and Rehurek evaluated the visual and refractive results of multizonal PRK for high myopic anisometropia and contact-lens intolerance in children. Twenty-one patients aged 7 to 15 years with high myopic anisometropia had multizonal PRK in the more myopic eye and were retrospectively analyzed. The scanning-slit Nidek EC-5000 Excimer laser was used. The safety, efficacy, predictability, and stability of the procedure were evaluated. Long-term binocular vision outcome was analyzed. All patients completed a 4-year follow-up. The mean preoperative spherical equivalent (SE) refraction was - 8.93 diopters (D) ± 1.39 (SD) (range - 6.75 to - 11.75 D) and the mean postoperative SE was – 1.66 ± 0.68 D (range -

0.50 to - 2.75 D). The mean preoperative uncorrected visual acuity (UCVA) of 0.034 ± 0.016 increased to 0.35 ± 0.15 postoperatively. The mean preoperative best spectacle-corrected visual acuity (BSCVA) was 0.53 ± 0.19 and changed to 0.64 ± 0.16 postoperatively. No eye lost a line of BSCVA; 9 eyes gained 1 line, and 5 eyes gained 2 lines. No eye had + 3 haze. There were no significant complications. In conclusion, PRK was safe and effective in correcting high myopic anisometropia in children who were contact-lens intolerant (30).

Yin et al. assessed the efficacy of LASIK in facilitating amblyopia management of children from 6 to 14 years old, with high hyperopic and myopic anisometropia. Between 2000 and 2005, 42 children with high hyperopic anisometropic amblyopia and 32 children with high myopic anisometropic amblyopia underwent LASIK to reduce their anisometropia. LASIK was performed under topical or general anesthesia. Follow-up ranged from 6 months to 3 years, the averages of which were 17,45 months in the hyperopic group and 18,31 months in myopic group. Hyperopic anisometropia correction ranged from + 3.50 D to + 7.75 D, and the mean postoperative anisometropia was +0.56 ± 0.75 D at 3 years. Myopic anisometropia correction ranged from -15.75 to - 5.00 D and the mean postoperative anisometropia at 3 years was - 2.20 ± 1.05 D. The best-corrected visual acuity for distance and reading in the myopic group improved from 0.4 ± 0.25 and 0.58 ± 0.27, respectively, before surgery to 0.59 ± 0.28 and 0.96 ± 0.35, respectively, 3 years after surgery. In the hyperopic group, best-corrected visual acuity for distance and reading improved from 0.23 ± 0.21 and 0.34 ± 0.32, respectively, before surgery to 0.53 ± 0.31 and 0.80 ± 0.33, respectively, 3 years after surgery. Study shows that LASIK is an alternative method for correcting high hyperopic and myopic anisometropia. The proportion of patients who had stereopsis increased from 19.1% preoperatively to 46.7% postoperatively in the hyperopic group and from 19% to 89% in the myopic group. In conclusion, LASIK reduced high hyperopic and myopic anisometropia in children, thus facilitating amblyopia management and improving their visual acuity and stereopsis (31).

Astle et al. assessed the refractive, visual acuity, and binocular results of LASEK for anisomyopia, anisohyperopia, and anisoastigmatia in children with various levels of amblyopia secondary to the anisometropic causes. Retrospective review was of 53 children with anisometropia who had LASEK to correct the refractive difference between eyes. All LASEK procedures were performed using general anesthesia. Patients were divided into 3 groups according to their anisometropia as follows: myopic difference greater than 3.00 diopters (D), astigmatic difference greater than 1.50 D, and hyperopic difference greater than 3.50 D. The children were followed for at least 1 year. The mean age at treatment was 8.4 years (range 10 months to 16 years). The mean preoperative anisometropic difference was 6.98 D in the entire group, 9.48 D in the anisomyopic group, 3.13 D in the anisoastigmatic group, and 5.50 D in the anisohyperopic group. One year after LASEK, the mean anisometropic difference decreased to 1.81 D, 2.43 D, 0.74 D, and 2.33 D, respectively, and 54% of all eyes were within ± 1.00 D of the fellow eye, 68% were within ± 2.00 D, and 80% were within ± 3.00 D. Preoperative visual acuity and binocular vision could be measured in 33 children. Postoperatively, 63.6% of children had an improvement in best corrected visual acuity (BCVA) and the remainder had no noted change. No patient had a reduction in BCVA or a loss in fusional ability after LASEK. Of the 33 children, 39.4% had positive stereopsis preoperatively and 87.9% had positive stereopsis 1 year after LASEK. In conclusion, LASEK is an effective surgical alternative to improve visual acuity in

anisometropic children unable to tolerate conventional methods of treatment or in whom these methods fail (32).

1. Introduction

Visual impairment remains a major public health problem world wide, with an estimated 161 million people with visual impairment, of whom 37 million are blind.[1] Uncorrected or inadequately corrected refractive errors have been shown to be a major cause of visual impairment in population-based studies[2-6]. While amblyopia is a significant cause of unilateral reduced visual acuity in a population aged 40 years and older.[7]

Genetic factors are thought to play a role in development of refractive errors. It has been established that myopia clusters within families, and familial high myopia (refraction of -6 diopter {D} or less) has been linked to long arm regions on chromosomes 7, 12 and 18[8,9]. Environmental risk factors have also been associated with refractive errors, myopia or hypermetropia. Education[10,11] and near-work[12] are both strongly associated with increasing severity of myopia.

In different parts of Asia such as in India, the Andhra Pradesh Eye Disease Study shows 15.2%[13] prevalence rate of myopia (spherical equivalent {SE} at least -1.0D). While study in a 15,068 Singapore military recruits aged 16 to 25 years, the prevalence rates of myopia (SE at least -0.5 D) were much higher with some racial variation, 82.2% in Chinese, 68.8% in Indians, and 65.0% in Malays[14]. Similar high rates of myopia (SE at least -0.25 D; 84%) were present in 16 to 18 years old Chinese children in Taiwan[15]. In Pakistan the prevalence rates of myopia, hypermetropia, astigmatism (with SE worse than –0.5 D, greater than +0.5D, and greater than 0.75D respectively) was 36.5%, 27.1%, and 37%, respectively in adults aged 30 years or more in the National Blindness and Visual Impairment Survey.[16]

In United states, the Baltimore eye survey[17] and Beaver Dam study[18] showed the prevalence rates of myopia (SE at least -0.5 D) were 28.1% in white adults aged 40 years or more and 26.2% in adults aged 43 to 84 years respectively.

Amblyopia is a frequent cause of unilateral or bilateral blindness. The prevalence of amblyopia ranges from 0.73% to 3.06%[7] in previous studies. However, the epidemiology of amblyopia among this region of Asia is not well described and may be different from other because of difference in distribution of refractive error or strabismus.

AIM: To assess the incidence of refractive error and associated amblyopia among young adult.

2. Methodology

2.1 Subjects

This six months study was conducted from June 2008 to November 2008 at tertiary referral center Liaquat University Eye Hospital, Hyderabad Sindh, Pakistan. Three thousand four hundred fifty two patients were included and examined in out patients department with age ranged from 20-40 years. The proportion of men and women was 1:0.54. Both rural and urban residents were evaluated. After taking written consent all subjects underwent a comprehensive ophthalmic examination, and a standardized form was used to extract the data, including the following variables: demographic information, best corrected visual acuity, types of refractive error including myopia, hypermetropia, astigmatism and amblyopia.

2.2 Methods

Monocular visual acuity was determined with current spectacle prescription if any. Pinhole acuity was assessed in eyes with presenting visual acuity <20/20. Non-cycloplegic auto-refraction followed by subjective refinements was performed in all subjects. The best corrected visual acuity was recorded. Refraction data was based on subjective refraction. Only the right phakic eye of each subject was considered for refractive error evaluation and amblyopia evaluated bilaterally.

Amblyopia was defined as best-corrected visual acuity of 20/40 or worse in the absence of any pathological cause. Hypermetropia was defined as a SE greater than +0.5 diopter sphere (DS)[17-21]. Emetropia was defined as a SE between -0.50 and +0.50 DS[20]. Myopia was defined as a SE worse than -0.50 DS[17--21] and a SE or worse than -5.00 DS[19] was classified as high myopia. Astigmatism correction was prescribed in minus cylinder format, and astigmatism was defined as cylindrical error worse than -0.50 diopter cylinder (DC) in any axis. The axis of any cylinder component was classified as with the rule (WTR) if the minus cylinder axis was within 15^{o} of 180^{o}, against the rule (ATR) for minus cylinder axis within 15^{o} of 90^{o}, or oblique (other than WTR or ATR)[22].

3. Results

Of the 3452 patients, 847 (24.54 %) patients had best corrected visual acuity 20/40 or better and remaining 2605 (75.46%) had less than 20/40 due to different anterior and posterior segment eye pathologies, or amblyopia.

Out of the 847 patients 525 (15.20 %) were phakic in right eye, and remaining 322 (9.32%) were pseudophakic. For refractive error the result was analyzed for only 15.20%

phakic ametropic patients. While for amblyopia all patients who met the criteria were evaluated.

There were 341 (64.95% of phakic ametropic patients) male and 184 (35.05%) were female. The age range from 20 to 40 years **(Table 1),** mean age being 26±3.9 years. The mean age of men and women was 28±3.9 and 24±6.3 years respectively (statistically significant at P<0.001). The mean refractive error was 0.75D.

Hypermetropia was found in 185 (35.24% of phakic ametropic) patients (Table 1). The mean age of hypermetropia was 26.31±4.51 years. Which was not significantly different from that of entire population (P=0.5476). There were 121 men (23.04% of total ametropic) and 64 women (12.19%). Man had significantly higher prevalence of hypermetropia than women (P<0.001).

Three hundred and fifteen (60% of phakic ametropic) patients had myopia (Table 1). The mean age of myopes was 23.69±3.98 years. Which was significantly lower than the entire population (P<0.001). There were 205 (39.05%) men and 110 (20.95%) women. The man had a significantly higher prevalence of myopia than did the women (P<0.001)

Twenty five (4.76%) patients of the study population were high myopes (Table 1). Among which 15 patients were males and 10 were females. The mean age among high myopes was 22. 50±3.25 years. Which was also significantly lower than the entire population (P<0.0002). However there was no significant different between the mean age of myopes and high myopes (P=0.1632).

Two hundred and fifteen (25.38 % of phakic ametropic) patients had astigmatism worse than –0.5 DC. The males were 134 (62.32%) of total astigmatic patients and remaining were females. The man had a significantly higher prevalence of astigmatism than women (P<0.001). One hundred and forty two (66.04%) patients had ATR astigmatism, 52 (24.18%) had WTR astigmatism and 21 (9.76%) had oblique astigmatism. The prevalence of against the rule astigmatism increased significantly with age (P=0.007).

The incidence of associated unilateral amblyopia was in 19 (3.62%) of phakic ametropic patients (Table 2). Ten (52.63%) patients were male and 09 (47.37%) were females. Amblyopia was not found to be significantly different by age (p=0.1312) group and gender (p=0.1211). Anisometropia was more common in amblyopic cases (41.75%) compared to the normal population (5.91%), and 69% of amblyopic eyes had visual acuity worse than 20/60. However, two amblyopic patients had strabismus in addition to anisometropia, but the prime reason of both conditions was anisometropia. While none of the case of bilateral amblyopia were seen in this study.

Age (yrs)	Hypermetropia		Myopia		High myopia		Total (%)
	M	F	M	F	M	F	
21-25	38	21	48	25	7	4	143 (27.23)
26-30	29	17	65	27	5	4	147 (28.00)
31-35	27	10	49	32	0	1	119 (22.68)
36-40	27	16	43	26	3	1	116 (22.09)
Total	121	64	205	110	15	10	525 (100)

Table 1. Age and type of refractive error

Age (yrs)	Frequency of amblyopia		Total (%)
	Male	Female	
21 -25	2	2	4 (21.04)
26 -30	3	2	5 (26.32)
31 -35	2	3	5 (26.32)
36 -40	3	2	5 (26.32)
Total	10	9	19 (100)

Table 2. Demography of amblyopia

4. Discussion

The incidence of hypermetropia in this study was 35.24% of total 525 phakic ametropic patients. In contrast to Andhra Paeye disease study (APEDS)[13], Barbados eye study[20], and several other studies[17,18] hypermetropia decrease with increasing age in our study

The incidence of myopia and high myopia in this study was 60% and 4.76% of the phakic ametropic patients and decreased with age. The Attebok et al[18], Wang et al[11], Katz et al[17] reported a significant trends of decreasing myopia with age. However the Chennai glaucoma study[3], Barbodos[20] study reported increase of myopia with age and also have an association of nuclear sclerosis with myopia. Saw[22], Guggenheim et al[23] and Dan et al[24] reported environmental influence such as near work, night lighting and ultraviolet exposure may be responsible for ageing of the crystalline lens and associated myopia. In contrast to population based studies from Australia[18], Singapore[19], and Indonesia[25], the incidence of myopia was more in males than females in our study.

The incidence of astigmatism in this study was 25.38% and increased significantly with age. The same has been reported from Chenni[3], Australia[18], Singapore[19], and Indonesia[25]. ATR astigmatism in this study was predominant that made the 66.04% of the total ametropic patients. In relation to the Chennai[3] study the incidence of ATR astigmatism significantly increased with age and WTR astigmatism decreased with age in our study. Gudmundsdottir et al[26], Pensyl et al[22] and Goss et al[28] reported same and the reason for this could be increased lid laxity with age causing flattening of vertical corneal meridian thereby decreasing WTR astigmatism and increased ATR astigmatism.

In this study the incidence, of associated amblyopia was 3.62% of phakic ametropic patients, which was less than Goel B.S[29] study in which amblyopia was reported 5.97%. One thing common in both were higher rate of amblyopia in ametropic then general population. In contrast to Karki JKD[30] study amblyopia was not found significantly different by age and gender in this study.

In conclusion, 15.20% of people had refractive error and 3.62% has the amblyopia. The prevalence of myopia was 60% and decreased with age. Hypermetropia was more common among men. The prevalence of astigmatism was 25.38%. It was interesting to note that against the rule astigmatism in contrast to other studies was observed more often (66.04%) in this study. Though the above study represent the regional population of limited age (20-40 years), but the differences in the pattern of refractive error in this study leads us to believe that genetic, racial, environmental and occupational influences may play an important role.

1. Introduction

Myopia has been investigated scientifically for over a century but the search for an effective remedy has been manifestly unsuccessful. The prevalence of myopia in developed societies has now risen to about 30% in USA (Vitale, Sperduto et al. 2009) and up to 70% in some Asian centres (Lin, Shih et al. 2004). In addition to the socio-economic burden of providing optical corrections for myopia, common myopia limits career choice and increases the risk of glaucoma and cataract. High myopia also increases the risk of retinal detachment, chorio-retinal degeneration and subsequent visual impairment (Saw, Gazzard et al. 2005). Both genetic and environmental factors have been implicated in the aetiology of myopia. Children with myopic parents have a higher than normal risk of developing myopia (Mutti, Mitchell et al. 2002) and twin studies show a higher level of concordance of common myopia in monozygotic compared to dizygotic twins (Dirani, Chamberlain et al. 2006). However, the rapid rise in myopia prevalence over recent decades argues strongly that changing environmental factors also play an important role in the aetiology of myopia.

In the early 1900s Fuchs asserted '*The following means are advised to put a stop to the extension of myopia in schools. First, the excess of work which many scholars have at present to struggle with should be reduced*'…. '*Instruction ought not to begin too early (if possible not before the completion of the sixth year) and more time should be allotted to bodily exercise, especially in the open air, than has hitherto been the case.*' (Duane 1919). Although the long-held view that myopia primarily results from too much near-work is now regarded as an over-simplification, several recent studies support Fuchs's idea that outdoor activity may have an important role in protecting against myopia.

There have been many attempts to inhibit the progression of myopia in children. More recently, these have included treatment with antimuscarinic agents such as atropine eye-drops (Chua, Balakrishnan et al. 2006) and optical devices including multifocal spectacle lenses (Gwiazda, Hyman et al. 2003), dual-focus contact lenses (Anstice and Phillips 2011) and orthokeratology (Kakita, Hiraoka et al. 2011). However, none of these approaches entirely arrests myopia progression in the long term and the vast majority of myopia is managed by optical correction alone. Although conventional optical corrections including refractive surgery restore acuity, they do not prevent the abnormal enlargement of the myopic eye, so children with myopia remain at increased risk of ocular disease later in life.

In this review we examine evidence from human and animal studies that one aspect of outdoor activity, namely exposure to natural light, may reduce the prevalence and

progression of myopia. We focus on the timing of light exposure in relation to the circadian cycle and on the potential roles of dopamine and melatonin in control of ocular growth and refractive development.

2. Human myopia and light

2.1 Outdoor activity

Current epidemiological research, as quantified by validated surveys, supports the idea that time spent in outdoor activities has a beneficial effect in reducing myopia prevalence in children and young adults (Jones, Sinnott et al. 2007; Rose, Morgan et al. 2008a; Rose, Morgan et al. 2008b). Whether the effect derives predominantly from increased natural light exposure or increased activity (e.g. sport) or from greater viewing distances outdoors has yet to be ascertained. An association between greater physical activity and reduced myopia progression has been reported in university students (Jacobsen, Jensen et al. 2008) although this association may have been confounded by other factors in the outdoor environment where much of the activity took place. Other studies have found an association between increased outdoor hours and lower myopia even when time spent playing sport outdoors was excluded (Rose, Morgan et al. 2008a). Moreover, indoor sport appears to have no beneficial effect (Rose, Morgan et al. 2008a; Dirani, Tong et al. 2009) suggesting that physical activity alone cannot account for the effect of outdoor activity. Whether the increased viewing distance typically associated with being outdoors has a positive effect in reducing myopia is unknown. The idea that time spent outdoors may act beneficially by substituting for time spent in near and mid-working distance activities seems not to be the case (Rose, Morgan et al. 2008a). In relation to distance viewing outdoors, the accommodative demand for viewing beyond about 6 metres is minimal. Indoor environments, particularly in city apartments, inevitably restrict viewing distance and typically include low dioptric stimuli for accommodation over the peripheral visual field (Charman 2011). However, the most obvious difference between spending time outdoors and time indoors is in light exposure. The spectral composition of light outdoors includes large amounts of ultraviolet (UV) and infrared (IR) in addition to light in the visible spectrum. Indoors, the UV portion of the spectrum is largely absent and if incandescent lighting is used the composition of the light is often biased towards the red end of the spectrum. Light intensity indoors is rarely more than 800 lux, whereas outdoor light intensity is around 50,000 lux on a sunny, blue-sky day and is rarely less than 5,000 lux, even when overcast. The cumulative light exposure for one hour spent outdoors is thus very much greater than for one hour spent indoors (Backhouse, Ng et al. 2011). This increased light exposure during the day is generally believed to be the most likely basis for the beneficial effect of outdoor activity in reducing myopia prevalence (Rose, Morgan et al. 2008a).

2.2 Light at night

Between birth and 2 years of age, the normal eye grows very rapidly, with axial length increasing at a rate of about 2 mm/year before slowing to about 0.1 mm/year until the eye reaches adult size (Larsen 1971). It has been suggested that environmental influences acting in this early period of rapid eye growth may potentially affect refractive development later in life. Quinn et al. (Quinn, Shin et al. 1999) investigated the effects of light exposure early in life on refractive status later in childhood. Their study, which was based on a questionnaire

completed by parents of children aged 2-16 years (median 8 years) on their child's night-time light-exposure, reported a strong, dose-dependent association between the prevalence of myopia at the time of the study and night-time lighting conditions experienced by the children before the age of 2 years. Remarkably, 55% of children who slept with the room lights on developed myopia whereas 34% of children who slept with night-lights, and 10% of children who slept in darkness, had developed myopia at the time of the study. On the statistical strength of their findings, the authors suggested that the absence of a daily period of darkness could be a precipitating factor in the later development of myopia. A similar study (Czepita, Goslawski et al. 2004) also reported increased prevalence of myopia in children who had experienced ambient light at night before the age of 2 years. However, several studies in different parts of the world, also based on parental questionnaires, have reported no difference in prevalence of myopia in children sleeping in darkness or with ambient light at night before the age of 2 years (USA (Gwiazda, Ong et al. 2000; Zadnik, Jones et al. 2000), Asia (Saw, Zhang et al. 2002), UK (Guggenheim, Hill et al. 2003)). Both studies from the USA found associations between the number of myopic parents in the family and nursery lighting experienced by the child before the age of 2 years, suggesting that the results obtained by Quinn et al. may have been confounded by the uncontrolled effect of parental myopia. However, exposure to light at night may also affect the refractive development of young adults. A study of law students (Loman, Quinn et al. 2002) reported an association between increased myopia progression during law school with less daily exposure to darkness (i.e. more artificial light at night).

2.3 Season of birth

Further evidence for the influence of light exposure early in life on later refractive error comes from studies on the effect of season of birth (and by implication perinatal photoperiod) on adult refractive status. In a study population of 276,911 adolescents born in Israel (Mandel, Grotto et al. 2008), moderate and severe myopia prevalence varied by birth month, with the summer months (June/July) being associated with a higher myopia prevalence than the winter months (December/January). Moreover, increasing photoperiod was associated with increasing myopia prevalence in a dose-dependent pattern. Mild myopia was not associated with either season of birth or photoperiod. Birth during the summer was also found to be significantly associated with high myopia in a UK study (McMahon, Zayats et al. 2009) but no association was found between postnatal photoperiod and prevalence of myopia in adulthood. Seasonal variations in photoperiod are particularly extreme above the Arctic Circle. However, in a study of Finnish military conscripts (Vannas, Ying et al. 2003) no associations between myopia prevalence and birth month, global irradiance at birth month or daily hours of darkness during the birth month were found, although there was a trend towards higher prevalence of myopia among conscripts living above the Arctic Circle.

The human data on light exposure and refractive development suggest that increased day-time outdoor light exposure is associated with reduced myopia prevalence whereas increased night-time exposure to artificial light may be associated with increased myopia development – a case of day-light good, night-light bad. The remainder of this review examines the underlying processes which could explain why perturbations in the daily light-dark cycle may affect eye growth and refractive development.

3. Light and animal models of myopia

Animal studies have shown that a diurnal light:dark photoperiod is required for the normal refractive development of the eye in chicks (Li, Troilo et al. 1995; Stone, Lin et al. 1995), tree shrews (Norton, Amedo et al. 2006) and Rhesus monkeys (Smith, Bradley et al. 2001). In normal chick eyes there is a diurnal growth rhythm in which greatest eye elongation occurs during the day with reduced growth rates at night (Weiss and Schaeffel 1993; Nickla, Wildsoet et al. 1998). The choroid also demonstrates a similar diurnal rhythm in which the choroid thins during the day and thickens at night (Papastergiou, Schmid et al. 1998). In eyes deprived of form vision in order to induce myopia, a phase shift occurs in the relationship between the axial length and choroidal rhythms such that peak axial growth occurs earlier than in normal eyes (Nickla, Wildsoet et al. 1998).

3.1 Effect of constant light

Rearing chicks under constant light with open eyes produces hyperopia, due to corneal flattening resulting in shallow anterior chambers (Li, Troilo et al. 1995; Stone, Lin et al. 1995). While the anterior chamber becomes shallower, the vitreous chamber lengthens, resulting in no net change in axial length at 2 weeks of age. Continued rearing of chicks in constant light beyond 2 weeks produces macrophthalmos (Oishi, Lauber et al. 1987). The final refractive state may be hyperopic despite the development of significantly deeper vitreous chambers (Li, Troilo et al. 1995). In form-deprived eyes, constant light also produces hyperopia despite overall longer axial lengths and enlarged vitreous chambers in both axial and equatorial directions; (Stone, Lin et al. 1995).

While rearing chicks under continuous light produces hyperopia, the effect is dependent on the level of ambient illumination. Thus, higher light intensities are correlated with higher degrees of hyperopia, lower corneal power and increased vitreous chamber depth. Cohen et al. (Cohen, Belkin et al. 2008) reported that chicks raised under continuous illumination at 10,000 lux for 90 days developed a hyperopic mean refraction of +11.97D, while those raised under 50 lux resulted in an emmetropic mean refraction of +0.63D. An illumination level of 500 lux also produced a relatively high hyperopic outcome of +7.90D. While vitreous chamber depth was positively correlated with light intensity, overall axial length did not vary significantly between groups due to the corneal flattening associated with increasing light intensity, resulting in an overall hyperopic refraction at the moderate and high illumination levels (Cohen, Belkin et al. 2008).

Monkeys raised under continuous light conditions (Smith, Bradley et al. 2001) do not exhibit the increase in ocular growth typically found in the chick. Rhesus monkeys raised under continuous light for 6 months developed hyperopic refractions similar in magnitude to animals raised under normal diurnal light cycles. However, the refractions were more variable in outcome, with some animals developing axial anisometropia and low myopia (Smith, Bradley et al. 2001). The authors cautioned that the animals may have been able to re-establish at least a partial diurnal cycle by shielding their eyes during sleep with their arms, although no significant difference in behaviour was observed (Smith, Bradley et al. 2001).

3.2 Effect of constant darkness

Rearing chicks in complete darkness also produces hyperopia irrespective of whether a diffusing goggle is worn (Gottlieb, Fugate-Wentzek et al. 1987). The degree of hyperopia

produced is approximately double that of normal chicks by 42 days. In contrast, tree shrews placed in continuous darkness eventually exhibit a myopic shift in refraction (Norton, Amedo et al. 2006). Although the animals initially stabilise at a low degree of hyperopia following 16 days of normal visual experience after eye opening, a subsequent period of 10 days of continuous darkness results in vitreous elongation and a myopic refraction (Norton, Amedo et al. 2006). While both chicks and tree shrews exhibit ocular growth under constant darkness, the significant corneal flattening which produces hyperopia in chicks does not occur in the tree shrew. Conversely, raising rhesus monkeys in continuous darkness appears to interfere with the emmetropisation process such that they retain their relatively high hyperopic neonatal refractions (Guyton, Greene et al. 1989).

Gottlieb et al. (Gottlieb, Fugate-Wentzek et al. 1987) proposed that two mechanisms may combine under dark-rearing in chicks to produce the hyperopic outcome: a visual deprivation mechanism which triggers enlargement of the eye, as occurs in form-deprivation myopia, and a second photoperiod-related mechanism which results in corneal flattening.

A phase advance in the cycle of eye growth is found in chicks raised under constant darkness which is associated with an overall increase in axial growth and choroidal thinning (Nickla, Wildsoet et al. 2001). As the rhythms in choroidal thinning and axial growth persist under constant darkness, they must be circadian in origin, rather than simply diurnal in response to external light-dark cycles (Nickla, Wildsoet et al. 2001). Nickla (Nickla 2006) provides further evidence for the role of a phase shift in the temporal relationship between axial length and choroidal thickness cycles in the control of ocular growth in a study comparing recovery from form-deprivation, myopic defocus and hyperopic defocus in chicks. It appears that where the treatment requires a decrease in ocular growth (such as recovery from form-deprivation) the axial length and choroidal rhythms shift into phase. The mechanism by which such a phase shift might influence ocular growth is not certain, although it has been proposed that the variation in thickness of the choroid may regulate diffusion of a signal molecule from the retina to the sclera, or may act as a mechanical scaffolding against the influence of diurnal intra-ocular pressure changes on the sclera (Nickla 2006).

3.3 Diurnal modulation of illumination

In order to determine the minimum period of darkness within the diurnal light:dark cycle that is required for normal eye growth, Li et al. (Li, Howland et al. 2000) investigated the effect of various periods of darkness from zero (constant light) to a standard 12:12 h light:dark cycle in chicks. They found that at least 4 hours darkness per diurnal cycle produced a normal emmetropisation response in the chick (Li, Howland et al. 2000). Further investigations demonstrated that the 4 hours of darkness was most effective in blocking the effects of excess light exposure when presented in a single period at the same time of day, rather than at random times or as multiple periods totalling 4 hours (Li, Howland et al. 2000). Li et al. (Li, Howland et al. 2000) concluded that this period of darkness may be sufficient to entrain the intrinsic circadian clock of the avian retina (Morgan and Boelen 1996). The requirement for periods of darkness during a diurnal cycle in order to produce normal eye growth in chicks has a potential corollary in humans. As noted earlier, the use of night lights in children's bedrooms under the age of 2 years has been associated with the development of myopia in later life (Quinn, Shin et al. 1999).

Diurnal modulation of ambient illumination rather than the need for periods of total darkness may be the significant requirement for normal emmetropisation in chicks. Liu et al. (Liu, Pendrak et al. 2004) reared chicks under light:dark, light:dim and constant light cycles with the aim of investigating the effect of ambient lighting at night on emmetropisation. The irradiance of the light phase was 1500 μW/cm², while the dim phase varied between 0.01 and 500 μW/cm². The eyes of chicks raised under light:dark and light:dim cycles had comparable ocular refractions and dimensions. Conversely, rearing under constant light levels from 1 μW/cm² (~0.3 lux) to 1500 μW/cm² (~500 lux) produced the typical shallow anterior chamber and hyperopic shift in refraction as found previously in chicks. These results imply that the modulation of light levels during a diurnal cycle may be of more importance in the maintenance of the normal emmetropisation response than the absolute light (or dark) levels. Consequently, the use of light:dim diurnal cycles may be a more pertinent paradigm for study as it more closely approximates the typical urban environment with artificial lighting at night (Liu, Pendrak et al. 2004).

3.4 Amplitude modulation of illumination

Recent animal investigations support the fundamental hypothesis that light exposure is the mediator of the antimyopiagenic effect of outdoor activity (Rose, Morgan et al. 2008a). Experiments in chicks have shown that exposure to high ambient light levels, either artificial or natural, modifies the development of experimental myopia due to either visual form deprivation using translucent occluders, or induced defocus using spectacle lenses (Ashby, Ohlendorf et al. 2009; Ashby and Schaeffel 2010). While exposure to high illumination levels of 15,000 lux for 5 hours per day significantly reduced form-deprivation myopia by around 60%, in lens-induced myopia the rate of compensation for the induced defocus was modified, but not the final degree of refractive error produced (Ashby and Schaeffel 2010). The normal emmetropisation process in chicks can also be directly influenced by ambient light levels: raising animals under low light levels (50 lux) produced myopic refractive outcomes on average, while high light levels (10,000 lux) produced hyperopic refractive outcomes (Cohen, Belkin et al. 2011).

In form-deprivation experiments in chicks, exposure to high artificial light (15,000 lux) indoors or natural light (30,000 lux) outdoors for 15 minutes per day with occluders removed was sufficient to produce a statistically significant decrease in axial myopia beyond that produced by the removal of the occluders under normal laboratory light levels (500 lux) (Ashby, Ohlendorf et al. 2009). The antimyopiagenic effect of high illumination levels was also demonstrated under constant occluder wear conditions where a significant decrease in axial myopia development was also demonstrated in chicks raised under 15,000 lux for 6 hours per day when compared to animals raised under 50 or 500 lux (Ashby, Ohlendorf et al. 2009). As the antimyopiagenic effect occurred during continuous occluder wear the authors conclude that the effect cannot be due to a reduction in image blur resulting from pupil constriction as these animals did not receive clear form vision at any time in the occluded eye. It has been suggested that high ambient illumination levels may affect the diurnal variation in retinal dopamine, which is disrupted in form-deprivation in chicks (Weiss and Schaeffel 1993), with the proposal that the chick retina has a graded release of dopamine under high illumination levels which results in a retardation of myopia development (Ashby, Ohlendorf et al. 2009). The intra-vitreal administration of a dopamine antagonist (spiperone) blocked the protective effect of high illumination levels against form-

deprivation myopia in chicks (Ashby and Schaeffel 2010) further supporting the hypothesis that this neurotransmitter is intrinsically involved in the control of the emmetropisation mechanism (Ashby and Schaeffel 2010; Mao, Liu et al. 2010; Nickla, Totonelly et al. 2010).

3.5 Chromaticity and refractive development

The contribution of the chromatic component of light to refractive development has been investigated in a number of animal models including chicks (Rucker and Wallman 2009), fish (Kroger and Wagner 1996) and guinea pigs (Long, Chen et al. 2009). Guinea pigs raised under long-wavelength light (peak at 760 nm) reportedly develop a significant degree of myopia, associated with a significant increase in vitreous chamber depth, over a period of 4 weeks when compared to animals raised under mixed-wavelength light (unfiltered halogen lamps) (Long, Chen et al. 2009). The myopiagenic effect of long-wavelength light was reversed by allowing the animals to recover under mixed-wavelength light conditions for two weeks, after which there was no significant difference in refraction (Long, Chen et al. 2009).

One possible explanation for the effect of wavelength on refractive outcome is based on the intrinsic chromatic aberration of the vertebrate eye (Mandelman and Sivak 1983) which could provide a sign-of-defocus signal for emmetropisation (Flitcroft 1990) as the long and short wavelength components would produce relative hyperopic and myopic defocus of the retinal image respectively. For example, in a comparison of the effects of raising guinea pigs under equiluminant short wavelength light (430 nm) or middle wavelength light (530 nm), Liu et al. (Liu, Qian et al. 2011) demonstrated that after 12 weeks the 530 nm group was less hyperopic due to faster vitreous elongation, while the 430 nm group was more hyperopic following slower vitreous elongation. The difference in refraction between the groups (4.50 D) exceeded the longitudinal chromatic aberration of the guinea pig eye (approximately 1.5 D) at the selected wavelengths, which was possibly due to additional accommodative effects produced by the monochromatic illumination (Seidemann and Schaeffel 2002), or by wavelength-dependent alteration of retinal or retinal pigment epithelium growth signals (Liu, Qian et al. 2011).

4. Light and circadian rhythms

The role of illumination level and the requirement for periodic light:dark cycles during normal refractive development points to a role for the intrinsic circadian clock and the associated dopamine-melatonin cycle in the control of eye growth (Cahill and Besharse 1995; Witkovsky 2004; Iuvone, Tosini et al. 2005). The presumed role of circadian rhythms, which persist in constant darkness independent of the diurnal light:dark cycle, is to regulate the timing of biological events so as to optimise the metabolic function and energy use of the organism (Roenneberg and Foster 1997; Levi and Schibler 2007).

4.1 The circadian pacemaker

Although the control of the circadian rhythm is a complex, multivariate process, it has been known for some time that light plays a pivotal role (Iuvone, Tosini et al. 2005). The underlying circadian rhythm is controlled by a circadian clock, through the expression of "clock genes" and their products, and entrainment cues known as zeitgebers ("time givers")

which influence the timing of these rhythms (Roenneberg and Foster 1997; Iuvone, Tosini et al. 2005). The primary, central time keeping clock in the body is the suprachiasmatic nucleus (SCN) of the hypothalamus (Roenneberg and Foster 1997). The primary input to the SCN is from the retina via the retinohypothalamic tract (RHT) (Simonneaux and Ribelayga 2003), which makes light the primary zeitgeber for entrainment of the circadian rhythm (Roenneberg and Foster 1997). While input via the RHT is not necessary for the generation of a circadian rhythm (evidenced by the free running nature of the SCN rhythm), it is necessary for the entrainment of the circadian rhythm to the normal light:dark cycle (Inouye and Kawamura 1979).

4.2 The light entrainment pathway

The traditional view of the photosensitive retinal organisation is of a dual photoreceptor system comprising both rods and cones. However, circadian entrainment has been found to originate from a small subset of retinal ganglion cells, the intrinsically photosensitive retinal ganglion cells (ipRGCs) (Berson, Dunn et al. 2002; Hattar, Liao et al. 2002). The photopigment melanopsin, first described in melanophores on frog skin and subsequently found in the inner retina of a number of mammals including humans, provides the ipRGCs with this photosensitivity (Provencio, Rodriguez et al. 2000; Hattar, Liao et al. 2002). Melanopsin has an action spectrum that peaks around 480 nm (Berson, Dunn et al. 2002). However, studies in melanopsin-knockout mice showed that melanopsin is not essential for light entrainment of the circadian pacemaker, but improves the magnitude of the response (Ruby, Brennan et al. 2002). It transpires that the melanopsin-containing ipRGCs also receive input from the traditional rod and cone photoreceptors (Perez-Leon, Warren et al. 2006). There is a loss of photo-entrainment, but a persistence of pattern vision, in animals without functional ipRGCs providing definitive support for the role of the ipRGCs in the entrainment of the circadian system by light (Guler, Ecker et al. 2008). The entrainment of the circadian system in mammals is thus mediated by the ipRGCs as a balance between intrinsic photoreception enabled by melanopsin and input from the traditional retinal photoreceptors. In chicks melanopsin is found in both the retina and the pineal gland, indicating light can entrain the circadian pacemaker through both retinal (via ipRGCs) and direct pineal routes (Torii, Kojima et al. 2007; Neumann, Ziegler et al. 2008).

The SCN, working as a central master clock, controls the circadian timing of the organism through a multisynaptic pathway. The SCN projects to neurones in the paraventricular hypothalamic nucleus, which synapse preganglionic sympathetic neurons in the intermediolateral cell column, stimulating postganglionic sympathetic neurons in the superior cervical ganglion, before finally providing sympathetic input to the pineal gland (Larsen, Enquist et al. 1998). The main circadian mediator from the pineal gland is melatonin, a hormone first isolated from bovine pineal glands and named for its ability to lighten the melanocytes in frog skin (Lerner, Case et al. 1958). Melatonin acts through melatonin receptors in a diverse range of tissues, performing a variety of roles in circadian entrainment, endocrine functions, cardiovascular responses, the immune system, and ocular physiology (Alarma-Estrany and Pintor 2007).

4.3 Melatonin precursors

Melatonin (N-acetyl-5-methoxytryptamine) is a circadian hormone produced through a pathway involving four precursor intermediaries (Fig. 1.). All of the components necessary

for the production of melatonin are active within the pineal gland, which is the main site of production (Axelrod 1974; Zawilska, Skene et al. 2009). The first step is the conversion of the dietary amino acid tryptophan to 5-hydroxytryptophan by the enzyme tryptophan hydroxylase (TPH); the second step involves the conversion of 5-hydroxytryptophan to serotonin via the enzyme aromatic $_{L}$-amino acid decarboxylase (AADC); serotonin is converted in the third step to N-acetylserotonin by the enzyme arylalkylamine-N-acetyltransferase (AANAT); the final step is the O-methylation of N-acetylserotonin to melatonin by the enzyme hydroxyindole-O-methyltransferase (HIOMT). The rate limiting enzyme in the production of melatonin is widely thought to be AANAT, although recent work suggests that HIOMT may be the crucial limiting factor (Liu and Borjigin 2005). The precursor components of melatonin synthesis also show inherent circadian rhythms of production (Axelrod 1974). The retina is another significant producer of melatonin in some animals, providing the basis for a peripheral clock in addition to the central clock of the pineal gland (Iuvone, Tosini et al. 2005)

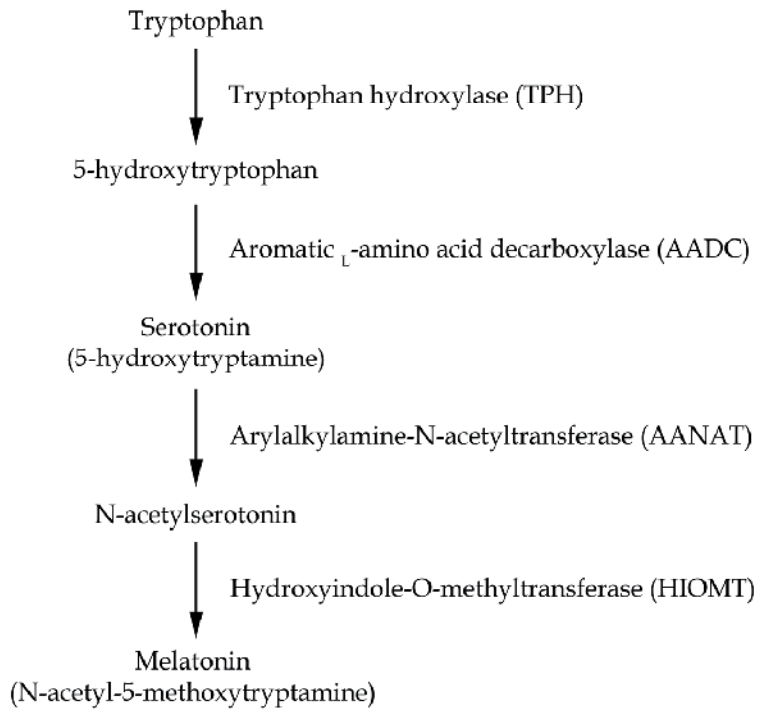

Fig. 1. Melatonin production pathway showing the precursor compounds and the enzymes involved.

4.4 Circadian melatonin rhythms

In the majority of species studied to date, whether they are diurnally or nocturnally active, there is a circadian secretion pattern of melatonin with high levels present at night and low levels during the day (Zawilska, Skene et al. 2009). The onset of darkness following a period

of light leads to an increase in pineal AANAT and melatonin levels in phase with each other (Wilkinson, Arendt et al. 1977). However, there appears to be a refractory period for dark-induced melatonin rises such that darkness during periods when the organism is expecting it to be light does not induce the rise (Binkley, Macbride et al. 1975). Three distinct patterns of nocturnal melatonin production have been described in mammals: Type A is uncommon and represents a peak in melatonin late in the dark phase (e.g. Syrian hamster and house mouse); Type B is most common and shows peak melatonin expression occurring around midnight (e.g. rat, guinea pig, and human); and Type C which is also common and shows elevated melatonin levels for most of the dark phase (e.g. sheep and cat) (Zawilska, Skene et al. 2009). The human melatonin cycle, like that of animals (Tast, Love et al. 2001), can be entrained to variations in the light:dark cycle. When the light:dark cycle is phase-shifted by 12 hours, the human rhythm in melatonin secretion re-entrains to the new dark phase over a period of 5 to 7 days (Lynch, Jimerson et al. 1978).

4.5 Light and melatonin suppression

Darkness is required for the rise in melatonin, as animals kept in constant light show a reduction or complete loss of melatonin synthesis (Perlow, Reppert et al. 1980). However, the factor mediating the entrainment of the melatonin rhythm appears to be light exposure. Presentation of light during the dark phase, when melatonin levels are elevated, results in a rapid suppression of production and a reduction in serum melatonin concentration (e.g. (Illnerova, Backstrom et al. 1978; Rollag, O'Callaghan et al. 1978)). Human melatonin suppression by light is intensity dependant, with brighter light leading to greater levels of melatonin suppression (McIntyre, Norman et al. 1989; Zeitzer, Dijk et al. 2000). Suppression to near daytime levels (67% suppression) is achieved with 1000 lux (McIntyre, Norman et al. 1989), while a half maximal suppression response can be seen between approximately 50 and 130 lux (Zeitzer, Dijk et al. 2000). This light induced suppression also shows an inverse correlation with duration, such that longer durations of light require lower intensities of light to induce suppression (Aoki, Yamada et al. 1998). However, independent of light level there appears to be an asymptote for melatonin suppression after around 60 minutes of light exposure (Figueiro, Rea et al. 2006). Interestingly the melatonin suppression by light appears to be sensitised/desensitised by the amount of light received during the day prior, such that less light exposure (as experienced during winter months) results in much greater melatonin suppression for a given amount of light at night (Smith, Schoen et al. 2004; Higuchi, Motohashi et al. 2007).

The action spectrum for melatonin suppression shows peak effect between 446 and 477 nm (Brainard, Hanifin et al. 2001; Thapan, Arendt et al. 2001). The light response of the melanopsin containing ipRGCs mirrors that of the melatonin suppression action spectrum, indicating that these cells are the likely mediators of the response (Berson, Dunn et al. 2002). Circadian photo-entrainment also appears to be mediated by a peak action spectrum response from the same blue wavelength portion of the spectrum (Hattar, Lucas et al. 2003). These responses are also seen in humans, although a greater response is seen when polychromatic light is used instead of monochromatic light at peak melanopsin sensitivity, suggesting melanopsin may not be solely responsible and that rod and cone input also play a role (Revell and Skene 2007). Despite uncertainty as to the exact cellular input driving the circadian entrainment, it is clear that the blue end of the spectrum is important. Interestingly, exposure to the blue part of the spectrum also appears to suppress myopia development in guinea pigs (e.g. (Liu, Qian et al. 2011; Wang, Zhou et al. 2011)).

Wang et al. (Wang, Zhou et al. 2011) raised guinea pigs under blue light (480 nm), green light (530 nm) and broadband white light. After 10 days the levels of melatonin in the pineal glands were significantly lower in both the blue light and white light groups when compared to the green light group. This difference existed in both daytime (10 am) and night-time (10 pm) samples. The green-light group were also about 2 D more myopic, had greater axial lengths and greater vitreous depths than the other groups. Furthermore the green-light group exhibited reduced expression of retinal melanopsin mRNA and reduced levels of melanopsin protein. MT1 receptor mRNA expression was higher in both the retina and sclera of the green-light group. Overall this study demonstrated a clear link between wavelength of illumination, refractive error development and modulation of the melatonin pathway in guinea pigs.

4.6 Light as a zeitgeber

Light is the primary zeitgeber for the entrainment of the circadian system (Roenneberg and Foster 1997). Phase response curves have shown that the timing of light exposure is critical to circadian responses to light (Daan and Pittendrigh 1976). When light is presented at the beginning of the subjective night there is a phase delay of the subsequent activity-rest cycle, while light presented at the end of the subjective night leads to a phase advance. Presentation of light during the subjective day has little effect on the phase response curve, suggesting the twilight zones of dusk and dawn are the key times for entrainment (Roenneberg and Foster 1997). The phase shifting effect of light also affects the timing of the dim light melatonin onset (the increase in melatonin levels at night) (Lewy, Sack et al. 1985). Bright light in the evening delays dim light melatonin onset while bright light in the morning advances it. Bright light presented both in the morning and evening gives an intermediate response between delay and advance (Lewy, Sack et al. 1987). Exposure to bright light results in immediate melatonin suppression, but longer exposure of greater intensity is required to entrain the pacemaker (Hashimoto, Nakamura et al. 1996). However, dim light exposure at the appropriate time and for a long enough period has also been shown to entrain the circadian system (Zeitzer, Dijk et al. 2000). The importance of the timing of the signal for entrainment has a parallel in form-deprivation myopia wherein removal of the occluder for 40 minutes in the evening is more effective at reducing the induced myopia than if the occluder is removed in the morning (Ohngemach, Feldkaemper et al. 2001).

4.7 Photoperiodism and photoperiodic history

Photoperiodism, the adaptation of an organism's physiological functions to changes in season, is thought to be determined by both the absolute photoperiod length and by changes (either increasing or decreasing) in photoperiod length (Goldman 2001). Three main hypotheses to explain the influence of melatonin on this phenomenon exist: the duration, coincidence, and amplitude hypotheses.

The duration hypothesis proposes that the duration of night-time melatonin release is used as a signal encoding day length, with a shorter duration melatonin signal indicating long day/short night periods and vice versa (Simonneaux and Ribelayga 2003). In pinealectomised animals, short duration infusion of melatonin replicates a long day reproductive response while long duration infusion replicates a short day response (e.g.

(Bittman and Karsch 1984; Maywood, Buttery et al. 1990)). The coincidence hypothesis proposes that there is a coincidence between a sensitive period for signal detection and the presence of the melatonin signal. Infusion of melatonin at specific circadian time points in pinealectomised individuals suggests a critical period of sensitivity either at the onset of the dark phase (Gunduz and Stetson 2001), or at a specific time after the initial melatonin rise (Pitrosky, Kirsch et al. 1995). More recent work suggests that the coincidence timing effect of melatonin acts through clock gene expression oscillations (for review see (Hazlerigg and Wagner 2006)). While the amplitude hypothesis, which proposes that the peak amplitude of melatonin secretion is the signal for seasonal timing, is often discussed (e.g. (Simonneaux and Ribelayga 2003)), very little experimental data exists to back it up. Thus duration and timing of circadian signals may be more important than signal amplitude for circadian entrainment.

During periods of intermediate day-length between the winter and summer solstices a single day-length signal is insufficient to determine whether the days are becoming longer or shorter, so photoperiodic history, based upon the length of the preceding days, is used. The photoperiodic history appears to rely on the summation of recent photoperiod information over a number of days (Prendergast, Gorman et al. 2000), and the prenatal photoperiod actually appears to modify the postnatal day-length threshold which controls the maximal rate of development (Shaw and Goldman 1995). The ability of the perinatal photoperiodic history to influence future development rates may explain the observed season of birth effect in human refractive development (see Section 2.3).

5. Peripheral clocks

In addition to the master central circadian clock, peripheral systems and indeed individual cells also possess clocks (reviewed by (Balsalobre 2002)). Of these the retina, which also provides the main entrainment cue for the central clock, constitutes the most relevant peripheral clock for refractive development. The retina is a highly circadian tissue, showing rhythms in a variety of functions including visual sensitivity, the electroretinogram response, rod outer segment disc shedding, melanopsin mRNA expression, melatonin synthesis, and dopamine synthesis (for excellent reviews see (Iuvone, Tosini et al. 2005; Tosini, Pozdeyev et al. 2008)).

5.1 Retinal melatonin

Melatonin is synthesised in the retina in a circadian manner, independent of the SCN, in both non-mammalian (Cahill and Besharse 1992; Thomas, Tigges et al. 1993) and mammalian (Tosini and Menaker 1996) vertebrates. The retinal photoreceptors appear to be the source of this retinal melatonin production, with AANAT and HIOMT activity having been localised mainly to these cells, and only minimal activity in the inner nuclear layer and ganglion cells (Guerlotte, Greve et al. 1996; Coon, Del Olmo et al. 2002). Moreover, melatonin continues to be produced despite partial or complete destruction of the inner retina (Cahill and Besharse 1992; Thomas, Tigges et al. 1993). Human and primate retinas appear to be missing activity of the HIOMT enzyme, with expression of HIOMT mRNA in such small quantities that it contributes little to the production of melatonin (Bernard, Donohue et al. 1995; Coon, Del Olmo et al. 2002). However, labelling and activity of HIOMT in human photoreceptors has been demonstrated (Wiechmann and

Hollyfield 1987), although this has not been repeated by other groups. It has been postulated that N-acetylserotonin might take the place of a local melatonin signal in the retina of humans and primates (Iuvone, Tosini et al. 2005), or that the signal is provided by circulating melatonin levels (Osol and Schwartz 1984). Interestingly, human RPE and ciliary body also synthesise melatonin (Martin, Malina et al. 1992; Zmijewski, Sweatman et al. 2009).

5.2 Central and retinal dopamine rhythms

Dopamine is a neurotransmitter that has a multitude of roles, such as in learning and movement (Witkovsky 2004). Plasma dopamine levels in humans show a circadian rhythm in concentration that is phase-shifted relative to melatonin by approximately 180 degrees, peaking in the light phase and reaching lowest levels during the dark phase (Sowers and Vlachakis 1984). Primates (Perlow, Gordon et al. 1977), rats (Schade, Vick et al. 1995), and birds (Kang, Thayananuphat et al. 2007) also show these circadian rhythms in dopamine production; high in light, low in dark, and out of phase with melatonin. In pinealectomised rats the administration of melatonin suppresses dopamine expression in a dose-dependent manner (Khaldy, Leon et al. 2002).

Dopamine also has many roles in the retina, for example in light adaptation and cell death, as well as a potential role in ocular growth (Witkovsky 2004). As in the brain, retinal dopamine shows a diurnal rhythm with peak levels during the day and low levels during the night in non-human vertebrates (Nowak, Zurawska et al. 1989; Megaw, Boelen et al. 2006), and in human retinas (Di Paolo, Harnois et al. 1987). The diurnal variation in dopamine levels persists in constant darkness in mice, indicating that it has a circadian rhythm of release (Doyle, Grace et al. 2002), although others have found no circadian rhythm but a light activated fluctuation in retinal dopamine (Melamed, Frucht et al. 1984).

5.3 Light and dopamine

Dopamine is released from the perfused retina on exposing it to light (Kramer 1971), and light also stimulates retinal dopamine synthesis and turnover (Iuvone, Galli et al. 1978; Cohen, Hadjiconstantinou et al. 1983). Moreover, the light-activated rise in dopamine levels in the retina is much greater than the rise seen with the underlying circadian rhythm in constant darkness (Megaw, Boelen et al. 2006), and the metabolism of dopamine in the light is much greater than in the dark (Parkinson and Rando 1983; Megaw, Boelen et al. 2006). Furthermore, the intensity of light appears to be important for dopamine release and synthesis in the retina, with maximal stimulation and saturation of the response occurring between 32 to 80 lux in rats (Proll, Kamp et al. 1982; Brainard and Morgan 1987).

It transpires that change in light, in the form of flicker, is a more potent stimulus to dopamine release than constant light levels. This effect has been shown in several species, with increasing release rates seen with increasing stimulus presentation rates, and an increase in dopamine release above that seen with constant light alone (Kramer 1971; Weiler, Baldridge et al. 1997). Flickering light appears to increase dopamine release two to three times that of basal release levels. High frequency flicker at 6 Hz has also been shown to inhibit both form-deprivation myopia and lens-induced myopia in the chick (Schwahn and Schaeffel 1997). The degree of suppression is correlated with the length of the dark

phase of the flicker duty cycle (Schwahn and Schaeffel 1997). This may be due to increased retinal dopamine levels as 2 hours of exposure to flickering light at 10 Hz was shown to restore the rate of dopamine synthesis under form-deprivation conditions in chicks, possibly due to increased transcription of the tyrosine hydroxylase gene in dopaminergic amacrine cells (Luft, Iuvone et al. 2004).

5.4 Dopamine and melatonin

When light is presented during the dark phase there is a rapid suppression of melatonin and an increase in dopamine to normal daytime levels (Adachi, Nogi et al. 1998). Interestingly, in knockout mice that do not produce melatonin there is a loss of the circadian dopamine rhythm when the animals are maintained in constant darkness, but the rhythm is restored on administering exogenous melatonin (Doyle, Grace et al. 2002). These results are intriguing as they show that in the absence of melatonin a normal dopamine rhythm can be maintained by light exposure in a rhythmic light:dark cycle, but that melatonin can, in the absence of a light driven zeitgeber, also influence dopamine rhythms. Indeed there is a complex interaction between melatonin and dopamine in the retina with mutual inhibitory effects between the two compounds. Intra-vitreal injection of dopamine into the eye at night suppresses melatonin while the injection of melatonin during the day suppresses dopamine (Adachi, Nogi et al. 1998). Melatonin leads to an increase in AANAT activity in the retina and a decrease in dopamine levels (Nowak, Zurawska et al. 1989; Nowak, Kazula et al. 1992), while dopamine inhibits retinal AANAT activity and melatonin release (Iuvone and Besharse 1986; Tosini and Dirden 2000).

As melatonin production has not been demonstrated in the human retina, endogenous melatonin released from the pineal gland potentially acts in the retina. Indeed high levels of melatonin are found in human retinas, and intraperitoneal injection of melatonin in mice leads to an increase in retinal melatonin levels (Osol and Schwartz 1984; Doyle, Grace et al. 2002). In chicks the pineal gland has been shown to have a significant influence over both expression of the dopamine D_2-receptor mRNA and dopamine release in the retina (Ohngemach, Feldkaemper et al. 2001). Dopamine has also been shown to increase the expression of melanopsin mRNA via a D_2-receptor pathway in ipRGCs (Sakamoto, Liu et al. 2005).

6. Dopamine, melatonin and refractive development

6.1 Dopamine

Retinal dopamine levels are reduced during the induction of form-deprivation myopia in the chick (Stone, Lin et al. 1989), rhesus monkey (Iuvone, Tigges et al. 1991) and guinea pig (Mao, Liu et al. 2010). In the chick, this reduction is due to a decreased rate of dopamine synthesis during the light phase of the diurnal light:dark cycle (Stone, Lin et al. 1989). The use of modified translucent occluders demonstrates that retinal dopamine levels inversely correlate with the degree of axial elongation (Stone, Pendrak et al. 2006). Retinal dopamine levels exhibit a bidirectional response to retinal blur in chicks, with lens-induced myopia decreasing and hyperopia increasing the levels respectively (Guo, Sivak et al. 1995) although this effect is not universally reported (Bartmann, Schaeffel et al. 1994). The increase in retinal dopamine associated with the slowing of axial growth in

lens-induced hyperopia parallels recovery from form-deprivation myopia in the chick where a similar relationship between dopamine level and axial growth is reported (Pendrak, Nguyen et al. 1997).

The role of dopamine in the control of ocular growth is further supported by the demonstration that ocular administration of dopamine agonists can inhibit the axial growth and myopic refractions produced by form-deprivation in chicks (Rohrer, Spira et al. 1993; Nickla, Totonelly et al. 2010) and primates (Iuvone, Tigges et al. 1991). Also, extraocular administration of the dopamine precursor levodopa by intraperitoneal injection in guinea pigs raises retinal dopamine content and reduces the development of myopia during form-deprivation (Mao, Liu et al. 2010). The relationship between retinal dopamine pathways and lens-induced myopia is less certain. At dosages sufficient to suppress form-deprivation myopia in chicks, development of lens-induced myopia was not suppressed by intra-vitreal injections of 6-hydroxy dopamine, a drug which inhibits dopaminergic pathways (Schaeffel, Hagel et al. 1994). Conversely the non-specific dopaminergic agonist apomorphine has been shown to block negative lens-induced myopia in other chick studies (Schmid and Wildsoet 2004; Nickla, Totonelly et al. 2010).

Investigations using dopamine receptor subtype-specific agonists and antagonists have shown that the antimyopiagenic effect of dopamine is primarily mediated by D_2 receptors. For example, in form-deprivation in chicks, the protective effects of the non-specific dopaminergic agonist apomorphine were blocked by the D_2 specific antagonist spiperone, but not by the D_1 specific antagonist SCH-23390 (Rohrer, Spira et al. 1993).

In lens-induced myopia in chicks, both apomorphine (non-selective) and quinpirole (D_2 specific) agonists prevent the axial elongation and development of myopia associated with hyperopic defocus (Nickla, Totonelly et al. 2010). The effect is associated with an initial period of choroidal thickening, which is implicated in the inhibition of ocular growth either by the action of the choroid as a diffusion barrier to a growth signal or as an additional mechanical resistance to the effects of intraocular pressure (Nickla 2006). The D_2 antagonist spiperone is not as effective in abolishing the protective effect of periodic lens removal as has been previously found for the removal of form-depriving diffusers in chicks (McCarthy, Megaw et al. 2007). This may suggest a partial role for D_1 receptors in the control of ocular growth (Nickla, Totonelly et al. 2010).

6.2 Melatonin

While experimental evidence supports the role of retinal dopamine in the control of ocular growth and in the protective effect of light on myopia development, the role of melatonin, with which it is intrinsically linked in a counterphase cycle, is less certain (Cahill and Besharse 1995; Witkovsky 2004; Iuvone, Tosini et al. 2005).

Evidence for the role of an intrinsic melatonin rhythm in the control of eye growth is provided by Li and Howland (Li and Howland 2003) who demonstrated that the use of an opaque hood preventing light reaching the pineal gland for 12 hours per day is sufficient to significantly reduce the development of constant-light hyperopia in chicks. Covering one eye alone with an opaque occluder for 12 hours also partially prevented hyperopia development in the fellow eye under constant light conditions. The conclusion was that the eyes and pineal gland act as independent photoreceptors able to entrain the melatonin

circadian rhythm which is protective against the effects of constant light on eye growth (Li and Howland 2003).

While diurnal retinal melatonin rhythms appear unaffected during form-deprivation (Hoffmann and Schaeffel 1996), the intra-vitreal injection of melatonin at relatively high doses (1000 μg) increases the level of form-deprivation myopia induced in the chick (Schaeffel, Bartmann et al. 1995; Hoffmann and Schaeffel 1996). Although retinal melatonin content was sampled twice a day (day and night) during monocular occlusion, and an expected diurnal variation in melatonin was found, no significant difference was found between the occluded and non-occluded eyes (Hoffmann and Schaeffel 1996). While the authors concluded that melatonin was not a significant component of the ocular growth control mechanism in form-deprivation in chicks a number of factors may have colluded to disguise the role of melatonin in form-deprivation myopia. These include the timing of the intra-vitreal injection of melatonin (between 2:00-3:00 pm) which may have occurred during a refractory period where the system was less sensitive, or that the duration (rather than the amplitude) of the nocturnal melatonin pulse may have been altered under form-deprivation conditions (see Section 4.7).

Rada and Wiechmann (Rada and Wiechmann 2006) demonstrated that the intraperitoneal injection of melatonin in chick at the beginning of each dark phase of the diurnal light cycle during a 5 day period of form-deprivation altered ocular growth patterns in both the form-deprived and control eyes. In form-deprived eyes, melatonin injection resulted in a significant reduction in anterior chamber depth, while vitreous chamber depth only exhibited a non-significant trend towards increased growth. The choroidal thickness was also significantly reduced in this group when compared to the sham-treatment group. The study also demonstrated the presence of melatonin receptors Mel(1A), Mel(1B) and Mel(1C) in the cornea, choroid, sclera, and retina of the chick. A diurnal rhythm in the expression of these receptors was identified where Mel(1C) expression was highest in the early morning around the onset of the light phase, while Mel(1A) and Mel(1B) expression was highest around the onset of the dark phase in the evenings. Rada and Wiechmann (Rada and Wiechmann 2006) concluded that the presence of melatonin receptors and diurnal rhythms of receptor expression, along with the effects of exogenous melatonin, suggests a significant role for melatonin in the control of ocular growth, and by extension, in the control of refractive development.

7. Conclusion

Recent human epidemiological studies propose that light exposure mediates the antimyopiagenic effect of outdoor activity. However, light may also have a causative role in myopia development when it is presented at an inappropriate time. Animal investigations demonstrate that light is a potent modulator of ocular growth and associated rhythms, including the interplay between dopamine and melatonin. One question is whether the effect of light on refractive development primarily acts through modification of circadian rhythms, or through some other intensity or wavelength dependent mechanism.

If the effect is circadian in origin, is there an optimal period for presenting light in order to control ocular growth and prevent myopia? Both constant light and constant dark disrupt ocular growth in animals and result in refractive error development. This can be

ameliorated by either pharmacological interventions or controlled light exposure which re-establish more typical circadian rhythms. Light at night disrupts the normal circadian rhythm, rapidly decreasing melatonin and increasing dopamine, which potentially upsets the normal balance in ocular growth. As bright light presented in the middle of the day does not affect the timing of the circadian rhythm, presentation of a light signal during the twilight zones (dawn and dusk) is the most potent circadian zeitgeber. We hypothesise that the phase-advancing properties of morning light would be the most effective means of regulating the dopamine-melatonin circadian rhythm for the purposes of myopia control.

If the effect is not circadian in origin, then does the timing of the light signal matter or is it the nature of the stimulus (intensity and/or wavelength) that is important? Time spent outdoors leads to a significantly greater light dose than that received indoors, resulting in greater melatonin suppression and an increase in retinal dopamine. Additionally, the blue light spectral bias of outdoor light preferentially stimulates the melanopsin-containing ipRGCs, which would also lead to greater melatonin suppression. Both the intensity and wavelength of outdoor light favour increased retinal dopamine levels at the expense of melatonin. We hypothesise that it is this bias towards retinal dopamine production when outdoors that influences human refractive development, because increased dopamine has antimyopiagenic effects in animal experiments.

While the adage 'day-light good, night-light bad' in relation to refractive development is appealing, the true relationship between light and myopia is likely to be far more complex, with intricate interactions between the circadian cycle and the timing, intensity, and wavelength of the light exposure.

Etiology and Clinical Presentation of Astigmatism

Sanja Masnec Olujić
Ghethaldus Ophthalmology Policlinics, Zagreb
Croatia

1. Introduction

A perfect point image of an object point is called a stigmatic image. The term „stigmatic"is derived from the Greek word stigma, which refers to a sharply pointed stylus (Liesegang et al., 2002). Thus, a stigmatic optical system is one able to focus all the light rays from a point source onto a single point. However, in most cases, images are not stigmatic.

In paraxial optics, the focus is stigmatic, and all paraxial rays (those extremely close to the optical axis) focus onto a point. With nonparaxial rays, the focus is generally not stigmatic. Deviations from stigmatic imaging are called aberrations, and, one of a number of ways to classify such aberrations is clinically: into spherical aberrations, regular astigmatism and irregular astigmatism.

Astigmatism is the unequal refraction of the same eye in two different meridians. Unlike the basic types of refraction- emetropia, myopia and hyperopia- where all the light rays enter one focus (on the retina, behind it, or in front of it), in astigmatism there is no a single focus. In basic types of refraction, the cornea is spherical and it refracts equally in all the meridians.

In astigmatism variations in the curvature of the cornea or lens along different meridians prevent the light rays from focusing onto a single point. Corneal refraction depends on the corneal curvature. If the cornea is more curved, the power of refraction is higher and vice versa. Corneal and lenticular astigmatism can complement or cancel each other. Their summation represents the so called "total astigmatism".

Due to the lack of a single focus, an astigmatic eye is not able to see clearly without correction. Astigmatic patients complain of visual disturbances in both far (in myopia) and near vision (in hyperopia), which causes astenopic problems (headache, dizziness, fatigue etc). Additionally, regular, symmetric objects might seem to them irregular, and /or elongated.

2. Astigmatism types

Astigmatism can be regular or irregular. It can also be divided into myopic, hyperopic and mixed/compound astigmatism (where one of the main meridians is hyperopic and the other one myopic).

2.1 Regular astigmatism

In regular astigmatism each meridian refracts regularly and equally, but differently from the other meridians. One of the meridians refracts the most and another one the least. Those two meridians are called the main meridians, and they are perpendicular to each other.

In most cases, one of the main meridians is located vertically and the other one horizontally, but there can also be oblique, still maintaining the 90° angle to each other.

In the remaining meridians, located between the both two main meridians, refraction changes gradually –increases or decreases (Fig 1).

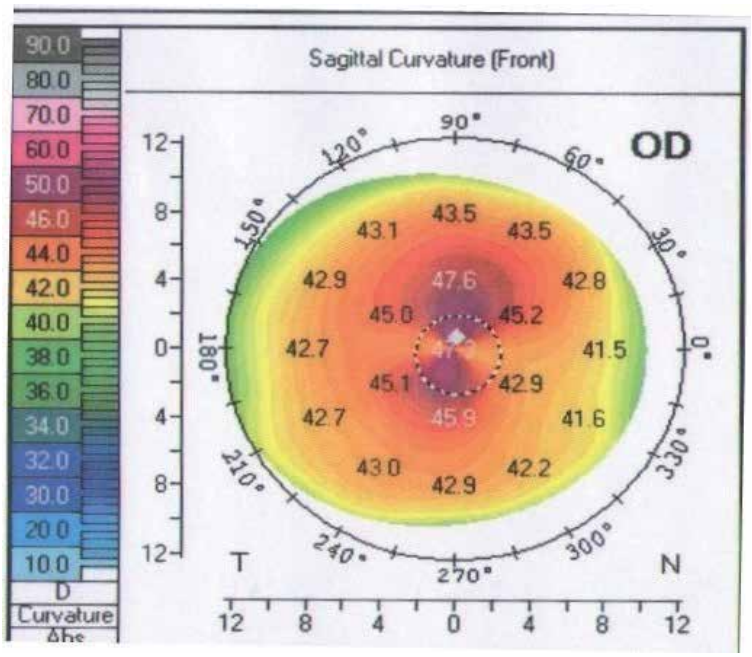

Fig. 1. With-the-rule astigmatism of 5.4 D shown on the topographical map of the anterior corneal surface , with quantitative information on the corneal curvature, astigmatism and its meridians.

Vertical meridian, in most of cases, refracts more then the horizontal, most likely due to the pressure of eyelids onto the cornea. This type of astigmatism is called *with- the- rule* astigmatism and is more common in children (Mohindra et al., 1978).

If the horizontal meridian refracts more, this is called *against- the- rule* astigmatism and is more common in older adults.

The difference in refraction of the two main meridians represents the amount of astigmatism and is represented in diopters (D).

When that difference is no more than 1/2 -3/4 diopters it is a so-called physiological astigmatism and a correction is usually not needed, as it does not lead to visual deterioration or subjective symptoms. Mostly, it is neutralized by the lenticular astigmatism (Parunovic et al., 1995).

Astigmatism over ¾ D can lead to visual disturbances and other subjective symptoms, because the lenticular astigmatism, which rarely exceeds 1-1.5 D, is not able to compensate for the corneal astigmatism.

Regular type astigmatism is rarely greater than 6-7 D.

For a better understanding of astigmatism and its correction, the most important optical concept is the **conoid of Sturm.**

The refractive power, as mentioned above, changes from one meridian to the next, and an astigmatic surface cannot bring a pencil of light rays to a point focus. Two focal lines instead of a single focus are formed. This complex geometrical envelope of a pencil of light rays refracted by a circular spherocylindrical lens is called the **conoid of Sturm.**

The conoid of Sturm has two focal lines, each parallel to one of the main meridians of the spherocylindrical lens. All the light rays in the pencil pass through each of the focal lines. The cross sections of the conoid of Sturm at various points along its length are mostly elliptical, including the portion of the conoid external to the two focal lines. At the dioptric mean of the two focal lines there is a circular cross section of the conoid of Sturm. This circular patch of light rays is called the *circle of least confusion*, and represents the best overall focus for the spherocylindrical lens. The circle of least confusion is the position where all the rays would be brought to focus if the lens had a spherical power equal to the average spherical power of all the meridians of the spherocylindrical lens (Michaels, 1980).

This average spherical power of a spherocylindrical lens represents the spherical equivalent of the lens, and can be calculated by the following equation:

$$\text{Spherical equivalent} = \text{sphere} + \text{cylinder}/2.$$

About 50% of infants in their first years of life show astigmatism of over 1D (Bennet et al., 1989; Mohindra et al., 1978).

Some authors have suggested that this high astigmatism helps the infant to bracket the position of best focus while it learns to accommodate (Howland et al., 1978).

In adults, this high incidence of astigmatism is much smaller. Different studies show that about 15 % of adults have astigmatism greater than 1D, and only 2 % of more then 3D (Yanoff & Duker, 2004).

In the leater group, it is most likely that much of the high astigmatism is due to some form of intraocular surgery, such as cataract surgery (particularly when extracapsular cataract extraction is performed), corneal transplants, corneal lacerations repair, …etc.

Regular astigmatism can be congenital and acquired. Congenital astigmatism is usually inherited. Acquired astigmatism is mostly against-the rule and as mentioned above, can result from various intraocular surgeries.

Most oftenly, astigmatism is static, but it can also change during the life time. With –the – rule astigmatism tends to lessen over the years, and the position of the main meridians can also slightly change during the lifetime.

Regular astigmatism is correctable by cylindrical spectacle lenses and contact lenses.

In with-the rule astigmatism, a correcting plus cylinder lens should be used at or near the 90° axis. In against-the rule astigmatism, a correcting plus cylinder lens should be used at or near the 180° axis.

2.2 Irregular astigmatism

Irregular astigmatism appears when the refraction of light is unequal and irregular in the same meridian of the eye.

That is usually a consequence of pathological changes especially to the cornea (maculae centrales corneae, ulcus, pannus, keratoconus etc) or lens (cataract, posterior capsular opacification, lens subluxation etc).

The visual acuity of such an eye is deteriorated and sometimes monocular diplopia or poliopia occurs. All eyes have at least a small amount of irregular astigmatism, but the term is used clinically only for the stronger irregularities, such as those mentioned above, or occurring with keratoconus.

In the past, irregular astigmatism was not a field of strong interest by clinicians, as it was not very common, and was not treatable. It could not be corrected with spectacles, and rigid contact lenses could alleviate the problem to some extent only if the irregular astigmatism was corneal in origin.

With the development of keratorefractive surgical procedures, it became increasingly of interest, as keratorefractive surgeries may produce visually significant irregular astigmatism, or be used to treat it.

2.2.1 Keratoconus

Keratoconus (conical cornea) is a condition characterized by a progressive corneal steepening, usually inferior to the center of the cornea (Fig. 2.). As a result of a noninflammatory thinning of the corneal stroma eventually myopia is induced, together with irregular astigmatism, leading to an impairment in the quality of vision.

Keratoconus is a bilateral, usually asymmetric, noninflammatory corneal ectasia, which belongs to a group of corneal shape disorders, together with pellucid marginal corneal degeneration and keratoglobus.

By keratometry keratoconus is classified as:

1. mild (< 48 D)
2. moderate (48-54 D)
3. severe (> 54 D).

Epidemiology and pathogenesis

Keratoconus occurs in all ethnic groups with no male or female preponderance.

Rarely, it can be congenital (Smolin, 1987).

In majority of the cases, its onset is at puberty and then progresses until the third to fourth decade of life, with an incidence of approximately 1 per 2000 in the general population, and a prevalence of 54.5 per 100,000 (Hofstetter, 1959; Kennedy et al., 1986).

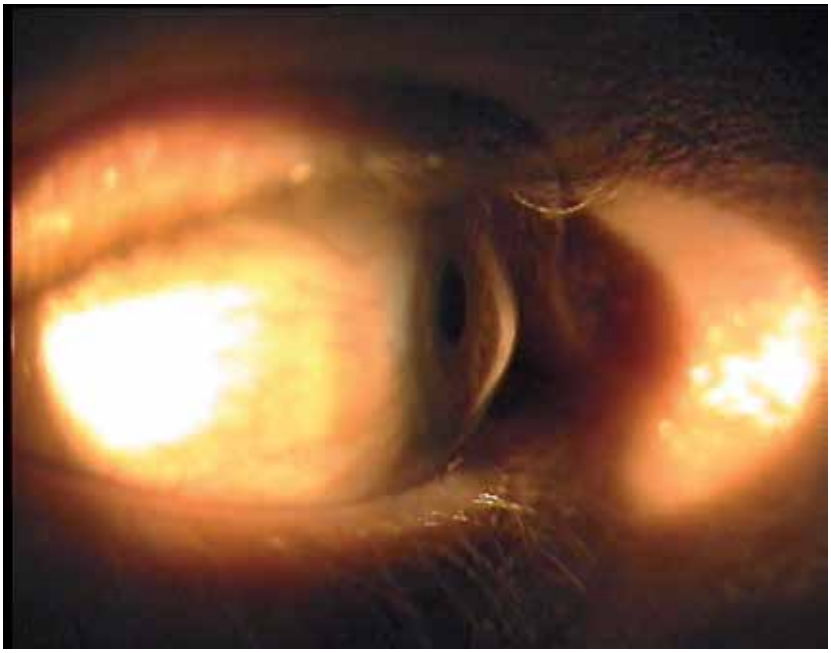

Fig. 2. Keratoconus (conical cornea)

In some cases it may also start later in life and progress at any age.

The etiology of the disease can be divided into three groups:

1. inherited
2. sporadic
3. acquired (secondary or in association to /with other diseases).

The inheritance of keratoconus is still not defined completely. Before the presence of videokeratography it was believed that more than 90 % of cases were sporadic, but recent studies revealed evidence that suggests an autosomal dominant pattern of inheritance (Gonzales & McDonnell, 1992).

Corneal thinning appears to result from a loss of structural components in the cornea, but why this happens is still not clear.

Recent biochemical studies of cornea with keratoconus suggest that enzyme abnormalities in the corneal epithelium, such as increased expression of proteases and other catabolic enzymes (Sawagamuchi et al., 1989) and decreased levels of inhibitors of proteolytic enzymes, may play a role in corneal stromal digestion and degradation (Fukuchi et al., 1994).

Investigations of corneal α1 proteinase inhibitor and α2 macroglobulin (also proteinase inhibitor) support the hypothesis that the degradation process may be aberrant in keratoconus (Sawagamuchi et al., 1994)

Evidence has been provided regarding abnormalities in gene promoters involved in these enzyme activities (Maruyama et al., 2001).

Other studies have reported abnormalities in corneal collagen and its cross-linking, as a potential cause of keratoconus (Bron, 1988).

Some authors have proposed a role for an IL-1 system in the cornea in the pathogenesis of keratoconus. It is suggested that the increased expression of the IL-1 receptor sensitizes the keratocytes to IL-1 released from the epithelium or endothelium, causing a loss of keratocytes through apoptosis and a decrease in stromal mass over time (Wilson et al., 1996).

It is most commonly a single disorder, although much evidence exists that it could be a phenotypic expression of many causes, or part of other multisystem or systemic disorders, as well as ocular non-corneal disorders (Rabinowitz, 1998, table 1).

Multisystem Disorders	Ocular Disorders
Alagille' s syndrome	Aniridia
Albers-Schonberg disease	Anetoderma and bilateral subcapsular cataracts
Angelman syndrome	Ankyloblepharon
Apert' s syndrome	Bilateral macular coloboma
Autographism	Blue sclerae
Anetoderma	Congenital cataracts
Bardet-Biedl syndrome	Ectodermal and mesodermal anomalities
Crouzon' s syndrome	Floppy eyelid syndrome
Down syndrome	Gyrate atrophy
Ehlers-Danlos syndrome	Iridoschisis
Goltz-Gorlin syndrome	Lebers congenital amaurosis
Hyperornithemia	Persistent pupilarry membrane
Icthyosis	Posterior lenticonus
Kurz syndrome	Retinitis pigmentosa
Laurence-Moon-Bardet-Biedl syndrome	Retinal disinsection syndrome
Marphan' s syndrome	Retrolental fibroplasia
Mulvihil-Smith syndrome	Vernal conjunctivitis
Nail patella syndrome	Atopic keratoconjunctivitis
Neurocutaneous angiomatosis	Axenfeld' s anomaly
Neurofibromatosis	Avellino' s dystrophy
Noonan' s syndrome	Chandler' s syndrome
Osteogenesis imperfecta	Corneal amyloidosis
Oculodentodigital syndrome	Deep filiform corneal dystrophy
Pseudoxanthoma elasticum	Essential iris atrophy
Rieger' s syndrome	Fleck corneal dystrophy
Rothmund s syndrome	Fuchs corneal dystrophy
Tourette' s disease	Iridocorneal dystrophy
Turner' s syndrome	Lattice dystrophy
Xeroderma pigmentosum	Microcornea
Congenital hip dysplasia	Pellucid marginal degeneration
False chordae tendineae of left ventricle	Posterior polymorphous dystrophy
Joint hypermobility	Terriens marginal degeneration
Mitral valve prolapse	
Measles retinopathy	
Ocular hypertension	
Thalesselis syndrome	

Table 1. Diseases associated with keratoconus, as reported by different authors

The most common association is with Down syndrome, connective tissue disorders, and Leber's congenital amaurosis (Cullen & Butler, 1963; Iwaszkiewicz, 1989).

Acquired etiologies can be divided into those which are attributed to inflammatory conditions, such as vernal conjunctivitis and those secondary to eye rubbing which can also release inflammatory mediators, such as Leber's congenital amaurosis and Down syndrome.

Many authors report a high incidence of mitral valve prolapse (58%) in patients with advanced keratoconus, while others report of eye rubbing in systemic atopy and cytokine interleukin-1, as a mediator of stromal degradation. Other factors, such as contact lens wear, may play a role in the development of the cone (Krachmer et al.,1984; Sharif et al., 1992).

Also, some studies report 6-8% of cases with positive family history or evidence of familiar transmission (Hallerman & Wilson, 1977; Krachmer et al., 1984).

Ocular manifestations

Early stages of the disorder may not present any symptoms. Cornea may appear normal on slit-lamp examination and there may be no symptoms of the disease. It maya be suspected by an ophthalmologist because the patient cannot be refracted to a 20/20 corrected vision. There might only be a mild steepening of keratometry mires, inferiorly or centrally. In such cases, anterior topography of the central and paracentral cornea will confirm the suspected diagnosis (Krachmer et al, 1984). In advanced cases, there can be a significant visual disturbance followed by a significant visual loss, but, fortunately, patients with keratoconus never become totally blind. Symptoms, as well as clinical signs, are variable and depend on the stage of the progression and on the severity of the disease.

The corneal manifestations include steepening (centrally or paracentrally, most commonly inferiorly or inferotemporally), thinning of the corneal apex, conical protrusion, a ring of iron deposits partially or completely accumulating in the epithelium surrounding the cone *(Fleischer's ring),* anterior scars at the level of Bowman's membrane, enlarged corneal nerves, increased intensity of the corneal endothelial reflex, and deep vertical lines in stroma and Descemet' s membrane, that disappear momentally under digital pressure during slit-lamp examination *(Vogt' s striae).*

The steeping of the cornea leads to clinical signs, which include the V-shaped protrusion of the lower eyelid on downgaze due to the ectatic cornea (*Munson's sign,* Fig. 3.*),* sharply focused light beam at the nasal limbus, produced by lateral illumination *(Rizzuti's sign)*, and a dark reflex using the retroillumination techniques in the area of the cone, when observing the cornea with the pupil dilatation *(Charleaux' s sign),* and an irregular "scissor" reflex on retinoscopy.

Some patients with advanced keratoconus may occasionally experience sudden visual loss and pain due to the acute rupture of Descemet's membrane (acute hydrops). In such cases the conjunctive may be injected, and diffuse stromal edema appears. These breaks in Descemet's membrane result in acute overhydration and a stromal imbibing of aqueous. The overlying corneal epithelium may become edematous. The edema may last for months and, after the resolution of redness and relief of pain over time, can be replaced by scarring (and the corneal steepness may be reduced).

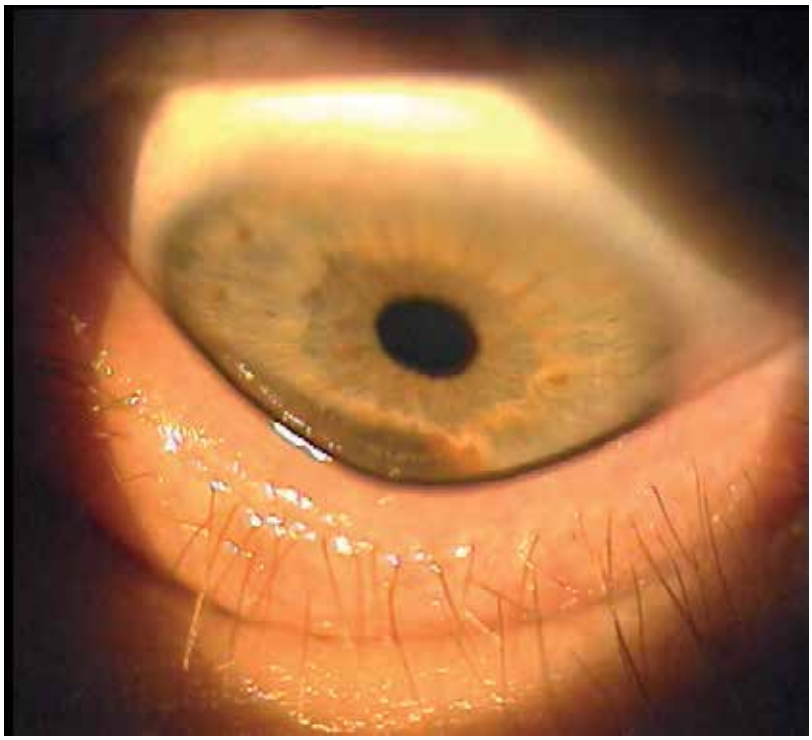

Fig. 3. V-shaped protrusion of the lower eyelid on downgaze due to the ectatic cornea (Munson' s sign)

Histopathology

The classic histopathological triad in keratoconus includes the thinning of the corneal stroma, breaks in Bowman' s layer and iron deposits in the basal layers of the corneal epithelium. Also, every other layer of the cornea can be pathologically affected, depending on the stage of the keratoconus. The endothelium is usually not affected, and the Descemet's membrane is rarely affected, other than in cases of acute hydrops.

Two types of cone morphology may be present. The first one is a „nipple" type cone, located centrally, characterized by small size (5 mm) and steep curvature; the second one is an „oval" type cone, located inferiorly or inferotemporally, characterized by larger size (5-6 mm), and an ellipsoid shape (Perry et al., 1980).

These can be distinguished in most cases on slit-lamp examination, or in the anterior corneal topography.

Diagnosis

To confirm the diagnosis several devices are available from handheld keratoscopes (placido disks), computer-assisted videokeratoscopes to (more recently) computerized videokeratography (Fig.4).

Computer-assisted topographic modeling systems allow the clinicians to detect subtle and minor variations in power distribution of the anterior and posterior corneal surface. The

forme fruste, or subclinical keratoconus, recognized by Placido disk-based topography, requires caution and is considered a contraindication to refractive surgery. With regard to the identification of forme fruste keratoconus, classification programs on corneal topographers may assist in differentiating between keratoconus suspects, corneal distortion, and even patients having undergone refractive surgery, and normal variations of corneal topography.

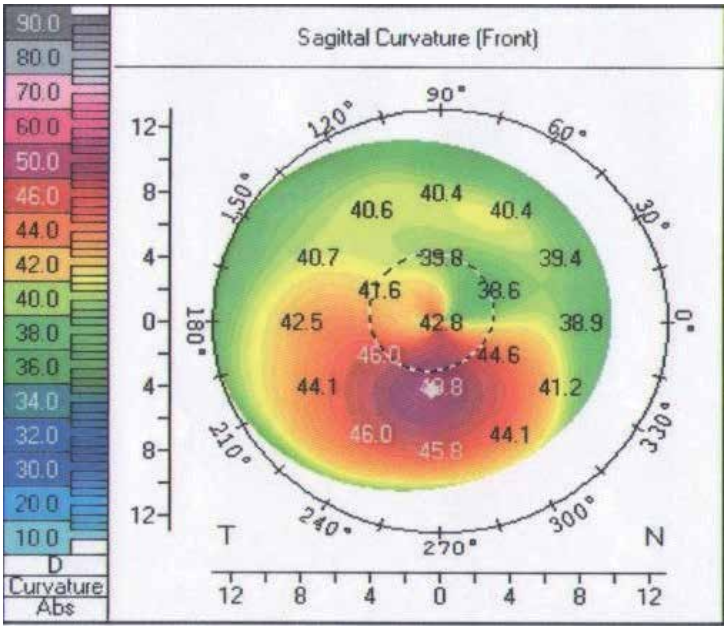

Fig. 4. Color-coded map of peripheral keratoconus. Note the inferior steepening

Rabinowitz has suggested that the diagnosis of keratoconus can be made when keratometry is greater than 47.20 D, the steepening of the inferior cornea compared with the superior cornea is more than 1.2 D, and the skewing of the radial axis of astigmatism is greater then 21° (Rabinowitz YS, 1995).

Differential diagnosis

The differential diagnosis of keratoconus includes other corneal ectasia disorders, such as pellucid marginal corneal degeneration and keratoglobus, and the posttraumatic or post-surgical (after refractive or cataract surgery) corneal ectasia or protrusion of the cornea after corneal ulceration thinning.

Treatment

Treatment of keratoconus starts with spectacles in very early stages, for astigmatism and myopia, and rigid gas permeable contact lenses in cases of inadequate visual acuity correction with spectacles. Contact lenses represent the treatment of choice in 90% of patients (Buxton et al., 1984).

In case of contact lens failure due to a lack of adequate visual acuity, or induced corneal abrasion, apical scarring, neovascularization due to hypoxia, poor lens tolerability and

discomfort and lens displacement, surgical procedure is indicated. The most frequent surgical procedure is penetrating keratoplasty, which refers to the full-thickness replacement of diseased corneal tissue with a healthy donor. The main difficulty during surgery is suturing to the thin corneal bed.

Lamellar keratoplasty is also effective, but is not as frequently used as the penetrating keratoplasty, due to technical challenges and it being more time consuming. It is a procedure in which a partial-thickness graft of donor tissue (donor stroma or sclera) is used to provide tectonic stability and /or optical improvement.

There are generally two types of lamellar keratoplasty: anterior and posterior. In the anterior lamellar keratoplasty, the transplanted tissue does not include corneal endothelium and this procedure avoids endothelial rejection. The aim in deep lamellar and posterior lamellar keratoplasty is to replace diseased corneal endothelium while keeping the anterior corneal surface intact, as well as reducing refractive error and irregular astigmatism. In a short amount of time, deep lamellar endothelial keratoplasty (DLEK), Descemet-stripping endothelial keratoplasty (DSEK), Descemet-stripping automated endothelial keratoplasty (DSAEK) and Descemet' s membrane endothelial keratoplasty (DMEK) have become the techniques of choice for partial corneal transplant surgeries.

Descemet's membrane endothelial keratoplasty (DMEK) and Descemet-stripping automated endothelial keratoplasty (DSAEK) are new types of partial-thickness corneal graft operations, in which only the innermost corneal layers are replaced. Visual recovery is quicker, there is less physical restriction on activities and no related suture problems.

The results of lamellar techniques are far better than epikeratoplasty which has been abandoned due to the suboptimal visual outcomes. A keratoconic patient has a 10-20% chance, over her/his lifetime, of needing a corneal transplant (Smiddy et al., 1988; Tuft et al.,1994).

Intracorneal ring segments Intacts can be also used in cases without corneal scarring to reduce myopia and astigmatism. The purpose of Intacts segment implantation is to defer the need for corneal transplantation and restore contact lens tolerance. The placement of Intacts generates the response that interrupts the biomechanical disease progression, and a biomechanical response that allows visual improvement over six months. The improvement in visual acuity and refraction is accomplished by shortening the path length of the portion of the collagen lamellae that are central to the segments. The redistribution of corneal curvature leads to a redistribution of corneal stress, interrupting the biomechanical cycle of the keratoconus progression.

A relatively new method of treating progressive corneal ectasia is **corneal collagen crosslinking (CXL).** Its clinical use has been rapidly increasing since it was originally introduced in 1997 as the first treatment that could improve the biomechanical stability of the weakened cornea. This method is based on combined action of the photo-sensitizer riboflavin (vitamin B2) and ultraviolet A light, which induce the formation of new covalent bonds between the collagen fibers.

This method has been widely accepted since the first introduction by Spoerl and his co-workers at Dresden University in Germany, in 1997 (Spörl et al., 1997).

The recent advances in diagnostic devices resulted in the detection of more subtle corneal changes, suggesting that the sublinical forms are more common than fully developed keratoconus. The iatrogenic post-LASIK ectasia is the second most common corneal ectasia. It usually appears as a result of refractive surgery performed in predisposed individuals or in patients with an undetected early form of keratoconus. Before the introduction of corneal collagen crosslinking, the only treatment that could halt the progression of keratoconus in most cases was the penetrating keratoplasty.

Studies which have been conducted so far demonstrated the beneficial effect in halting the progression of the diseases, with a very low complication rate (Koller et al., 2009; Tomkins & Garzozi, 2008).

The term „crosslinking"refers to the formation of bonds between natural polymer molecules.

The original crosslinking technique described by Wollensak and co-workers is still being used today, with the minor modifications. (Wollensak et al., 2003).

The photopolymerizing effect is induced by the combined action of riboflavin as a photo-sensitizer, and long wavelength ultraviolet (UVA) light of 370 nm. This particular wavelength was chosen so that riboflavin can achieve a maximal absorption while still remaining bellow harmful radiation levels. During the exposure, riboflavin is excited into a triplet state, generating the so-called reactive oxygen species which, in turn, induce the formation of new covalent bonds (disulphide /s-s) between the amino acids of neighboring collagen fibers.

After the application of a local anesthetic, a lid speculum is inserted and central corneal abrasion up to 9.0 mm in diameter is made. According to the protocol of the Institute for Refractive and Ophthalmic Surgery in Zürich, Switzerland, 0.1% riboflavin solution containing 10 mg of riboflavin-5-phosphate diluted in 10 ml of a 20% dextran solution is instilled every 3 minutes, for 30 minutes. After that, central corneal thickness (CCT) is measured. For safety reasons, additional riboflavin 0.1% hypoosmotic drops without dextran should be applied in corneas whose thickness is less than 400 μm. Otherwise, UVA light should not be applied. The cornea is then irradiated for 30 minutes with an UVA illumination device. The device must provide a homogenous UV radiation with irradiance of 3 mW/ cm^2 at the working distance of 5 cm. During irradiation, the cornea is moistened every 3 minutes with the riboflavin 0.1% drops. The total dosage delivered to the cornea in that way is 5.4 J/cm^2. At the end, antibiotic ointment is applied and bandage lens inserted to facilitate the epithelial healing.

Beside the standard CXL, as described above (with removal of the epithelium), the treatment can also be the transepithelial CXL (without removal of the epithelium). The later has less complications, such as death of keratocytes. Not being invasive, it is very well tolerated.

Indications for cross-linking today are clinical and instrumental progression (refractive, topographic, pachimetric, aberrometric) of corneal ectasia disorders such as keratoconus and pellucid marginal degeneration in the last 6-12 months, iatrogenic keratectasia after refractive lamellar surgery and corneal melting not responding to conventional therapy.

Contraindications include corneal thickness of less than 400 μm, central corneal opacity, epithelial healing disorders, such as map dot dystrophy and rheumatic disorders, refractive keratotomy, previous herpes simplex virus keratitis (UV-A may induce herpes reactivation), corneal melting disorders, concurrent infection, severe ocular surface disease, and pregnancy.

In recent years, corneal collagen crosslinking has become a standard treatment for the progressive corneal ectasia in numerous centers throughout the world. Additional basic and clinical research is necessary in order to establish more precise indications and to demonstrate the permanence of the treatment. Despite the evidence in support of the safety of new procedure, future studies are necessary to define its limitations and its long-term efficacy. It has the potential to reduce corneal curvature by approximately 1.0-1.5 D.

Despite the fact that no sight-threatening complications were recorded in the large prospective studies, there are some sporadic reports of stromal haze resistant to topical steroid treatment (Mazzota et al., 2007), diffuse lamellar keratitis in post-LASIK ectasia, herpetic keratitis and iritis (Kymionis et al., 2007), Acanthamoeba keratitis with corneal perforation (Rama et al., 2009), and microbial keratitis (Pollhammer & Cursiefen, 2009; Zamora & Males, 2009). Other potential complications include delay in reepithelization, sterile infiltrates, potential for induction of herpes simples virus and dendritic ulcer, and ocular surface disorders and tear dysfunction (Corkin, 2009).

The reliable data on the turnover rate of the collagen fibers are still insufficient due to the almost complete absence of corneal remodeling (Wollensak & Iomdina., 2009).

However, data such as the increased resistance to the enzymatic degradation in the crosslinked corneas support the theory of the long –lasting effect of the treatment (Spoerl et al., 2004).

2.3 Other corneal ectasias

Pellucid marginal corneal degeneration

Pellucid marginal corneal degeneration is a variant of keratoconus, characterized by a peripheral band of thinning of the inferior cornea and protrusion from the 4 to 8 o'clock position but a 2 mm uninvolved surface of the cornea between the thinning and the limbus.

It has also been described in scleroderma (Sii et al., 2004) and in Sjögren syndrome (Fernández-Barboza et al., 2009).

The thickness of the central cornea is usually normal but with marked against-the-rule astigmatism. It can nicely be recognized by videokeratography due to the typical „butterfly“appearance that represents a large degree of against-the-rule astigmatism (Maguire et al., 1987).

Treatment includes spectacles or contact lenses. Due to the extensive against-the-rule astigmatism, the success rate for fitting those patients with the hard contact lens is lesser than in patients with keratoconus. In case of inadequately vision corrected patients or in case of lens intolerability, large, eccentric penetrating keratoplasty may be considered.

Keratoglobus

In keratoglobus, in contrast to the localized thinning centrally or paracentrally in keratoconus, the entire cornea is thinned out, especially near the limbus, and has a globular protrusion (Krachmer et al., 1984).

It comes in two forms: a congenital or juvenile form and an acquired, adult form. The congenital form can be part of Ehlers-Danlos syndrome type Vl, or part of the corneal syndrome associated with blue sclera and red hair (Royce et al., 1990).

The adult form can be associated with blepharitis, vernal keratoconjunctivitis, and orbital diseases than cause proptosis (Cameron, 1993).

It has a recessive pattern of inheritance and is often associated with blue sclerae and other systemic features, such as Ehlers-Danlos syndrome and other systemic connective tissue abnormalities. These kinds of corneas can be so thinned that they are prone to corneal rupture from a minimal trauma.

It was also described in thyroid orbitopathy (Jacobs et al., 1974), and was acquired in pellucid marginal degeneration after extracapsular cataract extraction (Rumelt & Rehany, 1998).

Treatment includes protection from trauma, and protective spectacles are strongly recommended. Hard contact lenses are contraindicated. Lamellar epikeratoplasty should be considered to reinforce thin corneas, and in case of acquired keratoglobus, central penetrating keratoplasty may be successful.

Terrien's marginal corneal degeneration

Terrien's marginal degeneration is a bilateral, slowly- progressive condition with marginal corneal ectasia associated with corneal neovascularisation, lipid deposition along the central edge, thinning and opacification. The cause is unknown, but it is likely to be different from the causes of most degenerations that occurs with age. It can occur at any age, but most frequently in men, 20-40 years old. Two types have been described. First one is slowly-progressive and mostly asymptomatic, and occurs in older population. The second one occurs in younger patients, it is more inflammatory in type and may be associated with episcleritis and scleritis (Iwamoto et al., 1972).

Terrien's marginal degeneration initially starts superiorly with peripheral corneal haze, gradually vascularizes, and is followed by corneal thinning that starts between the limbus and line of lipid deposition. Characteristically, a steeper sloping of the cornea occurs at the advancing edge, without the overlying edge like as in Mooren's ulcer (see below).

The thinning progresses circumferentially, but the overlying epithelium is intact.

Unlike the Mooren's ulcer, usually there is no pain or inflammation, but occasionally, it may present with recurrent painful episodes of inflammation. Perforation may occur, but is rare.

A pseudopterygium may occur in an oblique axis in some patients.

Irregular astigmatism is characteristic in the progressive flattening of vertical meridian, and the high degree of against-the rule astigmatism.

Treatment includes the use of rigid gas-permeable contact lenses. More severe thinning may require crescentic, full-thickness or lamellar keratoplasty (Hahn & Kim, 1993).

Mooren's ulcer

Mooren's ulcer is a progressive, crescentic, peripheral corneal ulceration. Two clinical types have been documented. One type occurs primarily in the older population, it is typically unilateral and more responsive to local therapy. The other is bilateral, painful, progressive corneal destruction, mostly in younger individuals, more resistant to systemic immunosuppression. The pathogenesis of Mooren's ulcer is unknown but appears to involve an autoimmune reaction against a specific target molecule in the stroma, which may occur in genetically susceptible individuals (Gottsch et al., 1999).

It has a characteristic extensive, "overhanging" edge which is absent in Terrien's disease, and progresses with a stromal, yellowish infiltrate at the advancing margin. Over time, overlying epithelial defect develops, followed by stromal melting. In the second type, the inflammation may affect all the layers of cornea and perilimbal tissue, and perforation can occur.

Patients complain of severe pain, photophobia and tearing.

In chronic cases, topographical maps show severe irregular astigmatism and peripheral steepening as a result of peripheral corneal thinning and scarring. Unlike the other forms of peripheral ulcerative keratitis, no clear zone between the ulcer and limbus can be seen.

Treatment includes local, systemic, and surgical therapy. Local therapy includes topical corticosteroids, followed by conjunctival resection if inflammation is not controlled, as well as topical cyclosporine drops. Systemic immunosuppressive treatment of the more aggressive bilateral disease has included corticosteroids, cyclosporine and methotrexate (Brown & Mondino, 1984; Foster, 1985).

Other surgical procedures include epikeratoplasty, lamellar keratoplasty, delimiting keratotomy, conjunctival flap and patch grafts of periostium.

2.4 Residual astigmatism (non-corneal astigmatism)

Corneal astigmatism of more than 2D is present in 5% of general population, while at least 93% of the population has at least 0.5D of corneal astigmatism. The percentage of residual astigmatism is between 10% and 80% (Parunovic et al., 1995).

Spherical rigid contact lens can correct total astigmatism if the correction of cylinder with the spectacles is the same value as the value of corneal astigmatism. In some cases there is a difference in value between astigmatism corrected with the spectacles and corneal astigmatism. Astigmatism that rises from this difference is called residual astigmatism, and does not correlate with the anterior surface of the cornea. Residual astigmatism is in most cases lenticular, but can also be derived from a badly fitted contact lens (a decentrated or deformed contact lens).

Lenticular astigmatism may also be caused by lens subluxation, like in Marfan's syndrome (Konradsen et al., 2010; Yeung & Weissman, 1997), changes in lens contour, like in anterior and posterior lenticonus in Alport' s syndrome (Al-Mahmood et al., 2010; Blaise et al., 2003; Hentati et al., 2008; Kim et al., 2010), lenticular trauma etc.

Residual, lenticular astigmatism is most always against-the-rule astigmatism, rarely more than 1D, and usually is masked by correction of total refractive astigmatism. Residual astigmatism (RA) is calculated by subtracting the value of corneal astigmatism (CA) from the value of astigmatism corrected by the spectacles (SC), according the formula: RA = SC - CA.

Example:
Keratometry: 43.00 / 43.50 x 90
Spectacle correction: -2.00 /-1.50 x 180
Residual astigmatism = (- 1.00 x 180) - (- 0.50 x 180) = - 0.50 x 180

2.5 Surgically induced astigmatism

One of the possible complications of cataract surgery (especially extracapsular and intracapsular cataract extraction), as well as penetrating keratoplasty, is induced astigmatism, which is a major cause of functional disturbance and insufficient uncorrected visual acuity.

The aim of cataract surgery today is rapid visual rehabilitation, the best possible uncorrected visual acuity, and minimal postoperative astigmatism.

The phacoemulsification procedure results in less surgically induced astigmatism than extracapsular cataract extraction, in which the incision is much larger.

Clear corneal incision (CCI) is the most used type of incision in phacoemulsification surgery, because it is less time-consuming and doesn't require cauterization or wound suturing. The location of the CCI affects the degree of postoperative astigmatism.

CCI is made deliberately in the steepest meridian if astigmatism is addressed. It can be made at superior, oblique or temporal locations.

Temporal CCI induces regular astigmatism 90 degrees away from the incision (with-the-rule astigmatism) thus minimizing the postoperative astigmatism (Cilino et al., 1997; Cravy, 1991; Hayashi et al., 1994). It is known to induce the least postoperative astigmatism. Also, the smaller the CCI, the lesser the induced astigmatism.

Oblique scleral tunnel incision predictably reduces astigmatism by simultaneously producing corneal flattening and steepening (Simsek et al., 1998).

Some studies have shown that a small superior CCI induces greater postoperative astigmatism than a small supero-oblique CCI, and a small supero-oblique CCI induces higher postoperative astigmatism than a small temporal CCI (Mendivil, 1996; Reiner et al., 1999; Wirbelauer et al.,1997).

Some authors reported that, although temporal CCI is reported to result in the least induced astigmatism, locating the incision superotemporally or superonasally may ease surgical manipulations during the phacoemulsification cataract surgery for a right-handed surgeon who works from the 12 o' clock position relative to the patient (Ermis et al., 2004).

Performing the procedure from the patient's temporal side may not be possible with the most operating tables, and locating the CCI temporally in left eye may be difficult for a right-handed surgeon who sits at the 12 o' clock position.

Several groups of authors analyzed refractive astigmatism in patients who have had phacoemulsification cataract surgery performed by the oblique clear corneal incision. They provided evidence that the supero-oblique clear corneal incision does not induce the clinically significant amount of oblique astigmatism (Jacobs et al., 1999; Brian et al., 2001; Masnec et al., 2007).

Also, evidence is provided that the superotemporal or superonasal CCI has minimal effect on corneal astigmatism (Masnec et al., 2007).

Further studies on more patients should provide definitive conclusions about the influence of the superotemporal or superonasal clear corneal incision on postoperative astigmatism.

Many studies investigated the influence of different factors, such as the type of a surgery, length of incision and its type (curved, straight, frown), location and width of incision (central vs. peripheral-limbal or scleral), presence or absence of a suture and the suturing method, on postoperative astigmatism (Azar et al., 1997; Roman et al., 1998; Simsek et al.,1998; Wirbelauer et al.,1997).

Any incisions that are made in the cornea have the potential to change the curvature and therefore the dioptric power of the cornea in that meridian.

The location as well as the width of the incision affects the degree of postoperative astigmatism.

Typically, corneal incisions cause flattening at the axis where they are made. The basic concepts are:

- The larger the incisions, the greater the flattening

The larger the arc length of the corneal incisions, the more effect it has in flattening the cornea at that meridian. Due to the coupling effect, arc lengths of more than 90° are ineffective.

- The more central the incisions, the greater the flattening

Most surgeons prefer performing limbal relaxing incisions (LRIs) at the periphery of the clear cornea. Due to this location, they tend to be more forgiving, heal better, and are less likely to cause irregular astigmatism. But, due to the distance from the central cornea and increased thickness of the cornea at the periphery, these incisions have less effect than astigmatic keratotomy (AK) incisions, which are more centrally placed.

- For penetrating incisions, the shorter the tunnel length, the greater the flattening

Creating an "astigmatically neutral" clear corneal incision during cataract surgery requires the incision to have a sufficient tunnel length. This reduces the compromise of the corneal structure at the incision site and induces little change in the corneal astigmatism. For increasing the astigmatic effect of the corneal incisions, the surgeon can make the tunnel length shorter; however, this results in an incision that may be more prone to leaking during the postoperative period. Surgeon can also vary the position of the corneal incision so that it is placed on the steep axis and, therefore, any induced flattening will help the patient by reducing astigmatism.

- For nonpenetrating incisions, the deeper the incision, the greater the flattening

Most nomograms for LRIs call for nonpenetrating incisions that are placed perpendicularly to corneal tissue. With incisions that are made at 80% or 90% of the corneal thickness, as measured by pachymetry, there is a significant flattening of the corneal astigmatism. As the incisions become more shallow, their effect is lesser, and incisions at less than half corneal depth have little effect on the corneal curvature and power (Budak et al., 1998; Gills et al., 2003; Nichamin, 2006; Thornton, 1994; Wang et al., 2003).

3. Conclusion

Beside the congenital astigmatism which is usually inherited, acquired form of astigmatism can be a result of various intraocular surgeries.

Regular astigmatism is correctable by cylindrical spectacle lenses and contact lenses. In case of irregular astigmatism, cylindrical lenses usually do not help and rigid contact lenses may be useful.

That is usually a consequence of pathological changes of cornea, such as keratoconus, or the lens.

In the past, irregular astigmatism was not very interesting for clinicians because it was not very common and not treatable. However, with the development of keratorefractive surgical procedures, it became increasingly of interest as, in many cases, keratorefractive surgeries produce visually significant irregular astigmatism and, at the same time, may also be able to treat it.

Special focus still remains on keratoconus, a disorder characterized by progressive corneal steepening due to the loss of structural components in the cornea, but its cause is still unclear. It is difficult to treat, and a keratoconic patient has a 10-20% chance, over their lifetime, of needing a corneal transplant. Still, in 90 % of patients contact lenses represent the treatment of choice.

In recent years, corneal collagen crosslinking has become a standard treatment for the progressive corneal ectasia in numerous centers throughout the world, because much evidence has been provided that it can improve biomechanical stability of the weakened cornea.

Additional basic and clinical research is necessary in order to establish more precise indications and to demonstrate the permanence of the treatment. Despite the evidence in support of the safety of this new procedure, future studies are necessary to define its limitations and its long-term efficacy.

Wavefront Aberrations

Mirko Resan, Miroslav Vukosavljević and Milorad Milivojević
Eye Clinic, Military Medical Academy, Belgrade, Serbia

1. Introduction

The eye is an optical system having several optical elements that focus light rays representing images onto the retina. Imperfections in the components and materials in the eye may cause light rays to deviate from the desired path. These deviations, referred to as optical or wavefront aberrations, result in blurred images and decreased visual performance (1).

Wavefront aberrations are optical imperfections of the eye that prevent light from focusing perfectly on the retina, resulting in defects in the visual image. There are two kinds of aberrations:

1. Lower order aberrations (0, 1st and 2nd order)
2. Higher order aberrations (3rd, 4th, … order)

Lower order aberrations are another way to describe refractive errors: myopia, hyperopia and astigmatism, correctible with glasses, contact lenses or refractive surgery. Lower order aberrations is a term used in wavefront technology to describe second-order Zernike polynomials. Second-order Zernike terms represent the conventional aberrations defocus (myopia, hyperopia and astigmatism). Lower order aberrations make up about 85 per cent of all aberrations in the eye.

Higher order aberrations are optical imperfections which cannot be corrected by any reliable means of present technology. All eyes have at least some degree of higher order aberrations. These aberrations are now more recognized because technology has been developed to diagnose them properly. Wavefront aberrometer is actually used to diagnose and measure higher order aberrations. Higher order aberrations is a term used to describe Zernike aberrations above second-order. Third-order Zernike terms are coma and trefoil. Fourth-order Zernike terms include spherical aberration, and so on. Higher order aberrations make up about 15 percent of the overall number of aberrations in an eye.

2. Myopia

Myopia (nearsightedness, shortsightedness) is a refractive error where parallel light rays coming from a distance after refraction through the cornea and lens focus before the retina in the vitreous body and mature behind the focus in the state of divergence generate on retina wasteful circles (Fig. 1 and 3). Because of this, the image that one sees is out of focus when looking at a distant object but comes into focus when looking at a close object. Therefore, shortsighted people cannot see clearly at a distance (2).

Myopia can be classified by cause, degree, clinical features and age of onset. By cause myopia can be: *axial myopia*, attributed to an increase in eyes axial length (more than 24 mm), and *refractive myopia*, attributed to the condition of refractive elements of the eye, like curvature myopia (increased curvature of cornea) or index myopia (variation in the index of refraction of one or more ocular media, like in nuclear cataract). By degree myopia can be: *low myopia* (−3.0 diopters or less), *medium myopia* (between −3.0 and −6.0 diopters), and *high myopia* (−6.0 diopters or more). By clinical features myopia can be: *simple myopia*, characterized by the eye being too long for its optical power or optically too powerful for its axial length, and *degenerative* (*malignant, pathological, progressive*) *myopia* characterized by expressed fundus changes (conus myopicus, staphyloma posticum, degeneratio chorioretinae peripherica, maculopathia) and associated with a high refractive error and subnormal visual acuity after correction. This form of myopia worsen progressively over time and can become complicated with retinal tear and retinal detachment. By age of onset myopia can be: *congenital myopia*, present at birth and persisting through infancy, *youth-onset myopia* (*school myopia*) with onset between around 5 years of age and physical maturity, *early adult-onset myopia* with onset after physical maturity and up to about 40 years of age, and *late adult-onset myopia* with onset after around 55 years of age due to changes in the nucleus of the crystalline lens (2,3,4,5,6).

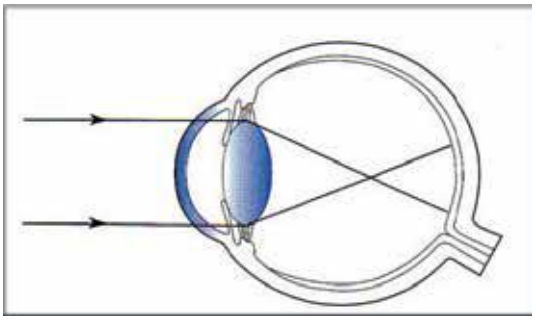

Fig. 1. Myopia with accommodation relaxed. Parallel light rays from infinity focus to a point anterior to the retina, forming a blurred image on the retina (6).

3. Hyperopia

Hyperopia (farsightedness, longsightedness) is a refractive error where parallel light rays coming from a distance after refraction through the cornea and lens focus behind the retina without participation of accommodation (Figs. 2 and 3). Causes of hyperopia are typically genetic and involve an eye that is too short or a cornea that is too flat, so that images focus at a point behind the retina (2).

Hyperopia can be classified by: cause, clinical features and accommodative status. By cause hyperopia can be: *axial hyperopia*, attributed to a decrease in eyes axial length (less than 24 mm), and *refractive hyperopia*, attributed to the condition of refractive elements of the eye like decreased curvature of cornea (cornea plana). By clinical features hyperopia can be: *simple*, *pathological* (resulting in amblyopia or strabismus), and *functional*. By accommodative status hyperopia can be: *total*, *latent*, and *manifest*. Total hyperopia occurs in state of full paralysis of accommodation (after application of cycloplegics) and represents the amount of entire refractive error. Latent hyperopia is that part of the refractive error being corrected with

accommodation. Manifest hyperopia is the accommodation uncorrected part of hyperopia and becoming closer to the total one with age (2,3,4,5,6).

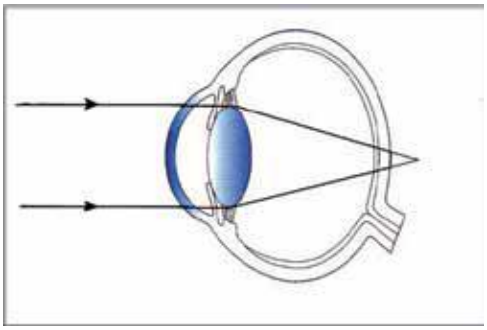

Fig. 2. Hyperopia with accommodation relaxed. Parallel light rays from infinity focus to a point posterior to the retina, forming a blurred image on the retina (6).

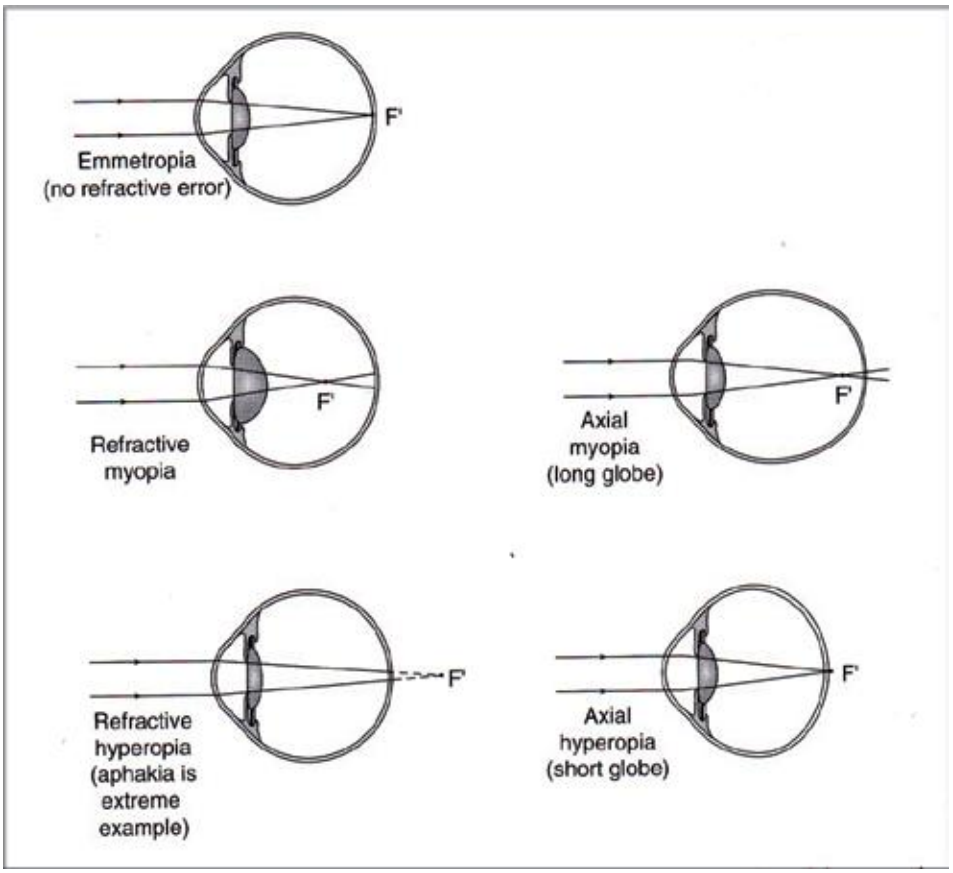

Fig. 3. Refractive errors (myopia and hyperopia) defined by the position of the secondary focal point with respect to the retina, with accommodation fully relaxed. The secondary focal point of a myopic eye is the front of the retina inside the vitreous, whereas the focal point of a hyperopic eye is behind the retina (7).

4. Astigmatism

Astigmatism is a refractive condition in which the eye optical system is incapable of forming a point image for a point object. This is because the refracting power of the optical system varies from one meridian to another. There are complex optical relationships in astigmatism: no focus (as in myopia and hyperopia), but the two focal lines corresponding to main meridians. The meridians of greatest and least refraction are defined as main (principal) meridians. Astigmatism is caused by the cornea or the crystalline lens. Clinically, most astigmatisms are corneal in origin and mainly related to the change in curvature of the cornea (3,4).

There are different types of astigmatism, according to the method of classification (2,3,4,5,6).

Astigmatism is *regular* when two main meridians are 90° to each other; it is correctable with cylindrical or spherocylindrical lenses. Otherwise, the astigmatism is *irregular*. Regular astigmatism is *with-the-rule (direct)* when the steepest corneal meridian is close to 90° (±20°) and *against-the-rule (indirect)* when the steepest meridian is close to 180° (±20°). When the astigmatism is regular but the main meridians do not lie close to 90° or 180°, it is *oblique*.

Astigmatic errors are also described by the location of secondary focal lines relative to the retina (with accommodation relaxed). *Compound myopic* astigmatism occurs when both of the main meridians are myopic, pulling the focal lines off the retina into the vitreous. In *simple myopic* astigmatism, one meridian is emmetropic and the other is myopic, one focal line is on the retina and the other is pulled into the vitreous. *Compound hyperopic* astigmatism occurs when both of the main meridians are hyperopic, pulling the focal lines behind the retina. In *simple hyperopic* astigmatism, one meridian is emmetropic and the other is hyperopic, one focal line is on the retina and the other is pulled behind the retina. *Mixed* astigmatism occurs when one meridian is hyperopic and the other is myopic (Fig. 4).

Astigmatism can be natural or surgically induced. *Natural* astigmatism is common, that is, around 15% of adult population have astigmatism > 1D and 2% have astigmatism > D. Special group of astigmatisms are those surgically induced, *postoperative* astigmatisms. Any surgical intervention in the fibrous mantle of the eye (cornea, sclera) may result in major or minor postoperatively acquired astigmatisms. Classic and most common postoperative astigmatism occurs after cataract surgery, especially after extra- and intracapsular cataract extraction. It is very minimal after phacoemulsification (2).

As noted, the cornea is usually the source of clinically significant amounts of astigmatism. The amount of *corneal* astigmatism, along with the location of meridians of least and greatest refraction, can be easily determined with a keratometer. The vast majority of corneas have with-the-rule astigmatism; a small minority of corneas have against-the-rule or oblique astigmatism, and a small minority have no astigmatism. As compared to corneal astigmatism, *internal* astigmatism is relatively small in amount, tending to slightly vary from one person to another, and is almost always against-the-rule. Main causes of internal astigmatism are the toricity of the back surface of the cornea and the tilting of the crystalline lens. There is no clinical method of measuring internal astigmatism. *Refractive (total)* astigmatism includes both corneal and internal astigmatism and can be determined with refractometry (total determination of refraction) (3).

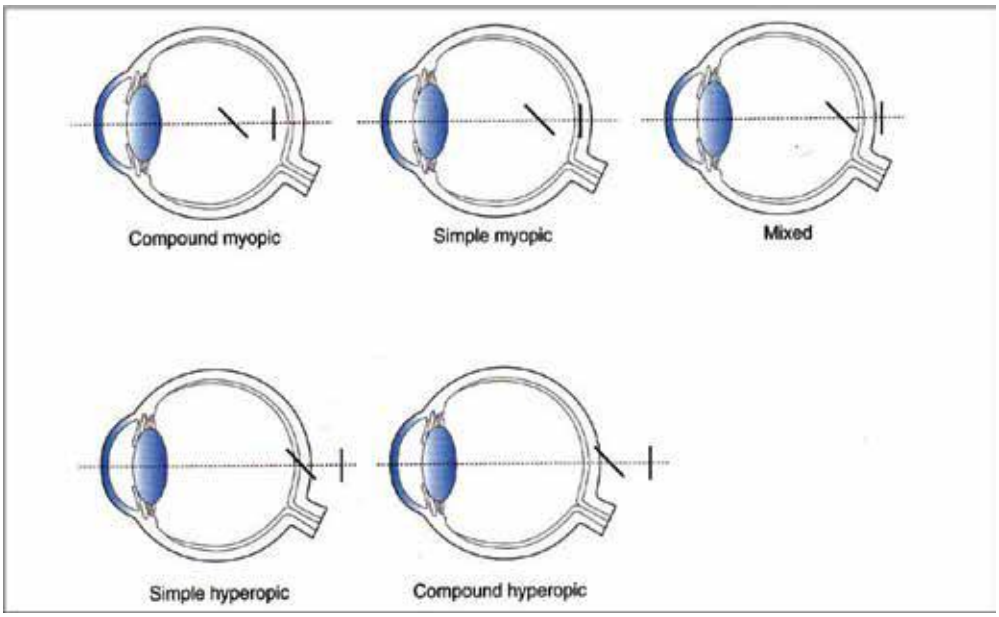

Fig. 4. The locations of focal lines with respect to the retina define the type of astigmatism (6).

5. Higher order aberrations (HOAs)

Within the past decade, rapid improvement in wavefront-related technologies, including the development of sensors for measuring optical properties of the eye in a clinical environment, allowed the ophthalmic community to move the wavefront theory of light transmission from an academic concept to one being central for better understanding of the effect of aberrations on visual performance and the corresponding image-forming properties of the eye. Imperfections in the optics of the eye are now measured and expressed as wave aberration errors. The wave aberration defines how the phase of light is affected as it passes through the eye's optical system, and is usually defined mathematically by a series of Zernike polynomials. Zernike polynomials are used to classify and represent optical aberrations because they consist of terms of same form as the types of aberrations observed when describing the optical properties of the eye, and can be used reciprocally with no misunderstanding. Moreover, the advantage of describing ocular aberrations using the normalized Zernike expansion, generally depicted as a pyramid (Figs. 5 and 6), is that the value of each mode represents the root mean square (RMS) wavefront error attributable to that mode. Coefficients with a higher value identify the modes (aberrations) that have the greatest impact on the overall RMS wavefront error in the eye and thus in reducing the optical performance of the eye (8).

The two most important HOAs are coma and spherical aberration. Coma is the distortion in image formation occurring when a bundle of light rays enters an optical system not parallel to the optic axis. Coma results in off-axis point sources such as stars appearing distorted, with a comet-like tail. Spherical aberration is the blurring of an image, occurring when light from the margin of a lens or mirror with spherical surface comes to a focus shorter than light from the central portion. The changing focal length is caused by deviations in lens or mirror surface from a true sphere.

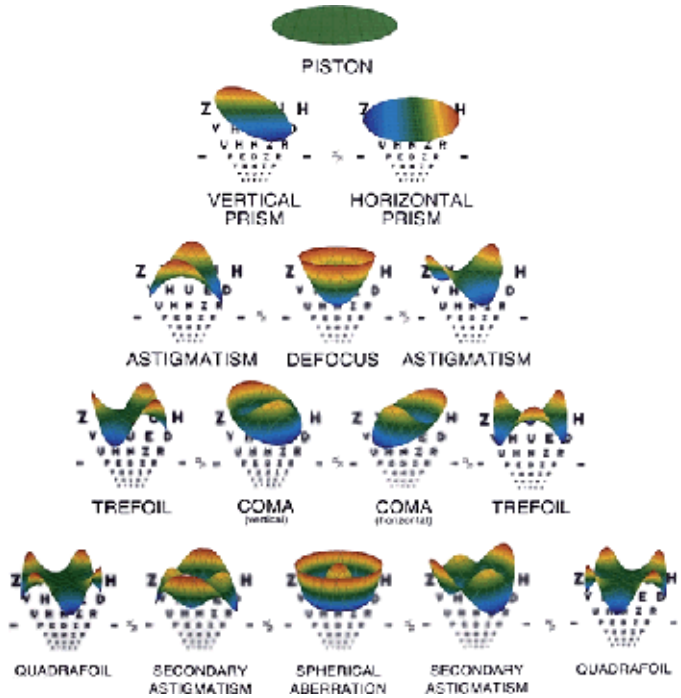

Fig. 5. This chart reveals more common shapes of aberrations created when a wavefront of light passes through eyes with imperfect vision. A theoretically perfect eye (top) is represented by an aberration-free flat plane known, for reference, as piston. (Image: Alcon Inc.)

HOAs are vision errors more complex than lower-order aberrations. HOAs have relatively unfamiliar names such as coma, spherical aberration and trefoil. These types of aberrations can produce vision errors such as difficulty seeing at night, glare, halos, blurring, starburst patterns or double vision (diplopia). No eye is perfect, which means that all eyes have at least some degree of HOAs. These aberrations are now more recognized because technology has been developed to diagnose them properly.

HOAs are measured by aberrometer (wavefront sensor). Aberrometers measure the distortion of a light wave as it is altered by passing through the optics of the eye. A plane wave of monochromatic light will be distorted by optical imperfections. Wavefront sensors do not measure light scatter (from stromal haze or corneal scars), chromatic aberrations or diffraction phenomena. Their effects on vision should be assessed by other means. A useful way to think of distortions in a wavefront is to think of the path length of parallel rays entering the pupil and projecting toward the retina. As light enters the eye from the air, its speed is retarded according to the refractive index of the material along its path to the retina. Arrival time is also influenced by the traveling distance. These two factors, refractive index and linear path variations, are measured with a wavefront sensor. A map can be made to show relevant retardation that a plane wave undergoes as it traverses the optics of the eye. Clinicians are now used to see this information displayed as Zernike polynomial expansion. In order to parcel the wavefront error into individual building blocks, a set of normalized Zernike polynomials is best fit to the measured wavefront error. The coefficient of each Zernike term reveals that term's relative contribution to the total root mean square (RMS) error (Fig. 7) (9).

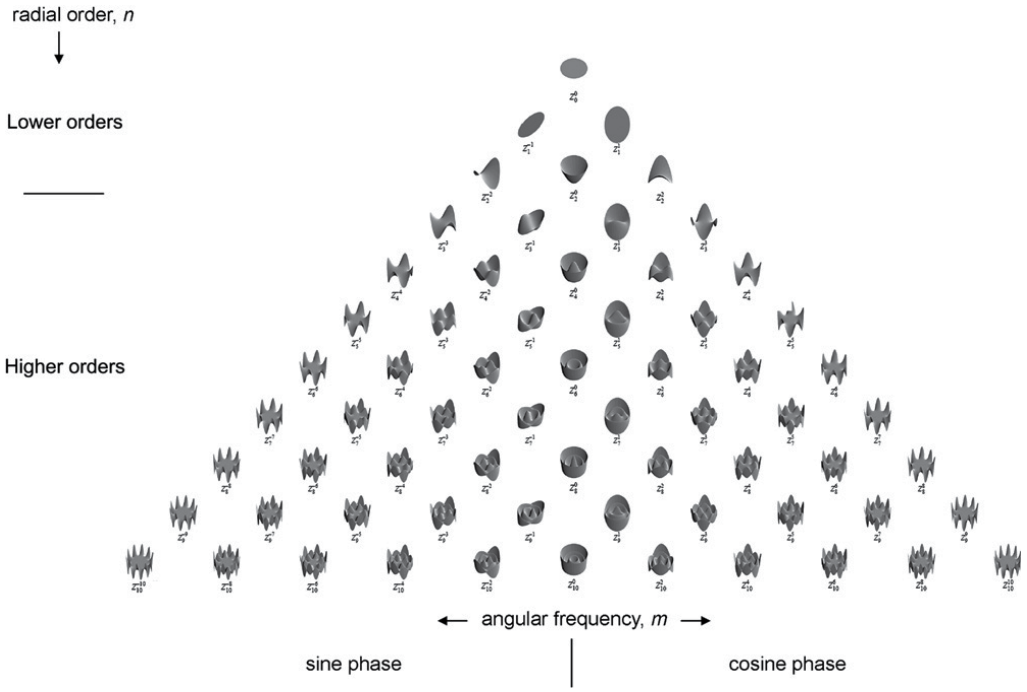

Fig. 6. The Zernike pyramid showing polynomials up to the 10th orders. The 0- to 2nd-order terms represent low optical aberrations in the eye, with 2nd-order terms (i.e. defocus and astigmatism) having the highest contribution to the overall wavefront aberration in the eye. Terms of the 3rd order and higher represent the HOAs. The 3rd- and 4th-order terms are the most prevalent HOA in the human eye (8).

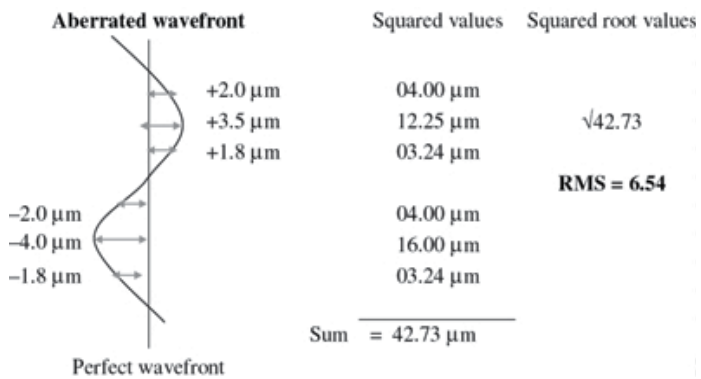

Fig. 7. Graphical representation of root mean squared wavefront error (9).

In the ametropic eye, defocus (i.e. myopia or hyperopia) is by far the largest aberration, followed by astigmatism. These are low order terms. The Zernike pyramid is useful (Table 1). As we follow down the rows from the top, we go from low order to high order. Low order encompasses the top three rows' piston, tilt, tip, and sphere and astigmatism. Row three (i.e. sphere and astigmatism) is what we normally measure and prescribe in spectacles. The fourth row is called third order aberrations, and it continues from there. Anything

beyond lower order is lumped under the term of higher order aberrations (HOAs). As observed from the diagram, they have individual names such as coma, and spherical aberration. When interpreting data, we need to know whether the wavefront refers to total aberrations (9).

Plot index	Term	Binomial representation	Polynomial (ρ,θ)
1	Tip	(1,1)	$2\rho\sin(\theta)$
2	Tilt	(1,1)	$2\rho\cos(\theta)$
3	Defocus	(2,0)	$\sqrt{3}\,(2\rho^2 \angle 1)$
4	Astigmatism	(2,2)	$\sqrt{6}\,\rho^2\sin(2\theta)$
5	Astigmatism	(2,2)	$\sqrt{6}\,\rho^2\cos(2\theta)$
6	Vertical coma	(3,1)	$\sqrt{8}\,(3\rho^3 \angle 2\rho)\sin(\theta)$
7	Horizontal coma	(3,1)	$\sqrt{8}\,(3\rho^3 \angle 2\rho)\cos(\theta)$
8	Trefoil	(3,3)	$\sqrt{8}\,\rho^3\sin(3\theta)$
9	Trefoil	(3,3)	$\sqrt{8}\,\rho^3\cos(3\theta)$
10	Spherical aberration	(4,0)	$\sqrt{5}(6\rho^4 \angle 6\rho^2 + 1)$
11	Secondary astigmatism	(4,2)	$\sqrt{10}\,(4\rho^4 \angle 3\rho^2)\sin(2\theta)$
12	Secondary astigmatism	(4,2)	$\sqrt{10}\,(4\rho^4 \angle 3\rho^2)\cos(2\theta)$
13	Tetrafoil	(4,4)	$\sqrt{10}\,\rho^4\sin(4\theta)$
14	Tetrafoil	(4,4)	$\sqrt{10}\,\rho^4\cos(4\theta)$

Table 1. Zernicke pyramid (9).

In the normal ametropic eye, HOAs are a relatively small component, comprising about 10% of eye's overall aberrations. This varies between individuals. Figure 8a shows a 2-D wavefront of a normal ametropic eye with a low amount of HOAs (0.14μm), and Figure 8b shows a subtle form fruste keratoconic eye with a larger amount (0.42μm) of HOAs. Both images are for data at a 6 mm pupil size. It is important to know what the pupil size was when aberrometry was performed, and at what pupil size data was presented, as HOAs increase with increased pupil size (9).

Three different wavefront measuring principles are available to measure aberrations: (1) Hartmann-Shack, (2) Tscherning or ray tracing, and (3) automated retinoscopy. A Hartmann-Shack aberrometer is an outgoing wavefront aberrometer. It measures the shape of the wavefront that is reflected out of the eye from a point source on the fovea. An array of microlenslets is used to subdivide the outgoing wavefront into multiple beams which produce spot images on a video sensor. The displacement of each spot from the corresponding nonaberrated reference position is used to determine the shape of the wavefront. A Tscherning, or ray-tracing, aberrometer is an ingoing instrument. It projects a thin laser beam into the eye, parallel to the visual axis, and determines the location of the beam on the retina by using a photodetector. Once the position of the first light spot on the retina is determined, the laser beam is moved to a new position, and the location of the second light spot on the retina is determined. Aberrations in the optical system cause a shift in the location of the light spot on the retina. The third type, automated retinoscopy, is based on dynamic skiascopy. The retina is scanned with a slit-shaped light beam, and the reflected light is captured by an array of rotating photodetectors over a 360° area. The time difference of the reflected light is used to determine the aberrations. Visser et al. compared total ocular aberrations and corneal aberrations identified with four different aberrometers and

determined the repeatability and interobserver variability. In this prospective comparative study, 23 healthy subjects underwent bilateral examination with four aberrometers: the Irx3 (Hartmann-Shack; Imagine Eyes, Orsay, France), Keratron (Hartmann-Shack; Optikon, Rome, Italy), iTrace (raytracing; Tracey Technologies, Houston, TX), and OPD-Scan (Automated Retinoscopy; Nidek, Gamagori, Japan). Six images per eye were obtained. Second-, third- and fourth-order spherical aberrations were exported for 5.0-mm pupils. Results demonstrate that significant differences in measurements were found for several total ocular aberrations (defocus [2,0], astigmatism [2,2], trefoil [3,-3], trefoil [3,3], and spherical aberration [4,0]) and corneal aberrations (defocus [2,0] and astigmatism [2,2]).

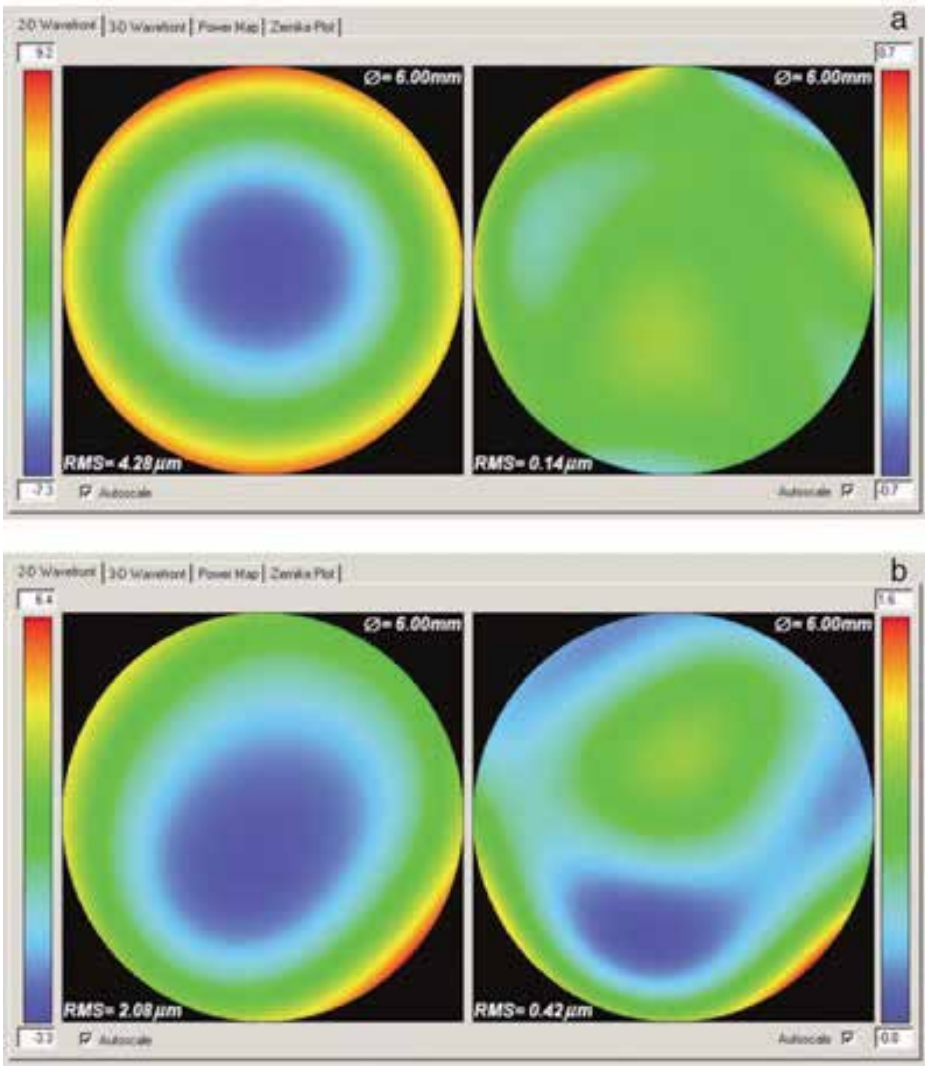

Fig. 8. HOAs represented by 2-D image: (a) eye with low degree, and (b) eye with high degree of HOAs (HOAs measured by Alcon LADARWave) (9).

The Irx3 showed the highest repeatability in measuring total ocular aberrations, followed by the Keratron, OPD-Scan, and iTrace. The repeatability of corneal aberration measurements was highest for the iTrace, followed by the Keratron and OPD-Scan. The OPD-Scan showed a lower interobserver variability, compared with the Irx3, Keratron, and iTrace. In conclusion, total ocular and corneal aberrations are not comparable when measured with different aberrometers. Hartmann-Shack aberrometers showed the best repeatability for total ocular aberrations, and iTrace for corneal aberrations (10).

In our clinic we use WaveLight Analyzer (WaveLight Germany) as aberrometer. Working in the same visible spectrum as the human eye, the WaveLight Analyzer is designed for wavefront measurements on the basis of the Tscherning principle. In order to perform measurements according to the Tscherning principle, an image of regular measurement spots is projected onto the retina and captured by a lightsensitive camera. The distortion of the light spots on the retina in relation to the reference light bundle is calculated and the wavefront error is displayed. Figure 9 shows HOAs in a male aged 32 with myopia on his left eye. Wavefront refraction: -6.54/-1.14 ax 72°, coma: 0.16μm, spherical aberration: 0.02 μm, and pupil diameter: 6.59 mm.

Can HOAs be corrected? Wavefront technology has been advanced enough only in the last few years to produce accurate measurements and diagnoses of HOAs. Some types of new wavefront designed glasses, contact lenses, intraocular lens implants and wavefront-guided laser vision correction can correct HOAs.

One of the most powerful clinical applications of aberrometry is wavefront-guided refractive surgery. With the development of wavefront analyses, the increase of the HOAs of the eye following conventional photorefractive keratectomy (PRK) has been confirmed (11). Wavefront-guided refractive surgery is a technique using excimer or other lasers to correct not only spherical and cylindrical refractive errors but also HOAs. Seiler et al. reported the first application of wavefront-guided laser *in situ* keratomileusis (LASIK) using a Tscherning aberrometer to measure the HOAs (12). McDonald performed almost simultaneously the first wavefront-guided LASIK using data obtained from the Hartmann–Shack wavefront sensor (13).

Several excimer laser platforms are available today. Although various terminology has been used to label, identify, and differentiate treatment modalities, the most commonly used include conventional laser in situ keratomileusis (LASIK); wavefront-guided treatments, which customize ablation patterns based on higher- and lower-order aberration profiles unique to the eye being treated; and wavefront-optimized treatments, which take some eye variables into account but use pre-programmed ablation profiles based on population analysis. Wavefront-guided treatments are intended to reduce preoperative HOAs, and wavefront-optimized treatments are intended to minimize the induction of postoperative HOAs; both modalities minimize significantly postoperative HOA changes compared with conventional LASIK treatments. There are some reported differences in the outcomes of wavefront-guided and wavefront-optimized platforms; however, few studies have directly compared the outcomes of these different technologies. The results in these studies are inconsistent, some indicating an advantage for wavefront-guided treatments and others finding no significant differences between the 2 treatment algorithms for patients without significant preoperative HOAs (14).

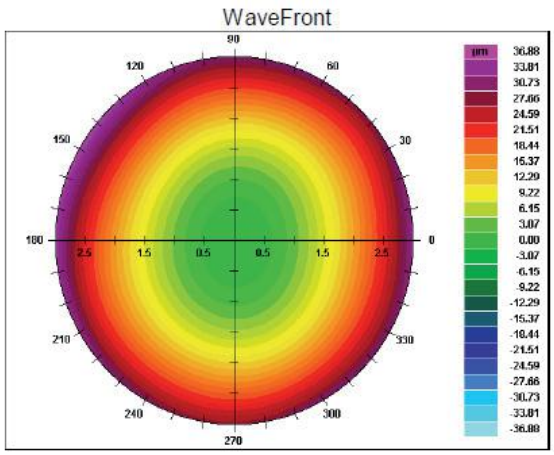

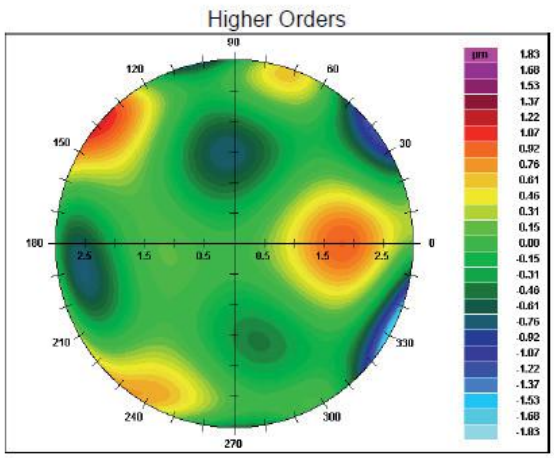

Fig. 9. Wavefront aberrations recorded on WaveLight Analyzer (WaveLight Germany).

Fares et al. compared the efficiency, predictability, safety, and induced HOAs between wavefront-guided and non-wavefront-guided ablations. Their meta-analysis showed that the increase in HOAs in patients who had wavefront-guided LASIK was lesser than in those who had non-wavefront-guided LASIK (15).

We experienced in our clinic that refractive surgical procedures (LASIK and PRK) induce HOAs and usually do not reduce visual acuity. Here is a brief overview of a case of increasing coma after successful correction of mild myopia using PRK: the patient was a male aged 27, and a PRK method was performed on his right eye with myopia. WaveLight Allegretto (400 Hz) excimer laser was used. HOAs were measured preoperatively and postoperatively on WaveLight Analyzer. Preoperative best spectacle corrected visual acuity of the right eye was with - 0.75/-0.25 ax 134° = 1.0, and postoperative uncorrected visual acuity was 1.0. Optical zone of 6.5 mm and ablated zone of 9.0 mm were used. Coma was increased from 0.02 μm preoperatively to 0.15 μm postoperatively, and sperical aberration was the same (0.08 μm) (Figs. 10 and 11).

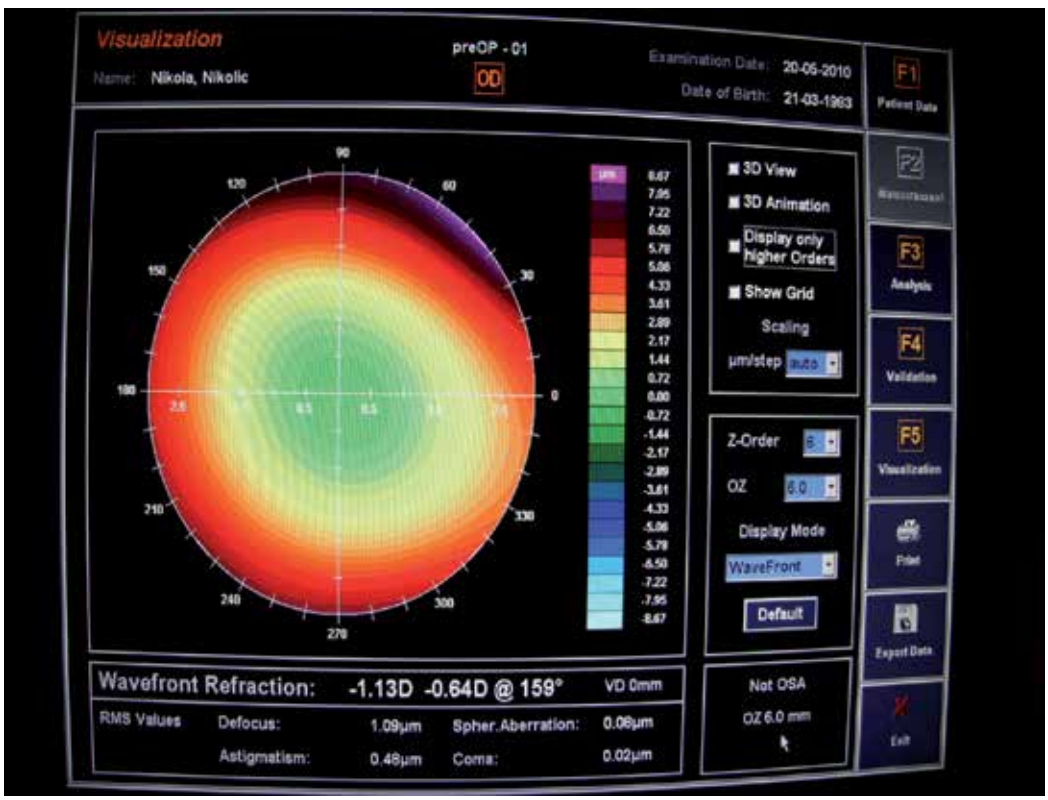

Fig. 10. Picture of wavefront aberrations preoperatively.

Non-Surgical Treatment of Astigmatism

Luciane B. Moreira
Ophthalmology Department, Federal University of Paraná, Curitiba
Brazil

1. Introduction

People with astigmatism have several options available to regain clear vision. They include eyeglasses, contact lenses, orthokeratology and refractive surgery procedures. In this chapter, we will talk about non-surgical treatment only.

2. Eyeglasses

Eyeglasses are a choice for correction for people with regular astigmatism and it doesn't improve vision for irregular astigmatism. They will contain a cylindrical lens prescription for the astigmatism in a specific meridian of the lens which designates the axis of the lens power. Myopia or hyperopia can be associated to astigmatism. Generally, a single vision lens is prescribed so as to provide clear vision at all distances. However, for patients over the age of 40 who have presbyopia, a bifocal or progressive addition lens may be needed in order to focus effectively for near vision work.

A wide variety of lens-types and frame designs are now available for patients of all ages. Eyeglasses are no longer just a medical device that provides needed vision correction, but also a means of enhancing appearance. However, any astigmatism correction numerically higher than a cylinder +1.50 or -2.50 should warrant special consideration of lenses and frames.[1]

Some consideration must be made with the intention of obtaining the best adaptation of the patient to their eyeglasses. A good frame should be lightweight, strong, fit comfortably and suit the wearer's sense of style. Over-sized lenses or much curved frames need to be avoided because they can induce distortion in the periphery of the lens. Eyeglasses with small scaffoldings have a minor possibility of producing alterations in the periphery of the lens. The lesser the distance-vertex, the less will be the disparity in the magnification of the image as it enters the meridians of the astigmatism. The use of negative cylindrical lenses for this sends information to locate the correction of the astigmatism in the posterior part of the lens and consequently next to the ocular globe.[2]

The design of the lens influences the adaptation of the eyeglasses. The lenses of spectacles for correcting astigmatism should have a toric or cylindrical surface in order to give a single focal point in the retina. The thickness of the lens is not the same across its surface. This difference in thickness is increased due to the strength of the astigmatism.[3]

Aspheric lenses are not like conventional lenses in that they do not have a spherical front curvature but instead have differing degrees of curvature. This allows wearers to see clearly whether they are looking directly ahead or to either side. Aspheric lenses can also be combined with a high index material so as to produce extremely thin lenses which provide the same great vision improvement.[1]

Lens material is also important. In general, lenses are made from three materials: plastic, glass, and polycarbonate.[3] Glass is still used for lenses and it is scratch resistant, but it is also heavy and breakable. Polycarbonate and Trivex lenses are designed for high impact resistance and are ideal for occupational hazards, children and athletes. They provide the best eye protection. Plastic is the most used material for lenses. The ones made of high index resin are thin, lightweight, provide good optical quality and do not magnify the eyes as with the others. The term 'Index of refraction' is used to describe the speed at which light travels through a material: a higher index results in thinner lenses.

The lenses of eye glasses can also be upgraded with scratch protectant, anti-reflective, UV-protectants, colour tints, or photochromics. A scratch protectant coating helps the lenses become more resistant against most abrasions. A UV coating helps to reduce the amount of UV rays that enter the eyes by blocking it through the lens. Anti-reflective lenses diminish glare and reflections, and allow people to see your eyes without any problem. They are designed to lighten up the tint when in the shade and darken the tint when in direct sunlight. Polarised lenses are like sunglasses in that they are tinted with a polarisation filter and they block vertical light from placing stress on the eyes. They are good for outdoor activities where the sun will be glaring down.[3]

Doctors should instruct patients about the best glasses for their needs, checking the history and the eye exam of each one. The ideal method is to prescribe the spectacles after eyeglass trials, giving the patients the opportunity to see how they feel in the situations that are common in their everyday life. Often, the physician will try to give the best monocular correction at the refractor to their patients; however, when the patient uses the eyeglasses, with both eyes open, they will not obtain much comfort and will sometimes feel dizzy and get a headache. Ultimately, one needs to take into consideration the binocular vision, the differences between the eyes, the interpupillary distance and the pantoscopic angle of the scaffolding.[4] (figure 1).

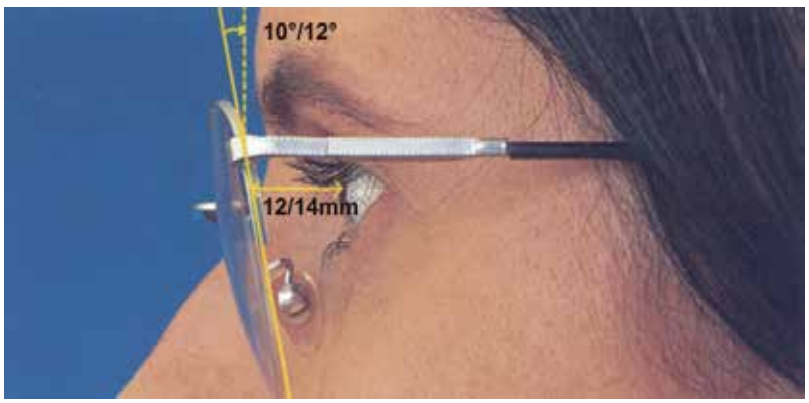

Fig. 1. Pantoscopic angle of glasses.[4]

3. Contact lenses

For some individuals, contact lenses can offer better vision than eyeglasses. They can be used for people with regular and irregular astigmatism, such as keratoconus. They may provide clearer vision and a wider field of view. However, since contact lenses are worn directly on the eyes, they require regular cleaning and care to safeguard eye health[5]

Contact lenses are the first choice for difficult cases such as corneal ecstasies (e.g. keratoconus, keratoglobus and pellucid marginal degeneration). For these cases, there are special lenses with a variety of designs. In this current chapter we will focus only on regular astigmatisms, since to address this kind of adaptation would require a whole chapter to itself.

Almost everybody has the option of using contact lenses. Before initiating any contact lens fitting, it is important to evaluate the patient's motivation, ocular needs, and ocular and medical history. There are four principal indications for contact lens fitting: 1) optical indications (myopia, hyperopia, astigmatism and presbyopia); 2) medical indications (keratoconus, irregular astigmatism, corneal opacification, anisometropia, unilateral aphakia, nystagmus, after refractive surgery or keratoplasty); 3) cosmetic or prosthetic indication to hide imperfections of the eye; 4) therapeutic indications for corneal abrasion.[4]

The contraindications are generally relative, and they will depend upon the criteria of the ophthalmologist's evaluation. Unmotivated patient; poor personal hygiene; inability to follow directions of lens maintenance and handling; inability to understand the risks associated with contact lens use; allergies that affect the eye; immunosuppressed patients, diabetic patients, and alcoholics have a large risk of complications; any effective eye disease affecting the cornea, the conjunctiva and lids as, for example, with inflammations, infections, dry eye, lagophthalmos and glaucoma; moreover, psychological intolerance can be a contraindication for contact lenses use.[4]

Contact lens can be classified by the nature of the material, by their design or by their wearing and replacement schedule, as will seen. A well-made clinical history, along with a complete ophthalmological examination and the patient's needs, determines whether contact lenses are appropriate for each patient[5]

As to the nature of the material of the lens, it can be hard, soft or hybrid. Hard lenses can be non-gas permeable or gas permeable. Polymethylmethacrylate (PMMA) is the polymer from which hard non-gas permeables are made. The disadvantage with this is a lack of gas permeability. The rigid gas permeable lenses (RGP) permit the passage of oxygen and carbon dioxide gas but they contain no water. The general categories of gas permeable polymers are: cellulose acetate butyrate, pure silicone, silicone acrylate and fluorocarbonate. The soft lenses can be hydrogel or silicone hydrogel, both of which have a low water-content (less than 50% water) or high water-content (greater than 50% water). The oxygen transmissibility of a hydrogel lens is directly related to its water-content. For the silicone hydrogel, a higher water-content gives more comfort because it diminishes the roughness of the lens.[6]

There are many designs of lenses. In this chapter, the three basic designs that exist will be addressed: spherical (having anterior and posterior spherical surfaces); aspheric (different radii of curvature in the centre and periphery, simulating the structure of the cornea); and

toric (two principal meridians having different radii of curvature; this may be the anterior or posterior surfaces of the lenses or both).[6] Other designs, such as multi-curvature, reverse curve, progressive and bifocal, are related to other refractive errors besides astigmatism and will not be considered here.

The wearing schedule can be: 1) continuous wear (overnight lenses – utilised both during waking and sleeping hours); 2) daily wear (removed daily and not utilised during sleep); 3) flexible wear (removed daily with sporadic sleepers wearing lenses); 4) occasional wear (utilises glasses most of the time and lenses only sometimes, in social activities or sports).[5]

The replacement schedule can be done in three ways: 1) a traditional or conventional way is used when the lens must be replaced annually; 2) the planned replacement way which is nowadays the most used and where the lens needs to be replaced every 15, 30 or 60 days (as defined by the manufacturer's guidelines); 3) disposable lenses, which are probably are the easiest way, because they are immediately discarded after use and do not need maintenance.[5]

Many people ask whether or not RGP lenses are better than hydrogel lenses. The answer to this question depends upon vision accuracy, the comfort and satisfaction of the patient and corneal health. The adaptation of contact lens is different for each person. Generally, to get used to them, the patients need between 1 and 15 days and seem to be easier for those wearing hydrogel lenses than for the ones who wear RGP lenses.

There are many pamphlets to help and teach users how to put on and take off contact lenses, as well as how to store them and keep them clean. However, it is necessary to review these steps at every follow-up visit to the ophthalmologist. The control of contact lens use needs to be done with a specialist every year or else every 6 months, depending on the lens fitting and eye condition.

3.1 Soft contact lenses

Soft contact lenses conform to the shape of the eye. Spherical soft lenses may not be effective in correcting astigmatism;[7] however, toric soft contact lenses can provide a correction for regular astigmatism similar to that of eyeglasses.

A strategy for correcting low degrees of astigmatism with spherical soft lenses is to increase the thickness of the lens. Considering that a thicker or stiffer lens may drape less on the cornea and mask more astigmatism, thicker lenses associated with a special design can give good vision even for irregular astigmatism, such as keratoconus.[5] Another strategy that has been described is the use of lenses with low water-content, since it is not so malleable. However, a low water-content spherical silicone hydrogel material has been shown to have no significant impact on the amount of astigmatism masked.[8]

Visual acuity with a spherical equivalent refraction remained at tolerable limits with the use of spherical contact lenses. Spherical lenses failed to mask corneal toricity during topography, while toric lenses caused central neutralisation and a decrease in corneal cylinder in low and moderate astigmatic eyes.[9]

Soft aspheric contact lenses have been recommended for low astigmatic patients because its design could decrease the level of spherical aberration that is a distortion in image

formation. However, clinical studies have reported that non-toric aspheric soft contact lenses did not improve visual acuity significantly when compared to spherical lenses on low astigmats. One reason for why these non-toric lenses do not improve visual acuity is that aspheric soft contact lenses do not correct astigmatism. Additionally, decentration of spherical aberration correction has been shown to induce a coma-like aberration that is another distortion in image formation.[9]

Visual acuity with toric lenses is better than with spherical or aspheric lenses, but initially lens quality and stability was a problem. Nowadays, improved lens designs and the availability of disposable toric contact lenses have resulted in improved health benefits and adaptation[10] Well-fitted hydrogel toric lenses can provide visual acuity and visual performance equivalent to that of spherical RGP lenses.[9]

All the literature agrees that the best way to fit a soft lens is by considering the response to the trial lens fitting. By slit lamp, the physician observes centralisation, the movement of the lens and the lens-cornea relationship. After this, over-refraction has to be done.[5] However, the fitting without trial lens has proven to be an efficient way to prescribe it. 50% to 80% of patients are being fitted successfully with this method for soft toric contact lenses.[11] To fit a soft contact lens, keratometry needs to be done. The base curve of the lens should be approximately 0.6 to 0.8 mm flatter than the average corneal curvature measurement. The lens diameter should be approximately 2.0 mm larger than the horizontal visible iris diameter. The dioptric power of the contact lens should consider the total eye refraction and, if it is greater than 4.00 D, a table for the correction of the vertex distance should be used.[6] It can also be calculated using the following formula:[5]

$$DL = \frac{DA}{1 - d \cdot DA}$$

DL= dioptric power of contact lens.
DA= dioptric power of glasses.
d= vertex distance (which has an average of 12mm).

There remains some disagreement as to when to fit soft toric lenses or else spherical lenses. In practice, high myopia associated with low astigmatism has good acuity with spherical contact lenses; however, low myopes with higher astigmatism had significantly better acuity with toric lenses than with the spherical equivalent.[5]

3.2 Rigid gas permeable lenses

Rigid gas permeable contact lenses maintain their regular shape while on the cornea, and they offer an effective way to compensate for the cornea's irregular shape and improve the vision of persons with astigmatism and other refractive errors.

Gas permeable (GP) lenses could be very acceptable as a viable option for the correction of moderate to severe astigmatism. Patients preferred RGP lenses for visual acuity, especially at near and intermediate distances.[12]

Spherical lenses can compensate for corneal astigmatism up to 3.00 D, although it is known that using them on corneas showing more than 2.00 D of toricity may be inappropriate. Because of this, it is recommended that spherical fittings should be done where the base

curve of the lens is equal to the cornea's flattest meridian. The limits of this approach are reached on highly toric corneas where the lens may alter the tear film flow, leading to peripheral desiccation of the cornea (known as 3–9 o'clock staining). This is why a spherical GP lens should be used with extreme caution on a cornea presenting toricity greater than 2.00 D. At present, it is recommended that reliance should be placed on a topographic map of the cornea so as to determine the optimal parameters.[13]

Many methods can be used to find the base curve. That most frequently used by practitioners involves adding 1/3 to 1/4 of the astigmatism measure to K (the flattest meridian of the topographic corneal map).[12] The diameter of the lenses is dependent to the base curve. A great diameter needs a flatter adaptation (table 1). Another tip is to remember is that steeper corneas require lenses with a smaller diameter, and that flatter corneas require lenses with a greater diameter (table 2).[5]

The selected trial lens is placed on the cornea and then, for the evaluation, it is necessary to take into account its comfort, position, movement and stability. The slit lamp evaluates the relationship between the lens and cornea with fluorescein. After the fitting is complete, the over-refraction should be done.

Corneal cylinder	8.6 mm diameter lens	9.2 mm diameter lens	10.2 mm diameter lens
0,00 to 0,50 D	0.25 D STK	On K	0.25 D FTK
0,75 to 1,25 D	0.50 D STK	0,25 D STK	On K
1,50 to 2,00 D	0.75 D STK	0.50 D STK	0.25 D STK
2,25 to 2,75 D	1.00 D STK	0.75 D STK	0.50 D STK
3,00 to 3,50 D	1.25 D STK	1.00 D STK	0.75 D STK

STK = steeper than K / FTK = flatter then K.

Table 1. Base curve lens determination in dependence of lens diameter and topographic corneal cylinder.

Corneal curvature (K)	Lens diameter
38.00 to 42.00 D	9.8 mm or bigger
42.25 to 44.25 D	9.1 to 9.7 mm
44.50 to 50.00 D	9.0 mm or smaller

Table 2. Correlation between corneal curvature flattest meridian of the topographic corneal map (K) and contact lens diameter

Aspheric lenses will always move in the direction of least resistance: this implies that a lens that is restricted along the vertical meridian and which is free along the horizontal meridian will move freely up and down. Conversely, if there is a restriction along the horizontal meridian, the lens will decentre on the nasal or temporal side.[13]

For those wearing RGP contact lenses, only 18% to 22% wear toric correction, suggesting that many practitioners tend to mask astigmatism using spherical equivalence with contact lenses. One reason for this behaviour is that toric gas permeable lenses are more complex to

fit and have variable results.[13] Some practitioners will consider toric lenses only if the patient reports unsatisfactory vision in spherical contact lenses or else when the corneal toricity is too great and the fitting has become unstable. Toric lens designs can have different radii of curvature on the front surface, back surface or both of what are known as bitoric lenses.

Back-toric design implies that the back surface of the lens is toric and that its front surface is spherical. This design is most successful when the corneal toricity represents more than two thirds of the refractive astigmatism. Back-toric gas permeable lenses are not designed with prism ballasts; their stabilisation is mainly achieved by the correspondence between the back curves and the corneal toricity. This type of lens is designed with only 66% corneal toricity so as to provide more comfort. However, because of this, the lens will quite certainly rotate in the eye. Clinically, this translates as induced astigmatism that can disturb the visual outcome where it exceeds 0.75 D.[5]

Front-toric designs are designed with the astigmatic correction on the front surface of the lens, leaving the back surface spherical. They are stabilised with a base-down prism and represent the best choice for correcting residual astigmatism, in which the cornea is spherical.[5] Residual astigmatism results from causes other than the shape of the anterior corneal surface and can refer to astigmatism of the posterior cornea surface, lens, and retina.

A bitoric lens offers both surfaces as toric. The back toric surface curves are designed to be aligned with the corneal toricity. Optically speaking, this generates an over-correction of the refractive astigmatism. This is why a front toric surface is needed to compensate the power of the lens. Bi-toric designs are the most popular toric design in RGP contact lens practice, and represent the best choice if corneal toricity is less than or exceeds refractive astigmatism.[5]

For RGP toric lenses, I believe that the most appropriate fitting method is a 4-step approach, known as the two-thirds rule, as seen below.[14]

Step 1. Calculation of corneal toricity: calculate the difference between the two principal meridians of the cornea.

Step 2. Calculation of Base curve 1 (BC-1): the base curve 1 of the lens is determined by dividing the corneal toricity (found in Step 1) into two-thirds and then adding it to the flattest meridian of the cornea.

Step 3. Calculation of base curve 2 (BC-2): the base curve 2 of the lens is determined by flattening the steepest meridian of the cornea according to Remba's rule (Table 3).

Step 4. Calculation of lachrymal lens power and induced astigmatism: this type of astigmatism is induced by the relationship of the back surface of the lens to the cornea, and can be seen doing the over-refraction. If this value is less than 1.00 D, a back-toric design should be ordered because the induced astigmatism is not considered to be a contributing factor affecting visual acuity. At this point, a spherical equivalence is made in order to determine the final power of the back-toric lens. However, if the induced astigmatism value exceeds 1.00 D, a bitoric design should then be selected because the induced astigmatism should be corrected by the addition of the cylinder power to the front-surface of the lens.

Cornea toricity	Flattening of the steepest meridian
2.0 D	0.25 D
3.0 D	0.50 D
4.0 D or more	0.75 D

Table 3. Usable values according to Remba's rule

3.3 Orthokeratology

Orthokeratology (ortho-k) involves the fitting of specially designed rigid contact lenses to reshape the cornea so as to temporarily reduce or eliminate refractive error. The contact lenses are worn for limited periods, such as overnight, and then removed. Persons with mild to moderate myopia and mild astigmatism may be able to temporarily obtain clear vision without lenses for most of their daily activities. Ortho-k does not permanently improve vision, and if the person stops wearing the retainer lenses, the cornea may return to its original condition and vision will be bad again. Ortho-k is a good option for people who need RGP contact lenses to improve vision but who cannot wear common lenses for many reasons.[5] The main reasons for using this kind of lens are: workers in polluted environments or who use chemical products; boxers or water-sports athletes; people who feel discomfort with regular lenses and cannot have refractive surgery; people who have problems with blinking, dry eye, giant papillary conjunctivitis or nystagmus.

Ortho-k makes many changes to the shape of the cornea, as can be seen by topography maps, wave front measurements and pachymetry. The corneal changes induced by reverse-geometry – because of the relatively flat-fitting base curve – create a central flattened zone called the treatment zone, corresponding approximately to the lens back optic zone. Successful ortho-k treatment produces a well-centred regular treatment zone which encompasses the pupil diameter, as revealed by inspection of the difference map on the corneal topographer's data display (figure 2).[15]

The induction of higher-order aberrations with the use of reverse-geometry lenses for overnight ortho-k has been reported.[16] The significant increase in spherical aberrations is seen by the annular zone of mid-peripheral corneal steepening induced by the reverse-geometry lens, and the consequent change in corneal shape from prolate[1] towards oblate[2] asphericity.[16] However, the patients do not complain about these kinds of visual problems. A higher-order aberration is a distortion acquired when light passes through an eye with irregularities. Everyone's eyes have it, but the quantity of it is what determines whether it will affect quality of vision, by giving symptoms as glare, halos, starburst effects and ghost images.

Most of the studies concern ortho-k for myopia of 4.0D and with-the-rule corneal astigmatism of less than 1.50D showing rapid results, with most change after the first night of lens wear and most stability in refractive change after 4 weeks.[17] However, a few studies show good results for irregular astigmatism, such as keratoconus.[15]

Spherical reverse-geometry lenses can be used on toric corneas in order to reduce astigmatism. In a retrospective analysis, Mountford and Pesudovs[18] demonstrated that up

[1] The normal cornea is a prolate surface - steeper in the centre and flatter in the periphery.
[2] The oblate surface is a surface after myopic laser photorefractive keratectomy – flatter in the centre and steeper in the periphery.

to 50% of corneal astigmatism could be reduced with standard reverse-geometry ortho-k lenses, provided that the toricity was with-the-rule and restricted to the central region of the cornea. Corneal toricity reaching from limbus to limbus on the topographic map was less amenable to modification by ortho-k lenses.

Toric ortho-k lenses were created for an oval treatment zone and different meridional topographic changes, with more corneal flattening in the meridian requiring more myopic refractive error correction. Details of corneal topographic changes induced by these different ortho-k lens designs over longer periods of wear are yet to be published.[19]

There is slight regression of effect (about 0.25 to 0.75 D) during the day, and lenses must be periodically worn overnight (from every night to every three to four nights) to retain the effect. No serious adverse events have been reported from published clinical studies, although overnight lens adherence and clinically significant corneal staining in the morning after lens removal appear to be relatively common and have caused some clinical concerns in some studies.[20]

Patient satisfaction with overnight ortho-k has been reported as similar to or better than other popular modalities of contact lens wear. Unlike refractive surgery, if patients fail to achieve a subjectively successful outcome, they can cease lens wear and return to other corrective options, such as spectacles or conventional contact lenses. The corneal changes induced by overnight ortho-k are fully reversible on cessation of lens wear.[20]

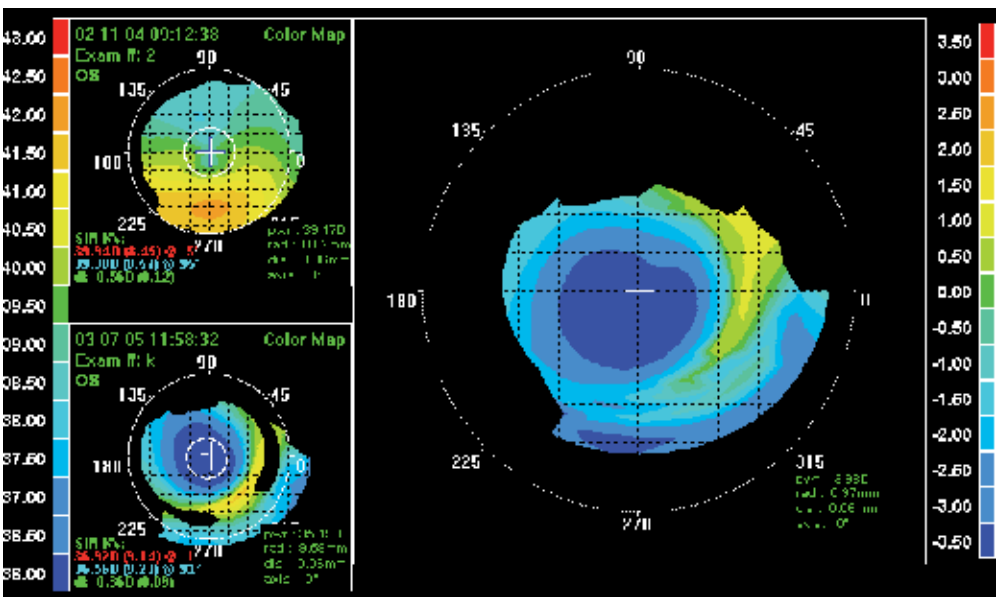

Fig. 2. Topography before and after orthokeratology in a case of irregular astigmatism (keratoconus).[15]

4. Visual stimulation

Brain plasticity in the visual functions of adults has been shown to improve with repetitive practice on specific controlled visual tasks. Through these repetitive practices are initiated

neural modifications that lead to an improvement in neuronal efficiency. These neural modifications can enhance image quality by compensating for blurred retinal images due to optical defocus for all the refract errors.[21] It is indicated by those who have good Snellen visual acuity but still have symptoms of ghost images. This commonly happens to people with low astigmatism.

RevitalVision by NeuroVision (NeuroVision Inc., Singapore), based on visual stimulation, have developed a computer programme for amblyopia, post lasik (laser assisted in situ keratomileusis) and post cataract. However, it can be extended for others refractive errors. During training sessions, the user is presented with a series of precise visual tasks consisting of Gabor patches with subtle differences in orientation, size and contrast. Through repetitive practice, the brain is trained to be more efficient and to improve visual processing by improving contrast sensitivity and visual acuity.[22]

Studies showed mean improvements of visual acuity of about 2.0 LogMar, and the contrast sensitivity function also improved at all spatial frequencies. However, the mean refractive error remained unchanged after treatment. Follow-up data for up to 12 months post-treatment showed that the gains were retained.[23] This method has never been proven. The effect is probably related to the memory of the patients, and this would be the reason that the refractive error remains unchanged.

Besides this, it requires more evaluation to see the real value of this kind of stimulation for the treatment of astigmatism.[21-23]

5. Advantages and disadvantages for each correcting method

There are many differences between contact lens and glasses, as can be seen in the chart below, but both need an eye doctor's prescription and periodic evaluation.

Eyeglasses	Contact Lenses
The distance between your eye and the lens sometimes creates distortion.	When worn right on the eye it sometimes can blur because of tears.
Glasses correct only regular astigmatism.	Contact lenses can also correct irregular cornea shape that distorts vision.
Glasses can be inconvenient during games and sports.	Contact lenses are a favourite among athletes.
Poor peripheral vision (visual field) because of the frame.	Your entire field of view is in focus.
Eyeglasses can get dirty and decrease vision.	Contact lenses can form deposits on the lens and blur the vision acuity.
Glasses must be sprayed and wiped several times a day.	Contact lenses should be cleaned, disinfected and stored properly after each use.
Periodic need for tightening or other adjustment.	Maintenance and handling of the lens every day.
Sometimes an uncomfortable weight on your face and ears.	Sometimes uncomfortable in the eye as a strange body, dry eye or allergy.
Glasses are fashionable, functional and complement your outfit.	Cosmetic lens may alter the colour of the eye.

Also, there are advantages and disadvantages associated with various types of contact lens, as seen below. All of the contact lenses require visits to the ophthalmologist for follow-up care.

Lens Types	Advantages	Disadvantages
Soft lenses	Very short adaptation period. More comfortable and more difficult to dislodge than RGP lenses.	Maintenance and handling every day. Do not last long comparing to RGP lenses. Vision may not be as sharp as RGP lenses.
Daily wear disposable lenses	Thinner lenses. Require no cleaning. Minimal risk of eye infection if the wearing instructions are followed.	Do not correct all vision problems.
Extended ware disposable lenses	Can usually be worn up to several days without removal (the wearing period is defined by the manufacturer's guidelines). Require no cleaning.	Do not correct all vision problems. Increases risk of complication with night and day wear. Requires regular monitoring and professional care.
Planned replacement lenses	Require simplified cleaning and disinfection. Good for eye health. Available in most prescriptions.	Vision may not be as sharp as RGP lenses. Maintenance and handling every day.
Rigid gas permeable lenses (RGP)	Excellent vision. Easier than the soft lens for maintenance and handling. Correct most vision problems. Durable, with a relatively long life.	Require consistent wear to maintain good vision. Can slip off the centre of the eye more easily than other types. Debris can easily get under the lenses. Longer period to get used to compared to soft lenses.
Ortoceratologia	Worn only at times of sleeping. Eliminates the use of the lens on walking hour. Short adaptation period. Comfortable to wear. Less friction with the lid. Durable, with a long life.	Correct only low astigmatism and low to moderate myopia. Vision may not be as sharp as with other lenses.

6. Conclusion

Individuals with astigmatism have a wide range of options to correct their vision problems and, together with an eye exam, the selection of the best treatment that meets vision and lifestyle needs must be done.

1. Introduction

An optical system with astigmatism is one where rays that propagate in two perpendicular planes have different foci. If an optical system with astigmatism is used to form an image of a cross, the vertical and horizontal lines will be in sharp focus at two different distances. The term comes from the Greek α- (a-) meaning "without" and στίγμα (stigma), "a mark, spot, puncture".

There are two distinct forms of astigmatism. The first is a third-order aberration, which occurs for objects (or parts of objects) away from the optical axis. This form of aberration occurs even when the optical system is perfectly symmetrical.

The second form of astigmatism occurs when the optical system is not symmetric about the optical axis. This form of astigmatism is extremely important in vision science and eye care, since the human eye often exhibits this aberration due to imperfections in the shape of the cornea or the lens.

If an optical system is not axisymmetric, either due to an error in the shape of the optical surfaces or due to misalignment of the components, astigmatism can occur even for on-axis object points. Ophthalmic astigmatism is a refraction error of the eye in which there is a difference in degree of refraction in different meridians. It is typically characterized by an aspherical, non-figure of revolution cornea in which the corneal profile slope and refractive power in one meridian is less than that of the perpendicular axis.

Astigmatism causes difficulties in seeing fine detail. In some cases vertical lines and objects such as walls may appear to the patient to be leaning over like the Tower of Pisa. Astigmatism can be often corrected by glasses with a lens that has different radii of curvature in different planes (a cylindrical lens), contact lenses, or refractive surgery.

Astigmatism is quite common. Studies have shown that about one in three people suffers from it. The prevalence of astigmatism increases with age. Although a person may not notice mild astigmatism, higher amounts of astigmatism may cause blurry vision, squinting, asthenopia, fatigue, or headaches.

Astigmatism is an optical defect in which vision is blurred due to the inability of the optics of the eye to focus a point object into a sharp focused image on the retina. This may be due to an irregular or toric curvature of the cornea or lens. The most of the astigmatism is corneal. Astigmatism may also be caused by crystalline lens subluxation, coloboma or lenticonus. There are two types of astigmatism: regular and irregular. Irregular astigmatism is often caused by a corneal scar or scattering in the crystalline lens. Regular astigmatism arising from either the cornea or crystalline lens can be easily corrected.

The refractive error of the astigmatic eye stems from a difference in degree of curvature refraction of the two different meridians (i.e., the eye has different focal points in different planes.) For example, the image may be clearly focused on the retina in the horizontal (sagittal) plane, but not in the vertical (tangential) plane. Astigmatism causes difficulties in seeing fine detail, and in some cases vertical lines (e.g., walls) may appear to the patient to be tilted.

In With-the-rule astigmatism, the eye sees vertical lines more sharply than horizontal lines. Against-the-rule astigmatism reverses the situation. Children tend to have With-the-rule astigmatism and elderly people tend to have Against-the-rule astigmatism. The prevalence of astigmatism increases with age.

Astigmatism may be corrected with eyeglasses, contact lenses, or refractive surgery. Various considerations involving ocular health, refractive status, and lifestyle frequently determine whether one option may be better than another. In those with keratoconus, toric contact lenses often enable patients to achieve better visual acuities than eyeglasses. Once only available in a rigid gas-permeable form, toric lenses are now available also as soft lenses.

2. Aspheric ablation strategies

An aspheric lens or asphere is a lens whose surfaces have a profile that is rotationally symmetric, but is not a portion of a sphere. The asphere's more complex surface profile can reduce or eliminate spherical aberration and also reduce other optical aberrations compared to spheric lenses. Aspheric elements are used to reduce aberrations.

In prescriptions for both farsightedness and nearsightedness, the lens curve flattens toward the edge of the asphere. Aspheric ablation strategies for spherical correction are modified by means of spherical aberration compensations, whereas aspheric ablation strategies for astigmatic correction are modified by means of high-order-asitmgatism aberration compensations.

3. Ocular wavefront (OW) customized ablation strategies

The treatment plan is developed using OW customised aspheric profiles based on Hartmann-Shack sensing[1]. The high-resolution Hartmann-Shack measurements (>800 points for a 7.0-mm pupil) referred to the entire eye. Optical errors centered on the line-of-sight are described by the Zernike polynomials[2] and the coefficients of the Optical Society of America (OSA) standard[3].

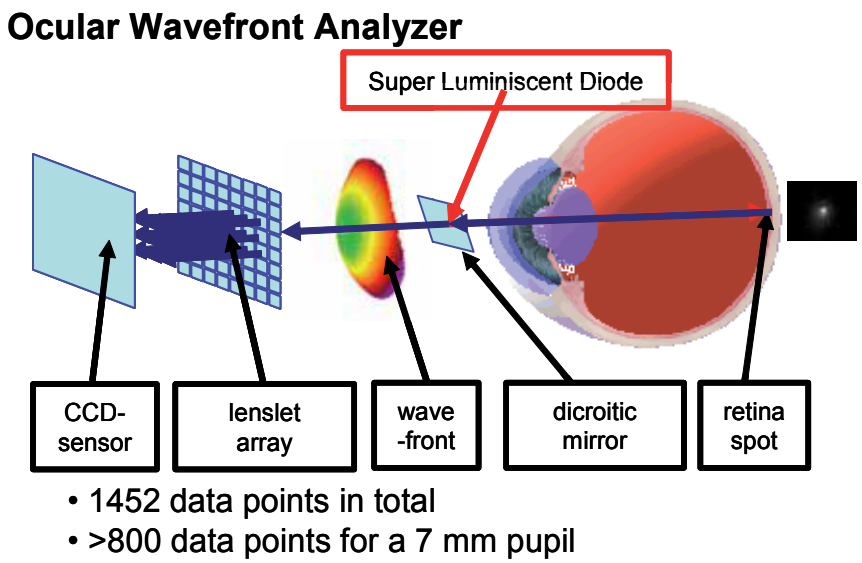

Fig. 1. Principle of the OW measurement.

3.1 Treatment modality

Preoperative topography and aberrometry measurements are taken, and visual acuity, and mesopic pupil size are measured. To determine the ablation profile of the Custom Ablation Manager (CAM), manifest refraction is measured in each eye and crosschecked with objective refraction from the SCHWIND Ocular Wavefront Analyzer[4]. Each eye is planned according to the manifest refraction using the CAM Wavefront customised treatments.

The CAM aspherical profiles were developed with the aim to compensate for the induction of aberrations (especially but not only spherical aberration) observed with other types of profile definitions[5], some of these sources of aberrations are those related to the loss of efficiency of the laser ablation for non-normal incidence[6,7]. Optimization is realized by taking into account the loss of efficiency at the periphery of the cornea in relation to the center, as there is a tangential effect of the spot in relation to the corneal curvature (K (Keratometry) -reading). The software provides K-reading compensation, which considers the change in spot geometry and reflection losses of ablation efficiency.

The base-line for correcting refraction (sphere and cylinder) is aspheric, whereas the high order aberrations measured based on Hartmann-Shack sensing of the entire eye are combined with manifest refraction.

Real ablative spot shape (volume) is considered through a self-constructing algorithm. In addition, there are a randomized flying-spot ablation pattern, and controls for the local repetition rates to minimize the thermal load of the treatment[8].

A central fully corrected ablation zone is used in all eyes with a variable transition size automatically provided by the laser related to the planned refractive correction. Immediately before the ablation, the laser is calibrated per manufacturer's instructions and the calibration settings are recorded.

The CAM software is able to import, visualize, and combine diagnostic data of the eye (manifest refraction and ocular wavefront data in this case) into a customised aspherical ablation profile to optimize the corneal shape. OW based ablations attempt to reduce the wavefront aberration of the entire eye (within Optical Zone, OZ) close to a zero level, compensating, as well, for the aberration induction observed with other types of profiles.

It should be noted that opposing the preoperative wavefront aberration in laser refractive surgery constituted only a first approximation of a perfect refractive correction, as tissue removal occurs. Considerations such as treatment duration or tissue removal make even more difficult to establish a universal optimal profile. Our data suggest that Ocular wavefront customized treatments can only be successful, if the pre-existing aberrations are greater than the repeatability and the biological noise. In particular, the OW customized approach is highly efficient in eyes with greater than 0.25 microns root-mean-square (RMS) ocular HOAb, or where individual components of the OW such as coma, trefoil or spherical aberration are greater than 0.2 microns RMS.

4. Corneal wavefront (CW) customized ablation strategies

The treatment plan is developed using CW customized aspheric profiles based on corneal ray tracing (Salmon 1999[9]). Using the Keratron Scout videokeratoscope (Mattioli & Tripoli 1997[10]) (Optikon 2000 S.p.A, Rome, Italy), the topographical surface and corneal wavefront are analyzed (up to the 7th order). Considering a balanced-eye model (Q-Val –0.25) the departure of the measured corneal topography from the theoretically optimal corneal surface is calculated. Optical errors centered on the line of sight are described by the Zernike polynomials (Zernike 1934[11]) and the coefficients of the Optical Society of America (OSA) standard (Thibos et al. 2002[12]).

Ray tracing is a procedure classically performed by applying Snell's law to the corneal surface. However, it is much simpler to understand corneal wavefront in terms of optical path difference and calculate it by Huygens-Fresnel or "least time" Fermat principles (Salmon 1999[9]; Guirao & Artal 2000[13]).

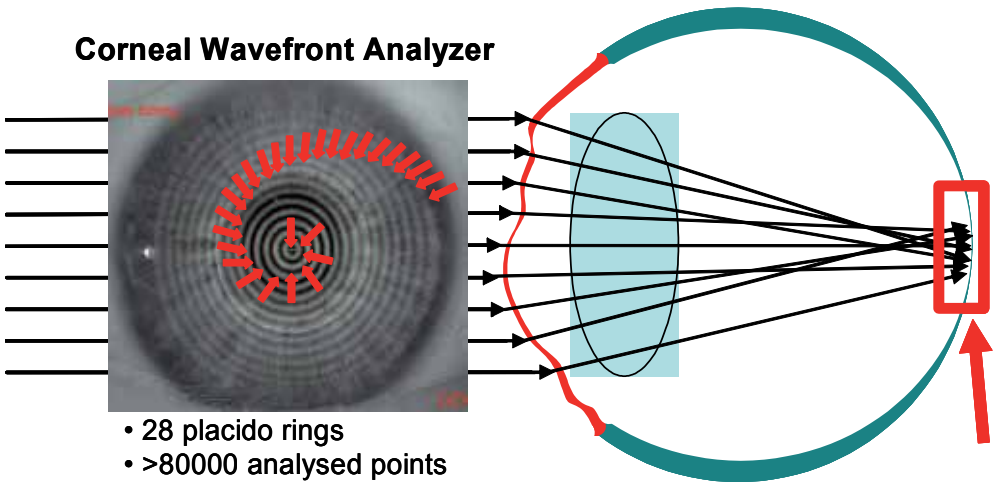

Fig. 2. Principle of the dderivation of the CW.

In corneal wavefront analysis, the type and size of any optical error on the anterior corneal surface are registered, thus allowing a very selective correction. The defects are corrected exactly at their origin – the anterior corneal surface. In this context, the precise localization of defects is crucial to successfully achieving optimal results in laser surgery. The corneal wavefront allows for a very precise diagnosis, thus providing an individual ablation of the cornea in order to obtain perfect results.

Applying this treatment strategy, measurement does not require pupil dilation of the eye, so that the treatment zone is not limited by the pupil and accomodation does not influence the measuring results. Mention is made that in this way forcing a fixed asphericity quotient (Q) on the eyes through the treatment is avoided. Instead, this strategy employs a dynamic postoperative expected asphericity quotient (de Ortueta & Arba-Mosquera 2008[14]), being expressed as:

$$Q_{\text{exp}} = \frac{\frac{1}{n^2} - \frac{1}{4}}{\left(1 + \frac{R \cdot SEq_{cp}}{n-1}\right)^3} - \frac{1}{n^2} \tag{1}$$

where Q_{exp} is the expected/predicted corneal asphericity quotient; R the apical radius of curvature of the preoperative cornea; SEq_{cp} the spherical equivalent to be corrected at the corneal plane; and n the refractive index of the cornea.

The expected quotient of asphericity does not incorporate any compensation for the effect of postop corneal biomechanics / healing response, and it is rather derived from a pure optical model of the cornea.

Preoperative topography and corneal aberrometry measurements are taken, and visual acuity, and mesopic pupil size are measured. Each eye is planned according to the manifest refraction using the CAM wavefront customized treatments. Immediately before ablation, the laser is calibrated according to the manufacturer's instructions and the calibration settings are recorded.

When evaluating the outcomes of wavefront customization strategies, wavefront aberration analysis is mandatory to be able to determine whether the customization aims could be achieved. It has been suggested, as well, that the surface ablation procedures are better suited for the wavefront guided ablation as they would avoid the induction of aberrations due to flap and interface (Chun et al. 2006[15]; Buzzonetti et al. 2004[16]). Now with the introduction of thin and ultrathin planar flaps with femtosecond laser and the newer microkeratomes such as the pendular microkeratome, this aspect of the debate will require further research.

Topography is measured under bright light conditions which might cause pupil constriction and also pupil center shift relative to normal photopic levels. Corneal wavefront customized treatments can only be successful, if the pre-existing aberrations are greater than the repeatability and the biological noise. Considerations such as treatment duration or tissue removal make it more difficult to establish a universal optimal profile.

Furthermore, coupling effects between different high order aberration terms, and between HOAs and manifest refraction is still one of the major sources of residual aberrations after refractive surgery. This topic has been discussed from a theoretical perspective by Bará et al. 2006 [17] and from a clinical perspective by MacRae 2007[18] or Buehren et al. 2007[19]. They all

found mutually affecting interactions, for example, between defocus and spherical aberration, or between 3 order aberrations and low order terms, between spherical aberration and coma, or between secondary and primary astigmatisms.

The accuracy, predictability, and stability of the refractive power change, together with the minimal external impact of the CAM ablation profiles on the HOAs, leads to very good results in terms of visual quality. In summary, aspheric CW ablation profiles, designed with CAM software for the AMARIs laser platform, yield visual, optical, and refractive results comparable to those of other wavefront-guided customized techniques for correction of myopia and myopic astigmatism. The CW customized approach shows its strength in cases where abnormal optical systems are expected. Apart from the risk of minimal additional ablation of corneal tissue, systematical wavefront-customized corneal ablation can be considered as a safe and beneficial method.

5. Decision Assistant Wizard

Our definition of "Customisation" is conceptually different and can be stated as: "The planning of the optimum ablation pattern specifically for each individual eye based on its diagnosis and visual demands." It is often the case, that the best approach for planning an ablation is a sophisticated pattern, which can still be simply described in terms of sphere, cylinder, and orientation (axis). The Decision Assistant Wizard, which we present here, is based on our experience with the SCHWIND AMARIS laser. While the general principles of this Decision-Tree based planning (Fig. 3) can basically be applied to any other laser platform offering aspheric and wavefront-guided profiles, some specific aspects concerning both diagnosis and treatments may depend on other manufacturers' specifications.

We begin by acquiring four corneal topographies (Corneal Wavefront Analyzer, SCHWIND eye-tech-solutions GmbH & Co.KG, based on Keratron-Scout, OPTIKON2000, Rome, Italy) and derived CW analyses centred on the line-of-sight for each eye of the patient. We extract the mean, and discard the less representative one (the one with the poorest similarity to the mean). From those remaining three maps, we calculate the mean, and select the most representative one (the one with the highest similarity to the mean).

We continue acquiring, under non pharmacologically dilated pupils, non-cycloplegic conditions, and natural dim light conditions (to avoid pharmacologically induced pupil shifts[20,21]), 3 aberrometries (Ocular Wavefront Analyzer, SCHWIND eye-tech-solutions GmbH & Co.KG, based on irx3, Imagine Eyes, Orsay, France) and objective refractions for each eye of the patient. To minimize the potential accommodative response of the patients, we ask them to "see-through-the-target" instead of "looking at the target." In this way, patients do not try to get a sharp image from the +1.5 D fogged target, since they were instructed to see-through-the-target. From those aberrometries, we calculate the mean, and select the most representative one (the aberrometry map with the highest similarity to the mean).

We continue assessing subjective refraction based upon non-pharmacologic and non-cycloplegic conditions, under natural photopic illumination. We use the objective refraction analyzed for a sub-pupil of 4 mm diameter, as starting refraction for this step. This is particularly useful for determining the magnitude and orientation of the astigmatism. We measure manifest refraction, uncorrected and best spectacle-corrected Snellen visual acuity[22] (UCVA and BSCVA, respectively). Further rules that we impose for accurately determining

the manifest subjective refractions among equal levels of BSCVA are: taking the measurement with the least negative (the most positive) spherical equivalent (unmasking latent hyperopia), if several of them are equal in terms of spherical equivalent, we choose the measurement with the least amount of astigmatism (reducing the risk of postoperative shifts in the axis of astigmatism). This is particularly useful for determining the magnitude and orientation of the internal astigmatism as a difference between the topographic astigmatism and the astigmatism of the corneal wavefront analyses compared to the subjective astigmatism the astigmatism of the ocular wavefront analyses.

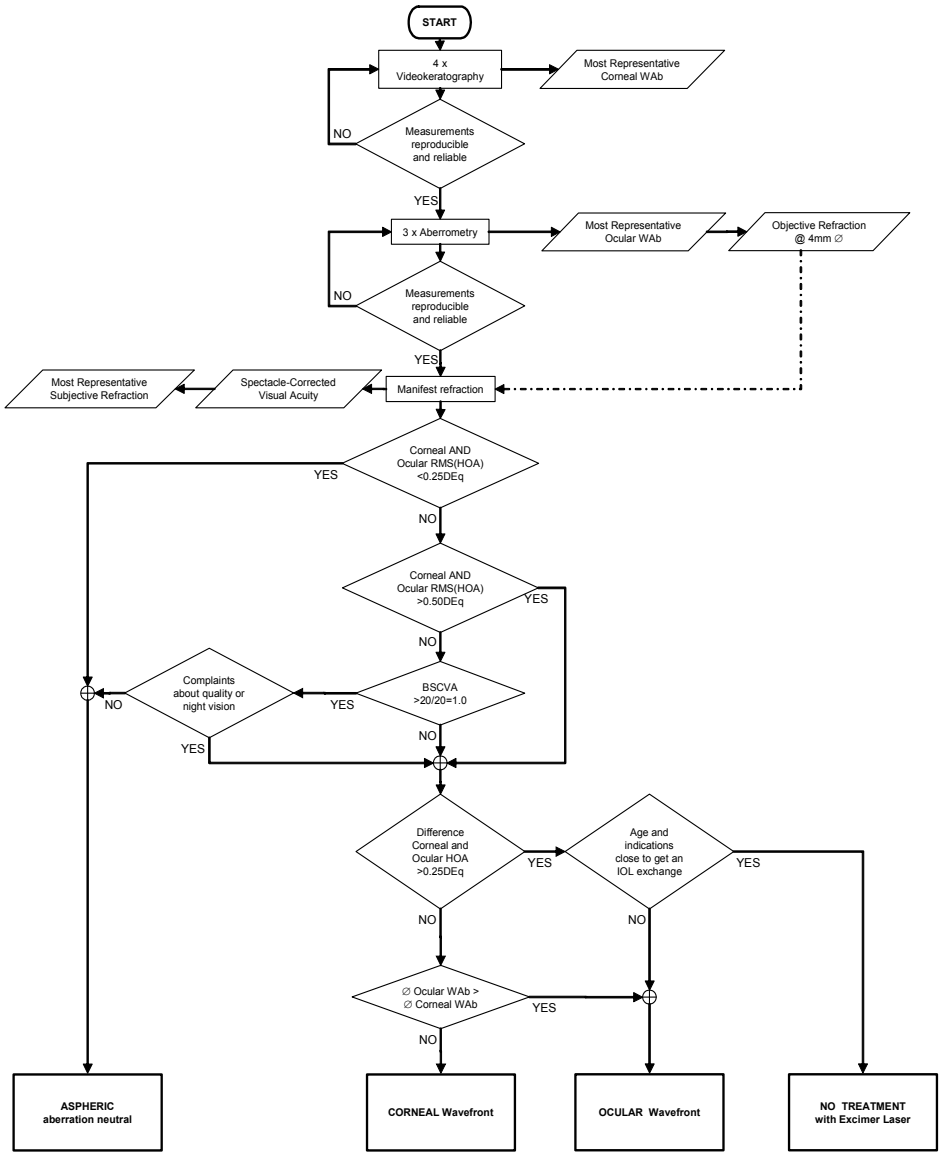

Fig. 3. Decision-Tree applied for selecting the treatment mode (Aspheric aberration neutral, Corneal-Wavefront-Guided, or Ocular-Wavefront-Guided).

The decision process starts by estimating the global optical impairment resulting from the measured wave aberrations. This is done by objectively determining the actual clinical relevance of single terms in a Zernike expansion of the wave aberration. In general, for the same magnitude of aberration, the optical blur produced by high order aberrations increases with increasing radial order and decreases with increasing angular frequencies. Based on this, the dioptric equivalent (DEq) was used.

If the global optical blur for both corneal and ocular wave-aberrations (CWAb and OWAb, respectively) are below 0.25 DEq for both eyes, then the treatment to be applied is Aspheric aberration neutral. If the global optical blur for any corneal or ocular wave-aberrations is between 0.25 DEq and 0.50 DEq for any eye, then we check the BSCVA achieved during the manifest refraction. If the BSCVA is better than 20/20 for both eyes, then we ask the patient about complaints regarding night vision or, in general, quality of vision. If the patient does not report complaints, then the treatment to be applied is Aspheric aberration neutral.

If the patient reports complaints regarding quality of vision, the BSCVA is worse than 20/20 for any eye, or the global optical blur for both corneal and ocular wave-aberrations are above 0.50 DEq for both eyes, then we compare corneal and ocular wave-aberrations. For this, we calculate the differential aberration (CWAb − OWAb, both centred at the line-of-sight) in terms of the Zernike expansion, and estimate the global optical difference. If this global optical difference between corneal and ocular wave-aberrations is below 0.25 DEq for both eyes, we consider both corneal and ocular wave-aberrations as equivalent. In this case, the treatment to be applied depends on the available diameter of the wavefront maps and the scotopic pupil size. If the diameter of the Ocular- or Corneal-WAb map (the one providing the largest diameter) is at least as large as the scotopic pupil size (in natural dark conditions) reduced in 0.25 mm, then Ocular- or Corneal-Wavefront-guided ablation is performed (the one providing the largest diameter), or Aspheric aberration neutral otherwise. Usually the size of the Ocular WAb maps is similar to the size of the scotopic pupils, whereas Corneal WAb maps are wider (up to 10 mm in diameter).

If the global optical difference between corneal and ocular wave-aberrations is above 0.25 DEq for any eye, we consider internal wave-aberration (IWAb) is relevant, then the treatment to be applied is Ocular-Wavefront-guided if the patient is neither in age nor in ophthalmic indications close to get an IOL exchange (due to e.g. lenticular opacities), otherwise no laser corneal refractive treatment is recommended (since IOL exchange is preferred).

Level of aberration	Aspheric aberration neutral	CW-guided	OW-guided
Corneal AND Ocular Wavefronts < 0.25Deq	**Always**	**No**	**No**
Corneal OR Ocular Wavefront between 0.25DEq and 0.50Deq	**If BSCVA > 20/20 AND no complaints about quality or night vision**	**If (BSCVA < 20/20 OR complaints about quality or night vision) AND Internal Wavefront < 0.25DEq**	**If (BSCVA < 20/20 OR complaints about quality or night vision) AND no lenticular problems**
Corneal AND Ocular Wavefronts > 0.50Deq	**If wavefront maps smaller than scotopic pupil**	**If Internal Wavefront < 0.25DEq**	**If no lenticular problems**

Table 1. Indications chart.

There are basically three types of approaches for planning a corneal refractive treatment. The first are those that have as their objective the elimination or reduction of the total aberrations of the eye. The main criticism to this approach argues that the goal "zero aberration" is inconsistent throughout the day due to accommodation, and little lasting, since aberrations change with age[23,24,25]. The second approach is intended to correct all corneal aberrations, since corneal aberrations do not change with age[26,27]. However, this concept might also be wrong considering corneal aberrations interact with internal aberrations, some of them being cancelled, and producing an aberration pattern of the total eye in general different from the aberration pattern of the cornea alone. Therefore, by only removing corneal aberration we might worsen the overall aberrations, since the internal aberration might not find a corneal aberration for compensation. In case that the corneal aberration is of the same sign as the internal aberration, the correction of the corneal aberration would be useful, as it would reduce the total aberration of the eye. A third approach tries not to induce aberrations. This type of treatment is not as ambitious, but much more simple to operate. The goal of the Aberration-Free™ ablation profile is to provide a neutral high-order-aberrations (HOAb) ablation, ie to maintain the same HOAb profile both preoperatively with best spectacle correction and postoperatively without correction.

There is evidence of neural adaptation to the baseline wavefront profile. The interaction between high-order-aberrations can be beneficial to visual quality regardless of the magnitude HOAb. Based on the random nature of the HOAb induction and current research, it may be beneficial to maintain the preoperative wavefront profile for a significant number of refractive surgery candidates.

We are not postulating that customized ablation algorithms in any form (ocular-wavefront-guided, corneal-wavefront-guided, topography-guided) are not be useful. Rather, that specific populations with specific demands deserve specific treatment solutions. Aspheric treatments aimed at preservation of the preoperative HOAb show their strengths in patients with preoperative BSCVA 20/20 or better or in patients where the visual degradation cannot be attributable to the presence of clinically relevant HOAb (e.g. lens opacities).

The corneal wavefront customized approach shows its strength in cases where abnormal corneal surfaces are expected. Apart from the risk of additional ablation of corneal tissue, wavefront customized corneal ablation can be considered a safe and beneficial method. Our experience suggests that wavefront customized treatments can only be successful, if pre-existing aberrations are greater than repeatability (e.g. repeatability of diagnostic[28] and treatment devices) and biological noise (e.g. day-to-day variabilities in visual acuity, refraction, or aberration in the same subject).

Furthermore, coupling effects between different high order aberration terms, and between HOAb and manifest refraction have been found[29,30] for example, between defocus and spherical aberration, or between 3rd order aberrations and low order terms, between spherical aberration and coma, or between secondary and primary astigmatisms. These interactions may provide some relative visual benefits[31], but may as well contribute as sources of uncertainty in the conversion of wavefront aberration maps to refractive prescriptions. Notice that for comparing OWAb and CWAb, the analysis of the IWAb as CWAb – OWAb is mandatory since RMS(IWAb) accounts for any deviation (i.e. inductions and reductions of the wave-aberration both contribute positively to increase the RMS value).

The Decision Assistant Wizard presented here may theoretically be applied to any other laser platform offering aspheric, topography-guided, and wavefront-guided profiles, if appropriate analysis functions for CWAb, OWAb, and IWAb are available. Simplified versions with limited functionalities are also possible, if, for example, neither CW-analyses (i.e. no IWAb) nor topography-guided profiles are available. The desired outcome of non-wavefront-driven refractive surgery is to balance the effects on the wave-aberration, and, to provide normal eyes with perhaps the most natural unaltered quality of vision. While Ocular Wavefront treatments have the advantage of being based on Objective Refraction of the complete human eye system, whereas Corneal Wavefront treatments have the advantage of being independent from accommodation effects or light/pupil conditions; Aspheric treatments have the advantage of saving tissue, time and due to their simplicity offer better predictability.

In highly aberrated eyes, manifest refraction may become an art, a sort of guessing around the least blurred image. In further studies, systematic deviations from the measured manifest refractions, as well as other foreseeable couplings among Zernike coefficients will be evaluated.

6. Minimization of depth and time in laser corneal refractive surgery

In laser corneal refractive surgery, one always aims to reduce the ablated tissue thickness (and, to a minor degree, to reduce the intervention time) because an ectasia of the cornea may result from excessive tissue removal. Customized laser corneal refractive surgery on aberrated eyes may yield better results than the standard procedure[18–21] but generally results in higher ablation depth, volume, and time. Therefore, optimizing the customized treatment to reduce the ablated thickness while retaining the positive aspects is pertinent.[22]

The development of new algorithms or ablation strategies for performing laser corneal refractive surgery in a customized form, minimizing the amount of ablated tissue without compromising the visual quality, and potentially maximizing visual performance without increasing risk factors would be of great value for the refractive surgery community and ultimately for the health and safety of patients. The real impact of tissue-saving algorithms in customized treatments is controversial. Minimizing the amount of tissue must be done in a way that does not compromise the refractive correction or visual performance, and it must be safe, reliable, and reproducible.

In general, for the same amount of equivalent defocus, the optical blur produced by HOAs increases with increasing radial order and decreases with increasing angular frequencies. Based on this blur effect of the single Zernike terms, we have defined a dioptric equivalent:

$$\mathrm{DEq}_n^m = \frac{8\sqrt{2(n+1)(1+\delta_{m0})}\left|C_n^m\right|}{\mathrm{PD}^2} \tag{2}$$

where DEq_n^m is the dioptric equivalent of the optical blur; n, the radial order of the considered Zernike term; m, the angular frequency of the considered Zernike term; δ_{m0}, the Kronecker delta function of the angular frequency and zero (1 for radially symmetric Zernike terms and 0 otherwise); C_n^m, the weight coefficient of the considered Zernike term; and PD, the analysis diameter for the optical blur.

In such a way, the dioptric equivalent produced by HOAs increases with increasing radial order and partly decreases with increasing angular frequencies. This dioptric equivalent metric is identical to the power vector notation for the low orders and allows defining a general optical blur as a general expression for the one proposed by Thibos et al[36]:

$$U_G = \sqrt{\sum \left(\mathrm{DEq}_n^m \right)^2} \tag{3}$$

where U_G is the general optical blur.

We have expressed each of the Zernike terms as a dioptric equivalent in familiar units to help judge the order of magnitude of the effect. Using common clinical limits, the following classification is proposed:

$$\mathrm{DEq}_n^m < 0.50 \text{ D} \Rightarrow \text{might be clinically relevant} \tag{4}$$

$$\mathrm{DEq}_n^m \geq 0.50 \text{ D} \Rightarrow \text{clinically relevant} \tag{5}$$

This represents the proposed objective determination of the actual clinical relevance of the single terms in a Zernike expansion of the wavefront aberration.[22]

6.1 Objective minimization of the maximum depth of a customized ablation based on the Zernike expansion of the wavefront aberration

One of the minimization approaches consists of simplifying the profile by selecting a subset of Zernike terms that minimizes the necessary ablation depth while respecting the Zernike terms considered clinically relevant. The minimize depth (MD+) function analyzes the Zernike pyramid as described in the previous section and evaluates the ablation depth of all possible free combinations of subsets of Zernike terms while fulfilling several conditions:

- Only terms of third or higher order can be disabled.
- Only terms with optical blur dioptric equivalent less than 0.5 D can be disabled.
- For each subset combination of Zernike terms, the low-order terms are recalculated using the automatic refraction balance method.

From this evaluation, the function selects the subset of Zernike terms that needs the minimum amount of maximum depth.

6.2 Objective minimization of the ablation volume of a customized ablation based on the Zernike expansion of the wavefront aberration

The other minimization approach consists of simplifying the profile by selecting a subset of Zernike terms that minimizes the necessary ablation volume while respecting the Zernike terms considered clinically relevant. The minimize volume (MV+) function analyzes the Zernike pyramid as described in the previous section and evaluates the ablation depth of all possible free combinations of subsets of Zernike terms fulfilling several conditions:

- Only terms of third or higher order can be disabled.
- Only terms with optical blur dioptric equivalent less than 0.5 D can be disabled.
- For each subset combination of Zernike terms, the low-order terms are recalculated using the automatic refraction balance method.

From this evaluation, the function selects the subset of Zernike terms that needs the minimum amount of volume for the ablation. Reduced ablation volumes lead to shorter treatment times.

One could use the equivalent defocus applied to each individual Zernike mode to compute its clinical relevance. The basis of the equivalent defocus concept is the notion that the imaging quality of an eye is determined primarily by wavefront variance, and it does not matter which Zernike mode produces that variance. This is only true when the wavefront variance is really small and the image quality is measured by the Strehl ratio. Otherwise, the relationship between wavefront variance and image quality becomes much more complex. It is important to bear in mind that 1 D of ordinary defocus does not necessarily have the same effect as 1 D of equivalent defocus because different types of aberrations affect the retinal image in different ways. Nevertheless, by expressing RMS error in terms of equivalent defocus, the data are put into familiar units that help us judge the order of magnitude of the effect.

Strictly speaking, one cannot consider the clinical relevance of every Zernike term independently without demonstrating whether a single Zernike term is alone responsible for the loss of visual quality. The visual effect of an aberration does not only depend on that specific aberration but also on other possibly present aberrations; for example, the sum of small aberrations, previously considered clinically irrelevant, could lead to a clear loss of overall optical quality. The idea of approximating a distorted wavefront by means of an equivalent dioptric error is much too controversial to be accepted without caution.

Coupling effects between different HOA terms and between HOAs and manifest refraction have been found,[44–46] for example, between defocus and spherical aberration, third-order aberrations and low-order terms, spherical aberration and coma, or secondary and primary astigmatisms. These interactions may provide some relative visual benefits[47] but may also contribute uncertainty in the conversion of wavefront aberration maps to refractive prescriptions.[48,49] One could use more sophisticated equations to model the equivalences between the optical blur produced by the different Zernike terms, but we have used a relatively simple approach driven primarily by the radial order. Different approaches for minimizing tissue ablation in refractive surgery have been proposed and extensively discussed.[22] When to use customized strategies in refractive surgery has been discussed previously as well.[18–21]

Considering that Zernike terms are either planned to be corrected or left uncorrected, visual performance is not compromised because all remaining uncorrected terms are below clinical relevance. The proposed approaches are safe, reliable, and reproducible because of the objective foundation upon which they are based. It is important to note that the selection of the Zernike terms to be included in the correction is not trivial. As mentioned, only Zernike terms considered not clinically relevant or of minor clinical relevance can be excluded from the correction, but they must not necessarily be excluded.

Actually, single Zernike terms considered not clinically relevant will only be disabled when they represent additional tissue for ablation and will be enabled when they help to save tissue. This way, particular cases are represented by the full wavefront correction by disabling all nonclinically relevant terms or by disabling all high-order terms. As per design, the MD group actually optimizes for minimum ablation depth and shows the largest

savings for this aim (−8 ± 4 µm, from −20 to −1 µm), whereas the MV group actually optimizes for minimum ablation volume (time) and shows the largest savings for this aim (−8 ± 2 seconds, from -26 to -22 seconds). In this context, and as a rule of thumb, MD minimization could be used in customized myopic treatments when reducing ablation depth is directly related to decreasing the risk of keratectasia, whereas MV minimization could be used in long customized treatments when reducing ablation time is directly related to better maintenance of homogeneous corneal conditions.

7. Surgical technique selection

Excimer laser refractive surgery has evolved full circle. Surface ablations in the form of photorefractive keratectomy (PRK) swiftly evolved into intra-stromal procedure of laser in-situ keratomileusis (LASIK) due to its rapid visual recovery and minimal postoperative discomfort. However, with increasing adoption of LASIK grew the concern for post-LASIK keratectasia. The last few years have therefore, witnessed a renewed interest in alcohol assisted surface ablation procedures to avoid complications of LASIK primarily corneal ectasia and flap and interface related problems.

The decision to perform alcohol assisted LASEK or LASIK is based on preoperative central corneal thickness (measured by ultrasonic pachymetry (DGH-550 Pachette 2, DGH Technologies, USA)) and calculated depth of ablation. LASEK is performed on all patients with central pachymetry less than 500 µm. Eyes with central pachymetry above 500 µm are assigned to either LASEK or LASIK techniques, depending on the central pachymetry and the depth of ablation. The decision is based on the target of limiting the ablation to the anterior one third of the cornea (so as to achieve a residual stromal bed thickness of at least 2/3rd of pre-operative pachymetry). Patients were tested for LASIK in case they do not meet the "2/3" condition they were assigned to the LASEK group.

For corneal and conjunctival anesthesia, two drops of proparacaine HCl 0.5% (Aurocaine®, Aurolab, Madurai, India) are instilled three times before shifting the patient to the operation theatre (OT).

LASIK - Pachymetry is performed before and after flap creation (stromal bed thickness) with both the integrated online coherence pachymeter (Heidelberg, Germany) and ultrasonic pachymeter. Flap is made using LDV femtosecond laser. Contact lens is applied at the end of surgery (Biomedics 55 evolution, Ocular Sciences, Cooper Vision, Hamble, UK) in eyes with 'achieved' flap thickness less than 110 microns to avoid flap displacements, dislocations or striae.

LASEK - 17% alcohol applied for 30 seconds is used for the creation of epithelial flap. Eight or 9 mm diameter epithelial flap is made after incising the corneal epithelium with a trephine. Contact lens is applied at the end of surgery in all LASEK patients.

Postoperative Treatment – For LASIK patients, eye drop Tobradex (Alcon Inc, USA) 3 times a day is used for 1 week along with Oasis soft plugs extended duration (6404 Glendora CA) and preservative free artificial tear drops during the first three months. A bandage contact lens is used during the first night in LASIK patients with flap thickness less than 110µm. For LASEK patients, prior to epithelial healing, eye drops lomefloxacin 0.3 % (Okacin) and pranoprofen (Ofralar, Alcon Inc, USA) are used along with Oasis soft plugs extended

duration. Bandage contact lens is applied in all LASEK patients for 5-7 days until complete healing of the epithelial defect. After epithelial healing, preservative free artificial tear eye drops are given along with efemoline eye drops (Fluoromethalone, Novartis Ophthalmics, Switzerland) 3 times a day for 3 months. The steroids are gradually tapered every month to once a day in the last month.

Postoperative follow-up – LASIK patients are followed on first postoperative day, at 1 month, 3 months, and 1 year. LASEK patients are examined on first postoperative day, at 1 week, 1 month, 3 months, and 1 year.

There has been a renewed interest in surface ablation modalities with epithelial repositioning like LASEK to overcome some of the flap and ectasia related complications of LASIK. Though the rate of visual recovery may be slower in surface ablation thus lacking the LASIK 'wow' effect, studies have shown that LASEK is an effective modality for surgical correction of low to moderate myopia.[8-10] However, its utility for correction of high myopia is limited.[11-13] With introduction of thin and ultrathin flaps using femtosecond laser and newer microkeratomes such as the pendular microkeratome, the indications for the 2 surgical modalities are getting indistinct. Introduction of newer ablation profiles such as customized and aspheric ablations has added another aspect to be evaluated.

It has been suggested that surface ablative procedures may be better suited for customized correction though it has not been proven clinically.[1,2,14] It has been suggested that the creation of corneal flap in LASIK patients can induce further higher order aberrations especially coma like aberrations.[15] This may be particularly relevant to thinner flaps which may have a higher incidence of flap striae. The clinical relevance of these flap induced higher order aberrations especially in relation to newer microkeratomes and femtosecond laser and the effect of flap thickness require further investigation.

The aspheric ablation profile is equally successful with both surface ablation as well as intrastromal excimer ablation minimizing the change in higher order aberrations. The latest development in excimer laser refractive is the thin and the ultrathin flap LASIK. It attempts to find the best of both worlds of standard LASIK and surface ablation. Besides pre-existing risk factors, low residual stromal bed thickness is the single most important modifiable factor that increases the risk of iatrogenic post-LASIK ectasia.[38] Thin and ultrathin flap LASIK achieves a thicker residual stromal bed and therefore is believed to decrease the risk of post-LASIK ectasia. Current study indicates that thin and ultrathin LASIK is safe, efficacious, and predictable after short term follow up of 6 months. However, future investigations with long-term follow-up are likely to prove if LASIK utilizing thin and ultrathin flaps translate into the anticipated decreased risk of post-LASIK ectasia.

8. 6D Eye-Tracker

Human eyes have six degrees of freedom to move: X/Y lateral shifts, Z levelling, horizontal/vertical rotations, and cyclotorsion (rotations around the optical axis). The analysis of these movements has been made since the middle of the 20th century. Schwiegerling and Snyder[32] measured eye motion in patients having laser in situ keratomileusis (LASIK) using a video technique and determine centration and variance of the eye position during surgery. They found a standard deviation in the eye movements in all eyes larger than 100 μm. Taylor et al.[33] determined the accuracy of an eye tracking system

designed for laser refractive surgery. The system demonstrated an accuracy of 60 µm for an intact cornea and 100 µm for a cornea with a thin flap removed.

Bueeler et al.[34] investigated the lateral alignment accuracy needed in wavefront-guided refractive surgery to improve the ocular optics to a desired level in a percentage of normally aberrated eyes. To achieve the diffraction limit in 95% of the normal eyes with a 7.0 mm pupil, a lateral alignment accuracy of 70 µm or better was required. An accuracy of 200 µm was sufficient to reach the same goal with a 3.0 mm pupil. Bueeler and Mrochen[35] quantified the parallax error associated with localizing corneal positions by tracking the subjacent entrance pupil center by means of optical ray-tracing in a schematic model eye. They found tracking error can amount to 30% (or more for eye trackers mounted closer than 500 mm to the eye) of the detected lateral shift. Thus, if the eye tracker registers a lateral shift of the entrance pupil of 200 µm away from the tracking reference axis, the point of interest located on the cornea would essentially be 260 µm away from this reference axis. A laser pulse fired at that moment would be systematically displaced by 60 µm.

Measuring rotation when the patient is upright[36] to when the refractive treatments are performed with the patient supine may lead to ocular cyclotorsion,[37],[38] resulting in mismatching of the applied versus the intended profiles[39],[40]. Recently, some equipment can facilitate measurement of and potential compensation for static cyclotorsion occurring when the patient moves from upright to the supine position during the procedure[41], quantifying the cyclorotation occurring between wavefront measurement and laser refractive surgery[42] and compensating for it[43],[44],[45]. Further measuring and compensating ocular cyclotorsion during refractive treatments with the patient supine may reduce optical "noise" of the applied versus the intended profiles[46],[47],[48].

In recent times, many studies have discussed the methodologies and implications of ocular cyclotorsion, but not many papers pay attention to the rolling and axial movements of the eye. The more irregular a cornea is, the more important proper eye-tracking. Astigmatism is the most common aberration with a vector nature, so usually are the astigmatic problems the ones more affected or the ones which benefit the most from advanced eye tracking.

8.1 Lateral movements during ablation (1st and 2nd dimension)

AMARIS system includes a pupil-registration module for the eye-tracker subsystem, in which, the first pupil image under the AMARIS system obtained with starting the ablation is taken as reference and its location referred to the limbus is used for any further eye-tracker image in order to determine the pupil centre shift compensation (PCSC).

8.2 Eye rolling during ablation (3rd and 4th dimension)

AMARIS system includes a scleral-registration module for the eye-tracker subsystem, in which, the first few scleral-tracker images under the AMARIS system obtained with starting the ablation are taken as reference (natural rolling) and compared to any further scleral-tracker image in order to determine the eye rolling (ER).

8.3 Static cyclotorsion between upright and supine positions (5th dimension)

AMARIS system includes an eye-registration module for the eye-tracker subsystem, in which, the diagnosis image is taken as reference and compared to an eye-tracker image

under the AMARIS system obtained prior to starting the ablation in order to determine the static cyclotorsion component (SCC).

8.4 Dynamic cyclotorsion during ablation (5th dimension)

AMARIS system includes an eye-registration module for the eye-tracker subsystem, in which, the first eye-tracker image under the AMARIS system obtained with starting the ablation is taken as reference and compared to any further eye-tracker image in order to determine the dynamic cyclotorsion component (DCC).

8.5 Axial displacements during ablation (6th dimension)

AMARIS system includes an scleral-registration module for the eye-tracker subsystem, in which, the first few scleral-tracker images under the AMARIS system obtained with starting the ablation are taken as reference (natural level) and compared to any further scleral-tracker image in order to determine the axial displacements (AD).

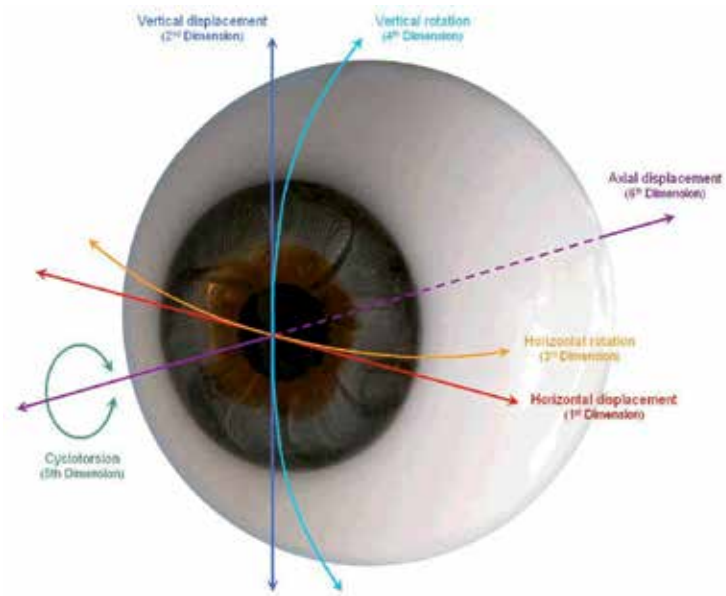

Fig. 4. Lateral movements (vertical and horizontal displacements) 1st and 2nd dimensions, Rolling movements – caused by a tilting of the head or of the eye 3rd and 4th dimensions, Rotations around the visual axis - This happens mostly when changing from upright to supine position, but also during the treatment 5th dimension, cyclotorsion, Movements along the z-axis 6th dimension. All dimensions measured and compensated for static and dynamic movements in an active/passive manner.

The AMARIS TotalTech laser includes compensation for the ocular cyclotorsions occurring from upright to supine position (static cyclotorsion from diagnosis to treatment), as well as the lateral movements, eye rollings, dynamic cyclotorsions, and displacements along the propagation axis occurring during the laser treatment. Further, the differences in pupil size and centre for and during the treatment compared to that during diagnosis[49] are also

compensated for, since the theoretical impact of cyclotorted ablations is smaller than decentred ablations or edge effects[50] (coma and spherical aberration[51]). In this way, additional lateral displacements[52] due to cyclotorsions occurring around any position other than the ablation centre are avoided (induced aberrations emanating from lateral displacements always increase with decentration[53]).

A six dimensional eye-tracker is important since uncompensated pupil movements (lateral movements) induce decentrations[32] which can be visually manifested as comatic aberrations[52]. Uncompensated rolling movements induce decentrations as well[35], which can be visually manifested as comatic aberrations[52]. Uncompensated cyclotorsional movements induce aberrations[40], whereas uncompensated axial movements induce undercorrections in an asymmetrical way. Axial movements produce that the laser spots are no longer in focus when they reach the cornea, i.e. ignoring absorption processes in air, for the same energy spot diameter is larger reducing the radiant exposure and the ablation depth of the spot. Axial movements produce as well that off axis pulses hit the cornea more centrally than planned if the eye moves towards the laser system and further peripherally if the eyes moves far from the laser.

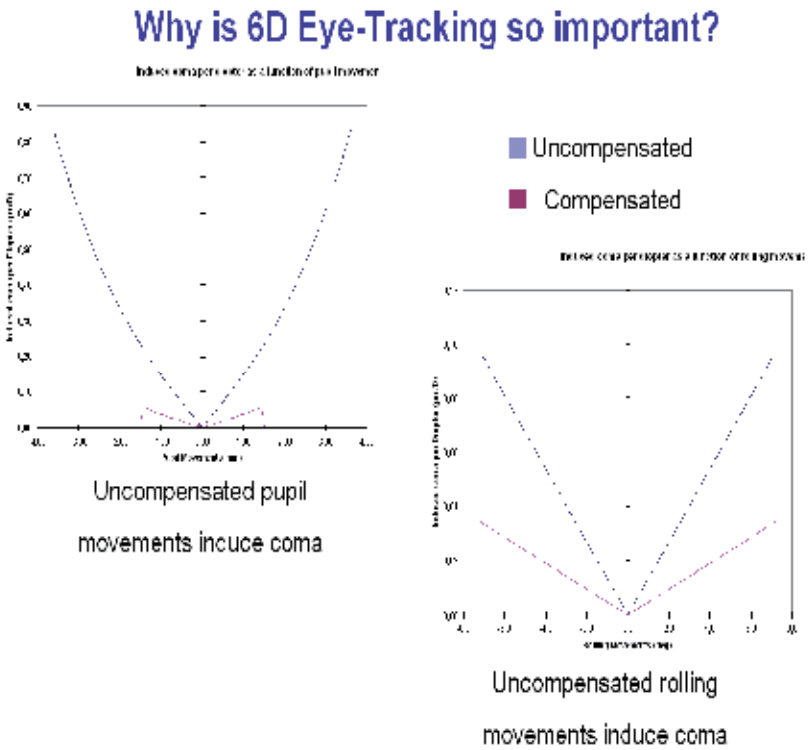

Fig. 5. A six dimensional eye-tracker is important since uncompensated pupil movements (lateral movements) induce decentrations which can be visually manifested as comatic aberrations. Uncompensated rolling movements induce decentrations as well, which can be visually manifested as comatic aberrations.

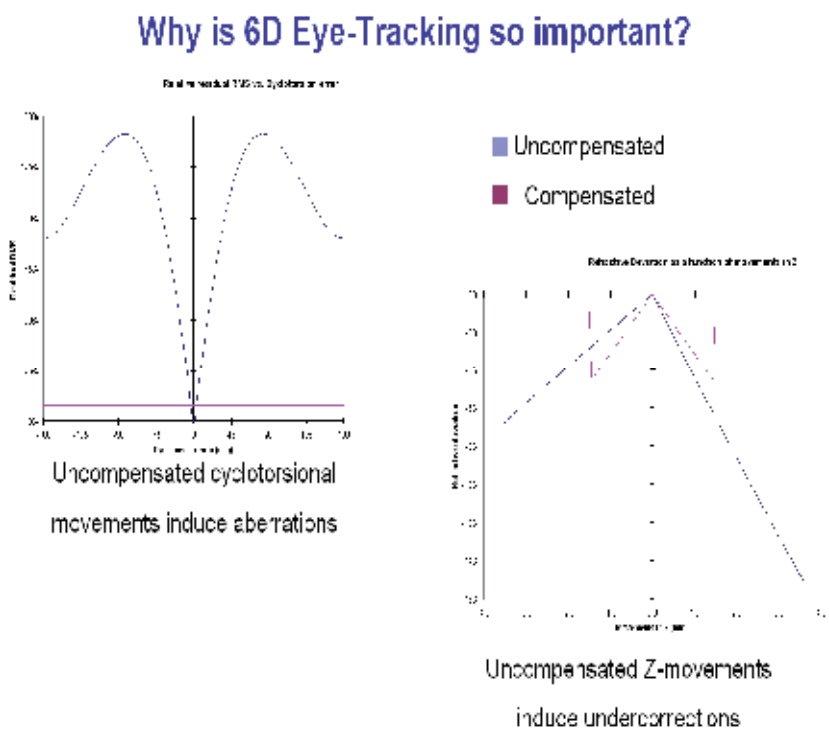

Fig. 6. A six dimensional eye-tracker is important since uncompensated cyclotorsional movements induce aberrations, whereas uncompensated axial movements induce undercorrections in an asymmetrical way. Axial movements produce that the laser spots are no longer in focus when they reach the cornea, i.e. ignoring absorption processes in air, for the same energy spot diameter is larger reducing the radiant exposure and the ablation depth of the spot. Axial movements produce as well that off axis pulses hit the cornea more centrally than planned if the eye moves towards the laser system and further peripherally if the eyes moves far from the laser.

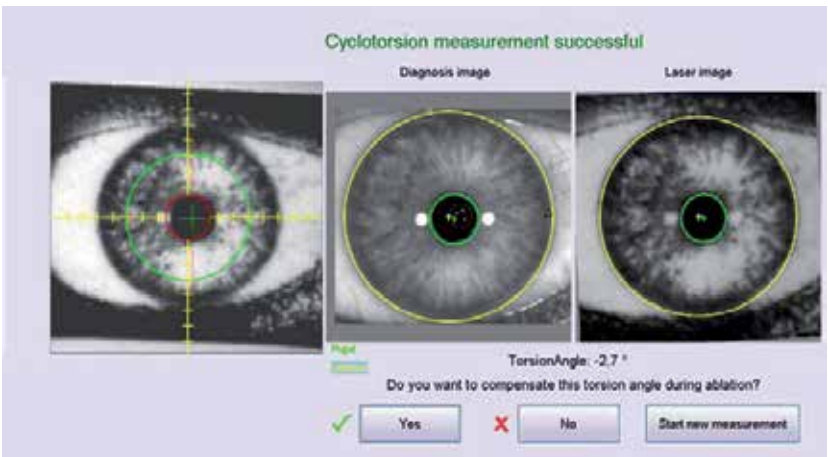

Fig. 7. Static cyclotorsion compensation.

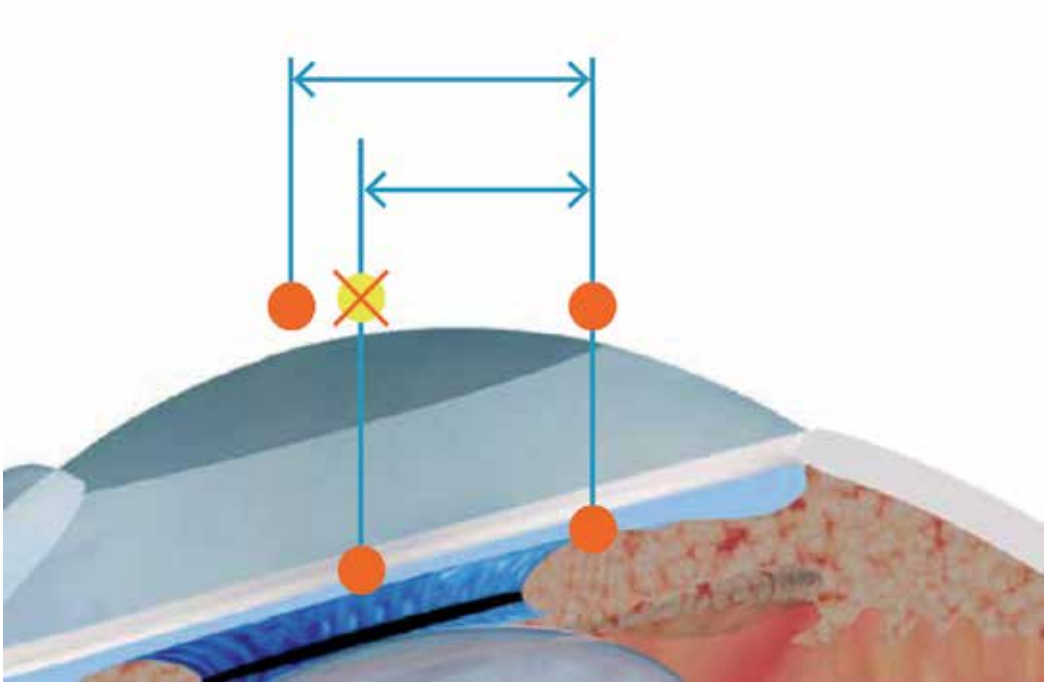

Fig. 8. Rolling compensation.

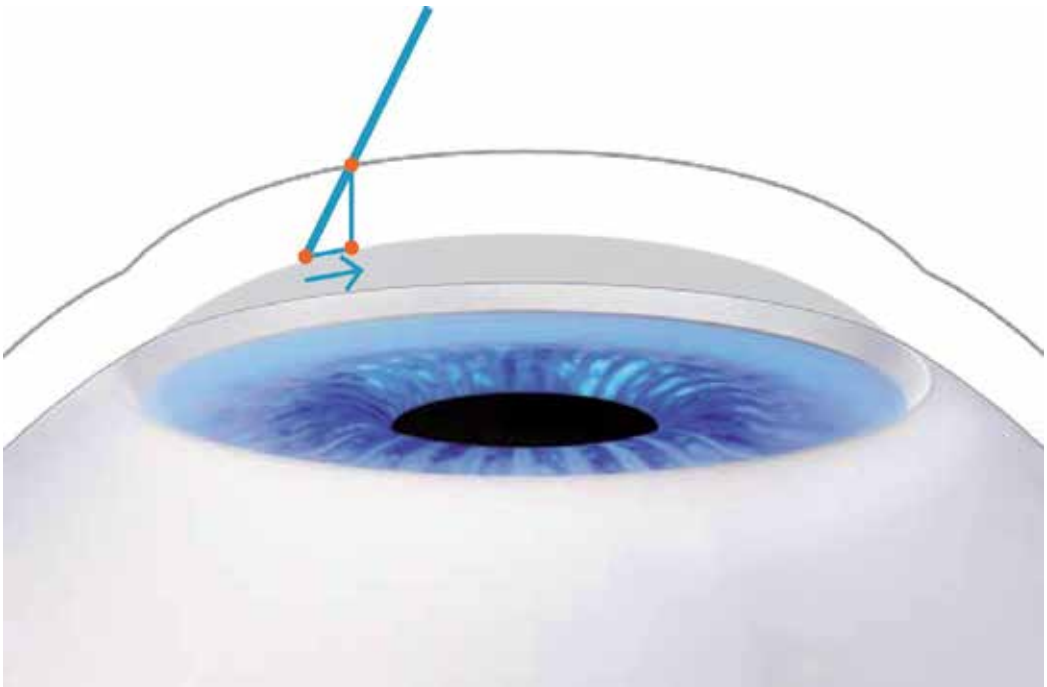

Fig. 9. Axial movements compensation.

In our experience with AMARIS system measuring the pupil displacements, we obtained an average of 150 μm. The distribution of the percentage of eyes vs. pupil displacement showed 3% of eyes had pupil displacements exceeding 1 mm. The ranges for pupil displacements over the treatment are relatively mild, but with peaks of up to about 1.5 mm.

With our system for measuring the rolling movements, we obtained an average value 5°. This value is actually the most commonly accepted value for "natural rolling" measured as angle alpha[54], lambda[55], or kappa[56]. The distribution of the percentage of eyes vs. rolling movements showes 3% of eyes had rolling exceeding 8 deg. The ranges for the rolling movements over the treatment are relatively mild, but with peaks of up to about 10 deg.

With our system for measuring the static cyclotorsional error, we obtained an average cyclotorsion of 1°, lower than the observations of Ciccio et al.,[57] who reported 4°. The distribution of the percentage of eyes vs. cyclotorsional error shows 3% of eyes had cyclotorsion exceeding 8 deg. The mean DCC values over the treatment are relatively small, but with peaks of up to about 5 deg. Considering that the average cyclotorsion resulting from the shift from the upright to the supine position is about ±4 deg,[57] it is not enough to compensate only for the static cyclotorsion without considering the dynamic cyclotorsion during the laser procedure. Finally, the effects of the DCC can be considered as optical "noise" of the applied versus the intended profiles.[58]

Without eye registration technologies,[59,60] considering that maximum cyclotorsion measured from the shift from the upright to the supine position does not exceed ±14 deg,[57] explains why "classical" spherocylindrical corrections in refractive surgery succeed without major cyclotorsional considerations. However, only limited amounts of astigmatism can effectively be corrected for this cyclotorsional error[40]. Currently available eye registration technologies, providing an accuracy of about 1 deg and measuring static and dynamic cyclotorsion components, open a new era in corneal laser refractive surgery, because patients may be treated for a wider range of refractive problems with enhanced success ratios. This requires high-resolution ablation systems as well.[61,62]

With our system for measuring the axial movements, we obtained an average of -300 μm. This negative value is fairly low, but means the patients use to push their head back at the beginning of the treatment and return smoothly closer to level during treatment. The distribution of the percentage of eyes vs. axial movement shows 10% of eyes had axial movements exceeding 1 mm. The ranges for axial movements over the treatment are relatively mild, but with peaks exceeding 1 mm.

In our AMARIS experience of over 8000 treated eyes, 91% of treatments result in a postoperative cylinder within 0.5 D, and 19% of treatments gain lines of BSCVA compared to the preoperative baseline. From the minor induction of aberrations can be inferred that mesopic and low-contrast VA have maintained, at least, the best-corrected preoperative levels. More clinical data are required before we can state how much improvement can be expected from the use of this technology.

6D Eye-Tracker with AMARIS yields excellent outcomes. Refractions are reduced to subclinical values: (mean postoperative defocus -0.12±0.17D and astigmatism 0.15±0.25D) with 70% eyes within ±0.25D of emmetropia and 19% eyes gain lines of BSCVA. Rate of registration is >90% for Cyclotorsion and >80% for Rolling and Axial movements. Mean

Rolling was within ±5° in 52% of the cases, Dynamic Rolling was within ±5° in 66% of the cases, Static Cyclotorsion was within ±4° in 69% of the cases, Dynamic Cyclotorsion was within ±2° in 72% of the cases, and Z-movement was within ±0.5mm in 69% of the cases.

6D Eye-Tracker Controls with the SCHWIND AMARIS are safe and very predictable. In summary, using SCHWIND AMARIS, six-dimensional movements of the eye can be effectively measured and compensated for both static and dynamic conditions during laser corneal ablation.

9. High speed refractive surgery

The range of repetition rates of the laser systems for refractive surgery currently available in the market runs from about 10 Hz to about 1000 Hz (median 250 Hz), with spot size diameters ranging from 6.5 mm to about 0.3 mm (median 1 mm), corresponding to treatment velocities from about 9 s/D to about 1.7 s/D (mean 5 s/D). If we compare these values to the situation at the beginning of the 21st century, a technological quantum leap is observed. In 2001, repetition rates of the laser systems for refractive surgery in the market ranged from about 10 Hz to about 300 Hz (median 50 Hz), with spot size diameters ranging from 6.5 mm to about 0.8 mm (median 2-6 mm), corresponding to treatment velocities from about 19 s/D to about 6 s/D (mean 12 s/D).

To foresee the future trends for these essential values when defining the technological capabilities of a system, four driving forces shall be considered:

- The technological progress of the last 10 years indicating an exponential improvement of the technology
- The non-linear cost-to-benefit ratio for new developments indicating a continued improvement of the technology at a slower rate
- The actual clinical needs for faster or more precise systems indicating a slow-down improvement of the technology achieving maturity and stability
- The limitations imposed by the biological tissue response to the laser interaction (e.g. thermal issues, haze development[63])

Considering these effects, we can hypothesize a scenario with repetition rates of the laser systems for refractive surgery ranging from about 300 Hz to about 1500 Hz, with spot size diameters ranging from 1.5 mm to about 0.2 mm, corresponding to treatment velocities from about 4 s/D to about 1.3 s/D.

However, due to the presence of local frequency controls, the duration of the treatments is no longer inversely proportional to the repetition rate. The duration of the treatments is inversely proportional to the repetition rate only for slow repetition rates (<180 Hz), and stabilizes asymptotically for high repetition rates (>1500 Hz).

10. Bilateral symmetry

Human vision is a binocular process. Having two eyes gives binocular summation in which the ability to detect faint objects is enhanced. It can give stereopsis in which parallax provided by the two eyes' different positions on the head give precise depth perception. Such binocular vision is usually accompanied by binocular fusion, in which a single image is seen despite each eye is having its own image of any object.

Literature suggests that marked anisometropia is uncommon, either in the magnitude of sphere or astigmatism, with few notable exceptions concluding that the axis of astigmatism does not follow any particular rule (mirror or direct symmetry) across right and left eyes.

Porter et al.[64] confirmed in a large population that although the pattern of aberrations varies from subject to subject, aberrations, including irregular ones, are correlated in left and right eyes of the same subject, indicating that they are not random defects. The Indiana Aberration Study by Thibos et al. characterized the aberration structure, and the effects of these aberrations on vision, for a reasonably large population of normal, healthy eyes in young adults, and verified the hypothesis of bilateral symmetry.

Wang et al.[65] found that anterior corneal wave aberrations varied greatly among subjects, but a moderate to high degree of mirror symmetry existed between right and left eyes. To our knowledge, very few studies in the literature have addressed the issue of symmetry of aberrations between eyes after corneal laser refractive surgery[66],[67]. Jiménez et al.[66] found that binocular function deteriorates more than monocular function after LASIK, and that this deterioration increases as the interocular differences in aberrations and corneal shape increase. They found that interocular differences above 0.4 μm RMS for 5-mm analysis diameter, lead to a decrease of more than 20% in binocular summation.

If binocular symmetry is manifested on virgin human eyes and it is important for binocular vision, it shall be interesting to assess whether existing symmetry is maintained after treating the cornea for correcting the ametropias using corneal laser refractive surgery. Further analysis of bilateral symmetry according to analysis diameter is also of interest. The analysis of bilateral symmetry should be related to binocular vision status of patients.

Cuesta et al.[68] found that even differences in corneal asphericity might affect the binocular visual function by diminishing the binocular contrast-sensitivity function. Arbelaez et al.[67] found that only four of 25 patients showed preoperatively clinically relevant differences OS vs. OD larger than 0.25 D, whereas 6-month postoperatively only 2 of 25 patients showed clinically relevant differences OS vs. OD larger than 0.25 D. 6-month postoperatively three Zernike terms lost significant correlation symmetry OS vs. OD and 4 Zernike terms gained significant correlation symmetry. However, two of them showed borderline correlations. 6-month postoperatively 6 Zernike terms significantly increased differences in symmetry OS vs. OD and 4 Zernike terms significantly decreased differences in symmetry. However, six of them showed borderline significances of the difference. 6-month postoperatively three patients lost significant correlation symmetry OS vs. OD and one patient gained significant correlation symmetry. However, two of them showed borderline significances of the difference. All these borderline situations actually shall be seen as “almost preserved” bilateral symmetry.

The presented results cannot be extrapolated to patients with symptoms of amblyopia[69], anisometropia, nystagmus, or aniseikonia[70] without further studies. Bilateral symmetry in corneal aberrations does not mean any "good or bad" point for binocular vision. We cannot evaluate exactly the role of aberrations monocularly (patients with high level of aberrations can have an excellent visual acuity and vice-versa); therefore it is more difficult binocularly.

The important question in binocular vision is "the role of interocular-differences," and if they can influence significantly binocular performance. Interocular-differences can be minor but significant for visual performance. Further studies shall help to determine the impact of this on binocular visual performance.

The more irregular a cornea is, the more important proper bilateral symmetry for adequate binocular summation. Astigmatism is the most common aberration with a vector nature, so usually are the astigmatic problems the ones more affected or the ones which benefit the most from losing or preserving bilateral symmetry.

11. Correction of high astigmatism

Because the corneal ablations for refractive surgery treatments induce aberrations (one of the most significant side-effects in myopic LASIK is the induction of spherical aberration[71], which causes halos and reduced contrast sensitivity[72]), special ablation patterns were designed to preserve the preoperative level of high order aberrations[73,74,75]. For the correction of astigmatism many different approaches have been tested, with different degrees of success, through the years[76,77,78,79,80,81].

LASIK has been successfully used for low to moderate myopic astigmatism, whether LASIK is acceptably efficacious, predictable, and safe in correcting higher myopic astigmatism is less documented, specially with regard to the effects of astigmatic corrections in HOA's[82].

The advantage of the Aberration-Free™ ablation profile is that aims being neutral for HOA, leaving the visual print of the patient as it was preoperatively with the best spectacle correction. The correction of astigmatism has been approached using several techniques and ablation profiles. There are several reports showing good results for compound myopic astigmatism using photorefractive keratectomy (PRK) and LASIK, but ablation profiles usually cause a hyperopic shift because of a coupling effect in the flattest corneal meridian. A likely mechanism of this coupling effect is probably due to epithelial remodeling and other effects such as smoothing by the LASIK flap[83]. In cases of large amounts of preoperative astigmatism, deviations from the target refractive outcome are usually attribute to "coupling factors". But, the investigation of the coupling factor remains a rather difficult task, because it seems to be dependent on various factors. Individual Excimer laser systems may have different coupling factors, cutting the flap could alter the initial prescription and also different preoperative corneal curvature (K-reading) may have an influence on the coupling factor.

The most dominant correlations of induced HOAb occurr for C[4,0], and C[6,0] versus defocus correction, for C[4,+2] versus cardinal astigmatism correction, and C[4,-2] versus oblique astigmatism correction. We evaluated the postoperative clinical outcomes and high order aberrations among eyes with astigmatism higher than 2 D that have underwent refractive surgery using the SCHWIND AMARIS laser system. SCHWIND CAM Aberration-Free Aspheric astigmatic treatments have been performed in all cases.

At six-month follow-up, 50 eyes with preoperative astigmatism higher than 2 D were retrospectively analysed. Ablations performed using the SCHWIND AMARIS flying-spot excimer laser system. LASIK flaps were created using Ziemer LDV Femtosecond laser system in all cases.

Inclusion criteria comprised:

- preoperative astigmatism higher than 2 D targeted for emmetropia
- BSCVA ≥ 20/25 (logMAR ≤ +0.1)
- <0.75 µm RMS-HO for 6-mm diameter
- successful completion of 6-month follow-up

We performed following analyses:

- UCVA
- BSCVA
- manifest subjective refraction (SR)
- corneal wavefront up to 7th order at 6-mm diameter without cycloplegia

50 eyes (100%) completed the 6M follow-up, with an average age at the time of the surgery of 28 years (from 17 to 46). 28 eyes were female, and 22 eyes male. 25 patients treated bilaterally. Mean preoperative defocus averaged -3.08 D ± 2.32 D (from -7.13 to -1.00), with mean astigmatism 3.54 D ± 0.85 D (from 2.00 to 4.75). Mean postoperative defocus averaged -0.06 D ± 0.25 D (from -0.75 to +0.75), with mean astigmatism 0.25 D ± 0.26 D (from 0.00 to 1.25). 92% of the eyes ended up in UCVA 20/20 or better. 38% of the eyes gained at least one line of BSCVA (p<.01*). >75% of the eyes within 0.50 D of astigmatism and U-vector, and >90% of the eyes within 1.00 D of astigmatism and U-vector.

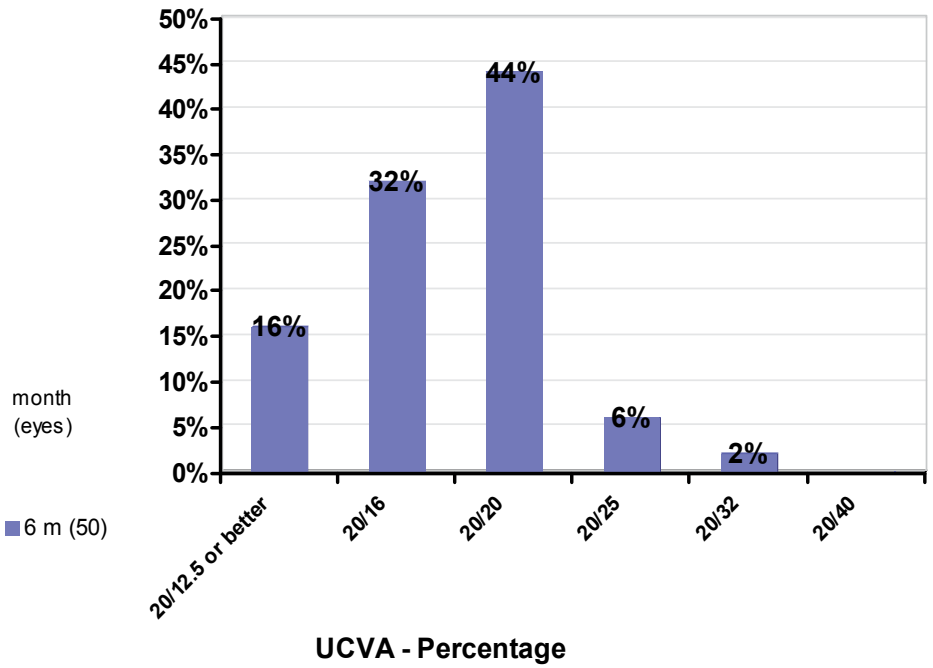

Fig. 10. Efficacy of the correction of moderate to high astigmatism in an aspheric astigmatic setting.

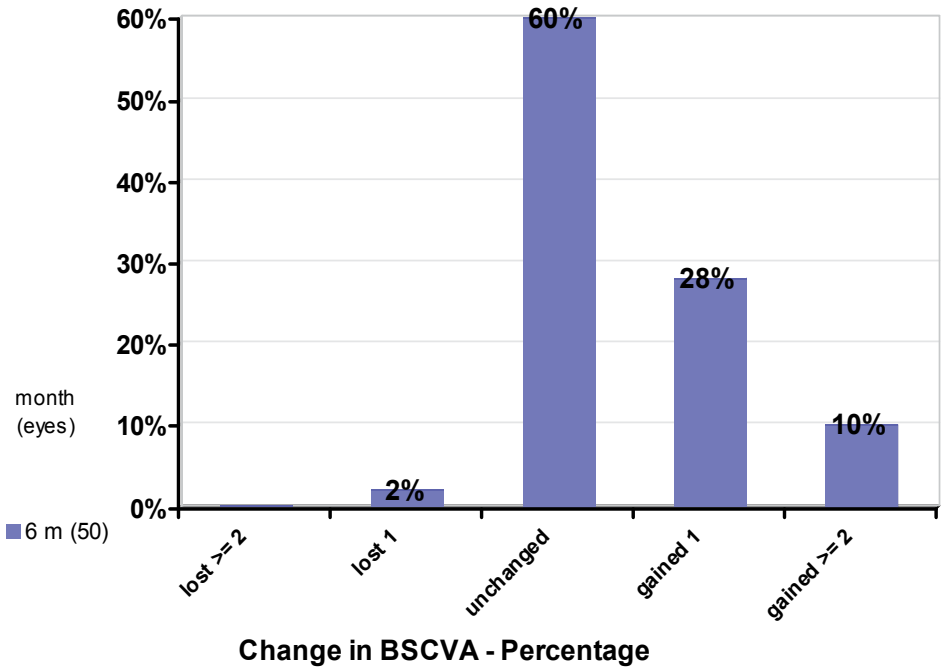

Fig. 11. Safety of the correction of moderate to high astigmatism in an aspheric astigmatic setting.

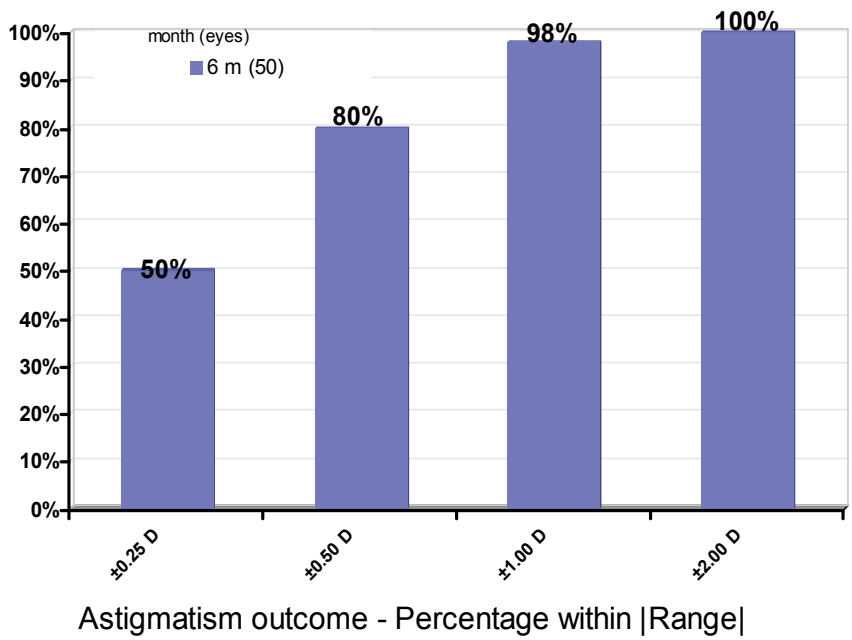

Fig. 12. Refractive astigmatic outcome of the correction of moderate to high astigmatism in an aspheric astigmatic setting.

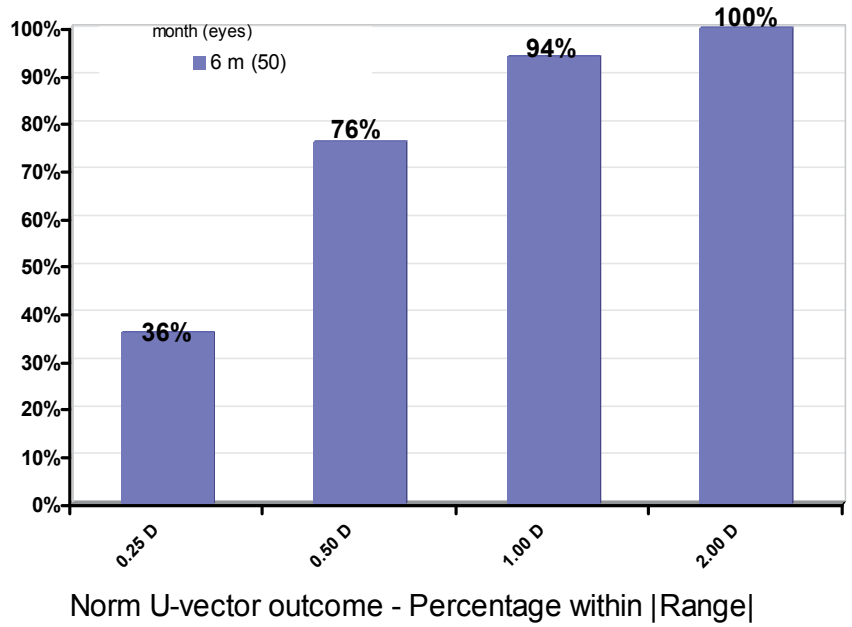

Fig. 13. Residual blur of the correction of moderate to high astigmatism in an aspheric astigmatic setting.

A very slight undercorrection in astigmatism was observed (both cardinal and oblique).

Only 5 HO Zernike terms (out of 30) changed significantly after treatment, whereas 25 HO Zernike terms (out of 30) did not change after treatment.

Zernike term at 6-mm Ø	Preoperative (μm)	Postoperative (μm)	p-value
C[3,-3]	-0.14	-0.02	**<.0001**
C[4,+2]	-0.08	-0.10	**<.05**
C[4,+4]	+0.03	+0.01	**<.05**
C[5,-3]	+0.01	-0.01	**<.0001**
C[6,0]	0.00	+0.03	**<.0001**
HO-RMS	**+0.47**	**+0.57**	**<.0005**

Table 2. Statistically induced Zernike terms.

For all of them, the variation was well below the clinical relevance.

50 high-astigmatism treatments were analysed at 6M follow-up. Results were achieved without applying additional nomograms (residual sphere about 0 D, residual cyl about -0.25 D) (>75% within 0.50 D, >90% within 1.0 D). 6-months follow-up time shows the excellent performance of the system (48% eyes 20/16 or better UCVA, 98% eyes 20/25 or better

UCVA). Aberration-Free astigmatic treatments with SCHWIND AMARIS are safe and very predictable (no eye lost >1 line BSCVA, 5 eyes gained >=2 lines BSCVA).

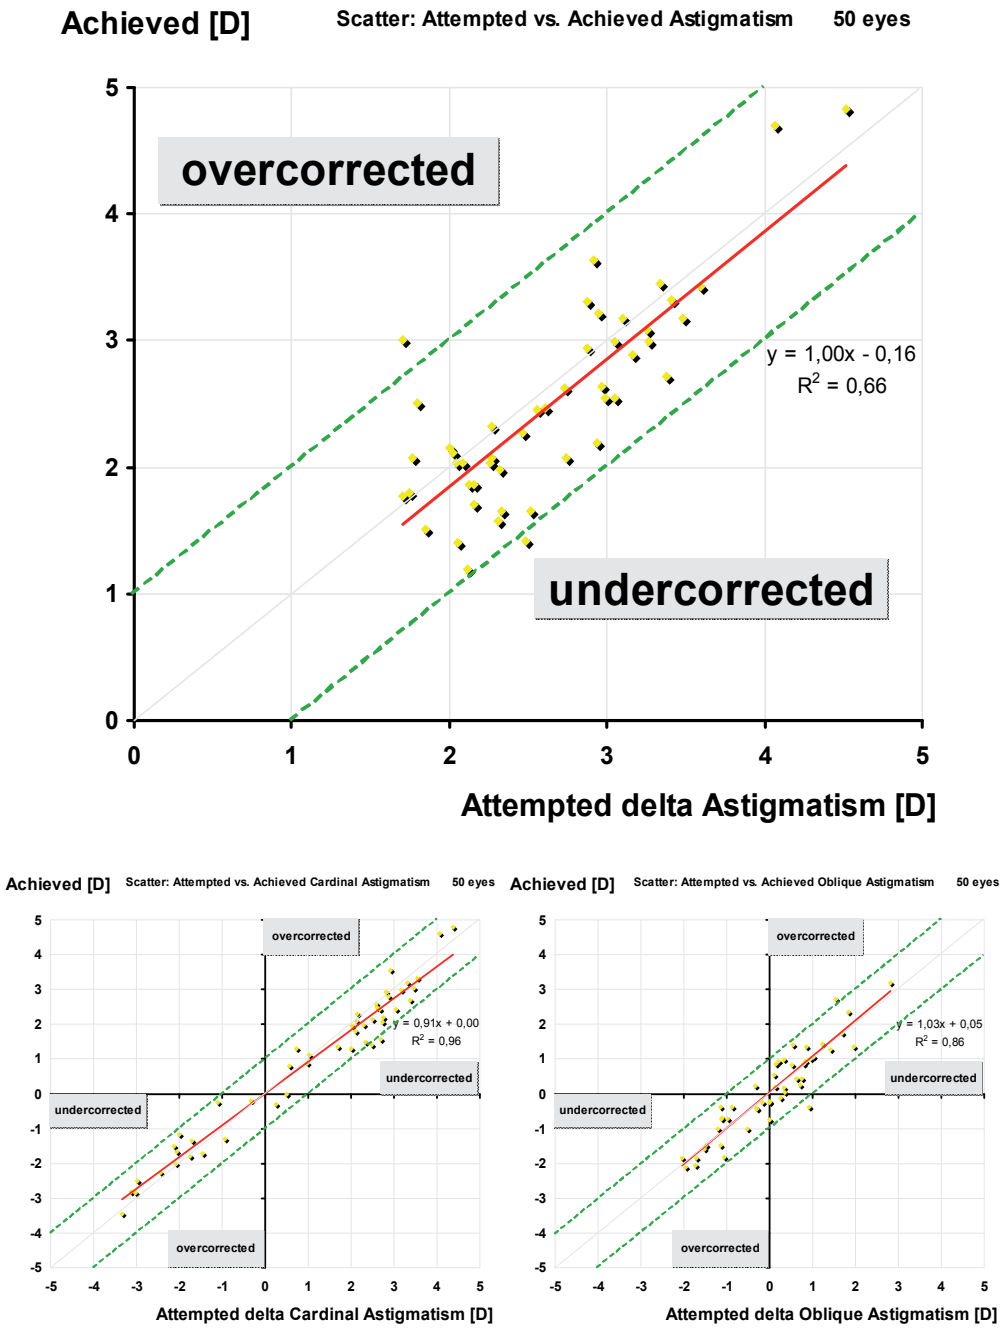

Fig. 14. Scattergram of the correction of moderate to high astigmatism in an aspheric astigmatic setting.

From VA, 92% eyes UCVA 20/20 or better and 38% eyes improved their pre-op BSCVA, due to the minimum aberrations induction by the AMARIS-CAM profile. Despite large defocus and astigmatism magnitudes, minor significant induction of some aberration terms, well below clinically relevant magnitudes. The most dominant correlations of induced HOAb occurred for: C[4,0] vs. Defocus correction, C[4,+2] vs. Cardinal Astigmatism correction, and C[4,-2] vs. Oblique Astigmatism correction.

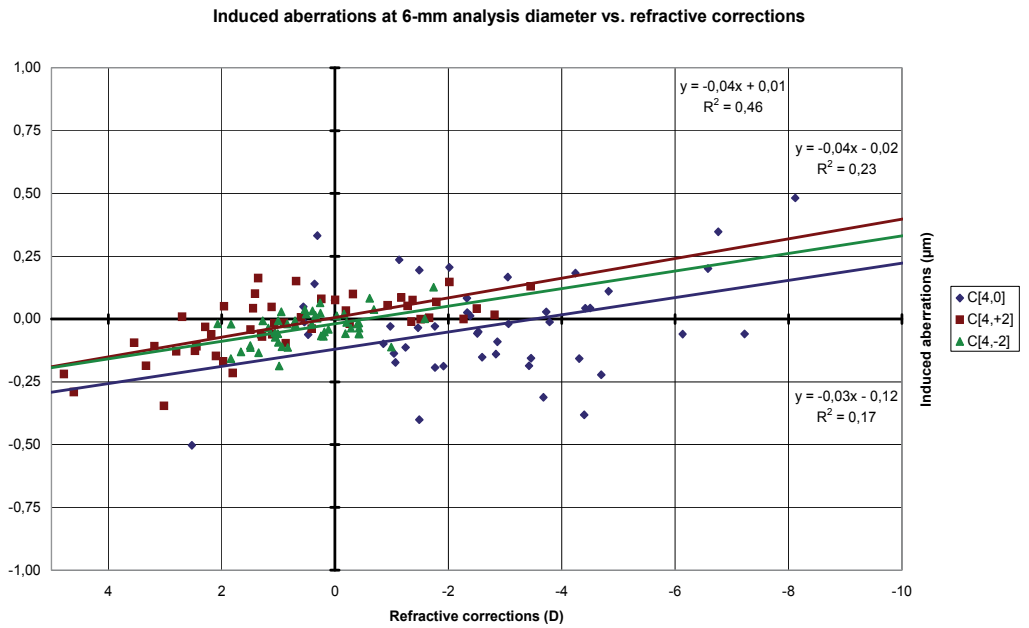

Fig. 15. Induction of aberrations after the correction of moderate to high astigmatism in an aspheric astigmatic setting.

All ablations were non-wavefront-guided treatments. Despite low aberrations, some astigmatisms were not regular. Treatments were centred at the corneal vertex. Despite myopic corrections, 40% of the treatments needed an offset >150 µm.

Laser settings were planned with the manifest astigmatism (magnitude and axis). Topographic astigmatism was not considered for the calculations. No nomogram compensations were applied. With a slight nomogram, further refinements could have been achieved.

Comparing Nomograms of Two Symmetric and Two Asymmetric Intacs® Segments Implantation for Treatment of Pellucid Marginal Degeneration

Luis A. Rodriguez and Anny E. Villegas*
Corneal Clinic, Centro Medico Docente La Trinidad (CMDLT), Caracas Venezuela

1. Introduction

Non-inflammatory progressive corneal ectasia and thinning disease are among the most common abnormalities that refractive surgeons diagnose. Pellucid Marginal Degeneration (PMD) is another ectatic pathology that is rarely detected. PMD is a bilateral, non-inflammatory, progressive peripheral inferior corneal thinning disorder (1,2). Diagnosis is based on the presence of corneal thinning with ectasia characterized by a peripheral band of thinning of the inferior cornea with 1 to 2 mm of normal cornea between this area and the limbus (2,3). The area of thinning typically is epithelialized, clear, avascular, and without lipid deposit. Like keratoconus, PMD is a bilateral progressive disorder although eyes may be asymmetrically affected. Topographic examination is very useful to differentiate this ectatic disorder. The topographic appearance shows a classical "butterfly" pattern that demonstrates large amounts of against-the-rule astigmatism as measured by simulated keratometry and inferior thinning. PMD can also be diagnosed by performing a pachymetric map of the entire cornea, as well as by elevation corneal maps using placido-ring-based videokeratoscopy technology (1).

The etiology of PMD is not clear, and it is not known whether PMD, keratoconus and keratoglobus are distinct diseases or phenotypic variations of the same disorder (4). PMD is usually asymptomatic except for progressive deterioration in uncorrected visual acuity caused by irregular astigmatism (5). Slit-lamp examination shows a peripheral band of thinning with a protrusion ("beer-belly" contour) of the inferior cornea (6,7,8). Topographically, this protrusion in the peripheral inferior cornea has high keratometry powers, radiating toward the center from the inferior oblique meridians, typically in the inferior peripheral cornea. There is an area of flattening in the center of the cornea (5). In transmission electron microscopy of the cornea, abnormal fibrous long-spacing (FSL) collagen with a periodicity of 100 to 110 nm in PMD is revealed, which contrasts with 60 to 64 nm found in normal corneas (9). A study reported in 2002 describes associations with

* None of the authors has a financial or proprietary interest in any material or method mentioned in this article.

vernal keratoconjunctivitis, Marfan's syndrome, ocular hypertension, keratoconus, keratoglobus and hydrops (23).

In the early stages, spectacles and contact lenses are the usual treatment approaches; however, in patients who cannot be rehabilitated with these options, a surgical procedure is necessary (10). Different surgical options include crescentic wedge resection, crescentic lamellar keratoplasty, penetrating keratoplasty, epikeratophakia and thermokeratoplasty. However, all these techniques have disadvantages: unpredictability, irreversibility, long period of rehabilitation and significant complication rates (11-16). Authors suggest the use of intracorneal rings (ICR) in glasses/contact lens-intolerant patients affected by early and moderate PMD with against-the-rule astigmatism and inferior peripheral corneal thickness of >450 μm (10). Since ICR mechanically lifts the inferior ectasia of PMD, flattens the soft ectatic corneal tissue, and decreases asymmetrical astigmatism, visual acuity is expected to improve following this procedure (17). Intacs® works on the principle of tissue addition. Peripheral distention is directly proportional to the degree of central corneal flattening, and by an arc-shortening effect it manages to change the shape and power of the central cornea in ectatic eyes without weakening the central or the paracentral cornea (17,18). The aspheric shape of the natural cornea reduces aberrations and minimizes refractive error fluctuations as the pupil changes its size, and therefore reduces visual disturbances such as glare and halos. It is important to observe that Intacs® maintains an aspheric cornea. After placement of ring segments, central cornea has been shown to maintain a prolate shape because Intacs® flattens the peripheral cornea more than the central cornea (19). The major objective of corneal ring segment inserts is to reshape the abnormality by neither removing corneal tissue nor touching the central cornea (20). Various reports have been published illustrating either the symmetrical (inserting two same-size segments) or the asymmetrical (inserting two different size segments) Intacs® implantation techniques for the management of PMD. Both these techniques have been independently shown to improve UCVA, BSCVA and topographic findings (9,10).

Intacs® are polymethylmethacrylate crescent-shaped segments with arc length of 150° and inner and outer diameters of 6.8 mm and 8.1 mm respectively. The ring segments are available in sizes ranging in thickness from 0.25 to 0.45 mm (Table 3).

2. Patients and methods

Symmetric ring segments were implanted in ten (10) eyes and asymmetric ring segments were implanted in nine (9) eyes. Swanson nomogram was used to calculate segment thickness in each eye.

De-Centered Cones (Posterior Float 50% outside the 3 mm optical zone)**		
Spherical Equiv	**Inferior Intacs®**	**Superior Intacs®**
+1.00 to -2.00	.250 mm	.300 mm
-2.00 to -3.00	.250 mm	.350 mm
-3.00 to -4.00	.300 mm	.400 mm*
-4.00 and -5.00	.300 mm	.450 mm*
-5.00 and higher	.350 mm	.450 mm*

**Keratoconus, Pellucid Marginal Degeneration or "Pellucid Like" Nomogram (24)

The election of using asymmetric and symmetric ring segments was based on spherical equivalent and was randomly chosen.

Besides the demographic details, key parameters evaluated during the preoperative and postoperative examination included: slitlamp microscopy, manifest refraction, spherical equivalent (SE), uncorrected visual acuity (UCVA), corneal pachymetry, tonometry, flat and steep keratometry readings and topography (Orbscan II). Postoperatively patients were evaluated at one month, three months, six months and one year.

3. Surgical procedure

Intacs® implantation was performed under topical anesthesia. After the patients were prepared through corneal hydration with balanced saline solution and sterile fields, the geometric center of the cornea was measured and marked. A radial 2 mm incision was performed in the steep corneal meridian with a diamond knife that was calibrated to 85% corneal depth. A vacuum centering guide - sloped shelf ring connected to a KV2000 vacuum system (Addition Technology® 155 Moffett Park Drive, Suite B-1 Sunnyvale, CA 94089-1330 U.S.A.) was positioned to stabilize the globe. Clockwise and counterclockwise stromal dissectors were introduced into the base of the incision to create stromal tunnels. Intacs® of selected thicknesses were placed in the stromal tunnels from each side of the incision. The incision site was closed with one interrupted 10-0 nylon suture. Post-operative medication included an antibiotic/steroid combination taken every six (6) hours for two (2) weeks. All procedures were uneventful and performed by the same surgeon, (LAR).

4. Statistical analysis

The two groups were analyzed for any bias with respect to age, size of segments, initial values of visual acuity, astigmatism, spherical equivalent, flat and steep keratometry readings. Both groups were found to be comparable.

Our study was descriptive and results were represented as averages and percentages (±standard deviations). Confidence intervals were set at 95%.

Paired t test was used to compare the two groups with respect to changes in the following parameters: visual acuity, astigmatism, spherical equivalent, keratometries (flat and steep readings). Visual acuity was expressed in log mar (Snellen equivalent). One-way Anova test was applied to compare the changes in values throughout time in both the symmetric and asymmetric groups. Bonferroni post test was applied in cases where the values were statistically significant. Any value of P less than or equal to 0.05 ($P > 0.05$) was considered statistically significant.

5. Results

Preoperative values in asymmetric group: UCVA 1.00 (log mar); astigmatism: -4.00D; SE: -2.90D, K (flat) 43.09 D; K (steep) 47.02D. (Table 1) UCVA 0.85 (log mar); astigmatism: -4,50D; SE: -2.74D; K (flat) 43.03 D; K (steep) 47.05D. (Table 2)

Tables 1 and 2 show an improvement in visual acuity, reduction in astigmatism, spherical equivalent and decrease in steep and flat keratometry post-op.

Parameter	Initial			Final		
	Mean	SE	CI 95%	Mean	SE	95% CI

Table 2. Initial and Final Values for Visual Acuity (LogMAR), Astigmatism, Spherical Equivalent and Keratometry (Flat and Steep) in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion Symmetrical Intacs ® Segments

The characteristics of the implanted segments were the following:

Asymmetric segments implanted: 300/250 (3), 450/300 (2), 350/250 (2), 450/250 (2).

Symmetric segments implanted: 450 (1), 400 (1), 350 (1), 300 (4), 250 (3).

The asymmetric group had an average age of 29.67 ± 3.42 years, and the symmetric group had an average age of 34.5 ± 3.42 years. The study showed a non-significant statistical difference between the groups (p=0.357).

Visual Acuity in the symmetric group was better than the asymmetric group. In order to compare the two groups and showed a non-significant statistical difference between the two groups (p=0.550). Figure 1

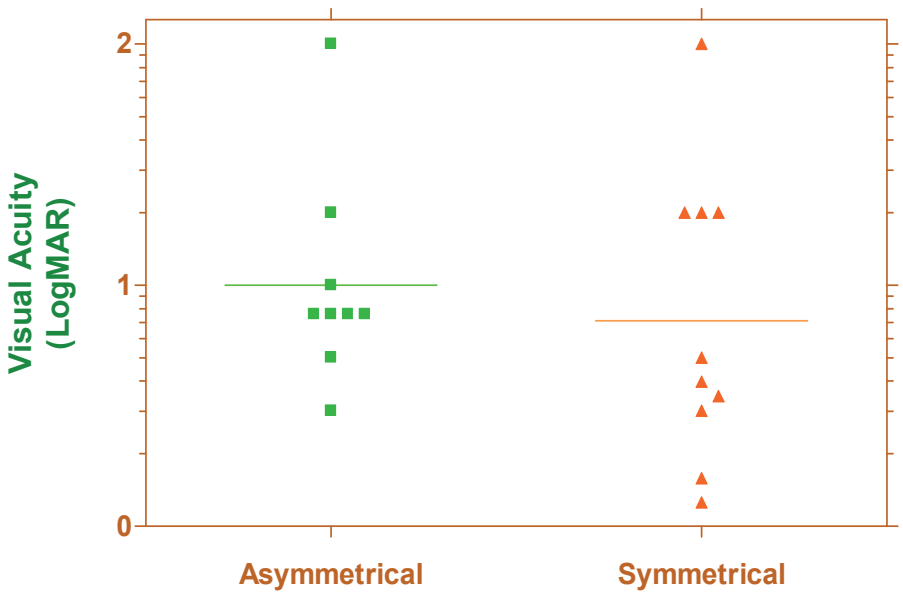

Fig. 1. Initial Values of Visual Acuity in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical or Asymmetrical Intacs ® Segments

Spherical equivalent and steep keratometry showed no significant statistical difference in astigmatism between the two groups (p=0.456; p=0.914; p=0.647 respectively). Figure 2, 3 and 4

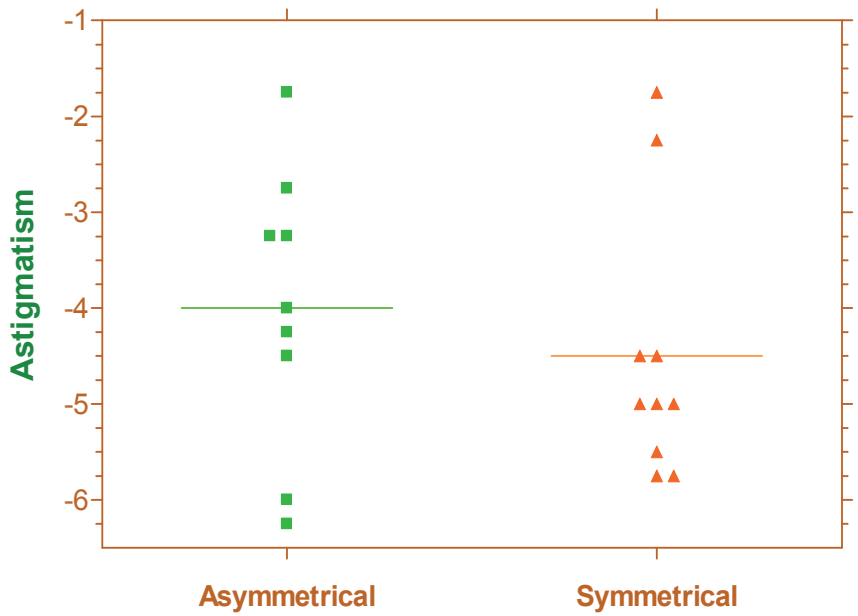

Fig. 2. Initial Values of Astigmatism in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical or Asymmetrical Intacs ® Segments

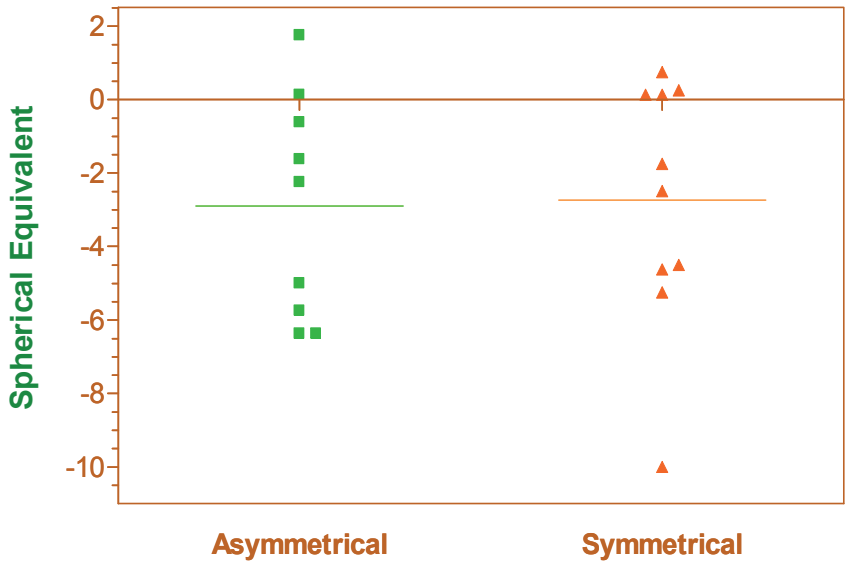

Fig. 3. Initial Values of Spherical Equivalent in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical or Asymmetrical Intacs ® Segments

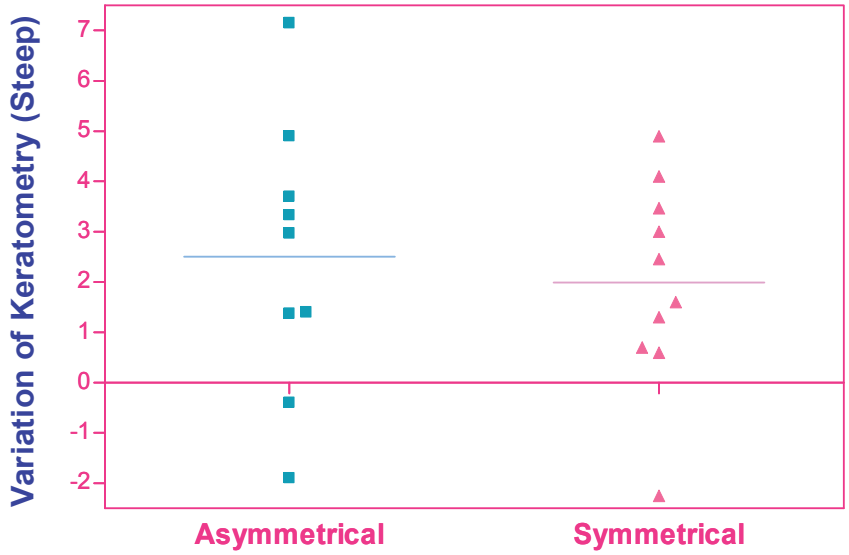

Fig. 4. Variation of Keratometry (Steep) in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical or Asymmetrical Intacs ® Segments

After comparing the groups with flat keratometry, a significant statistical difference was found (p=0.025). This variation was greater in the asymmetric group. Figure 5

In Figure 6 and 7 the evolution of visual acuity for the asymmetric and symmetric group can be seen. After applying one-way Anova, a significant statistical difference was evidenced ($p<0.0001$ and $p=0.0003$). We subsequently applied the Bonferroni multiple comparison test

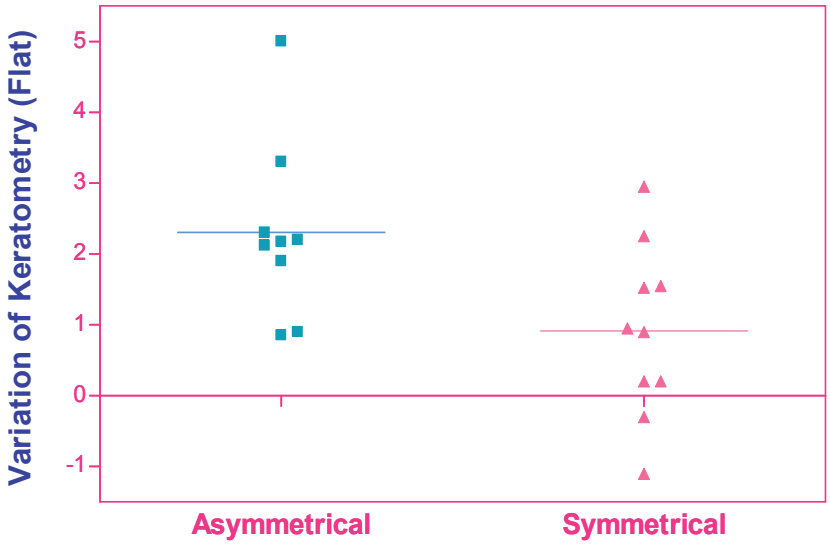

Fig. 5. Variation of Keratometry (Flat) in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical or Asymmetrical Intacs ® Segments

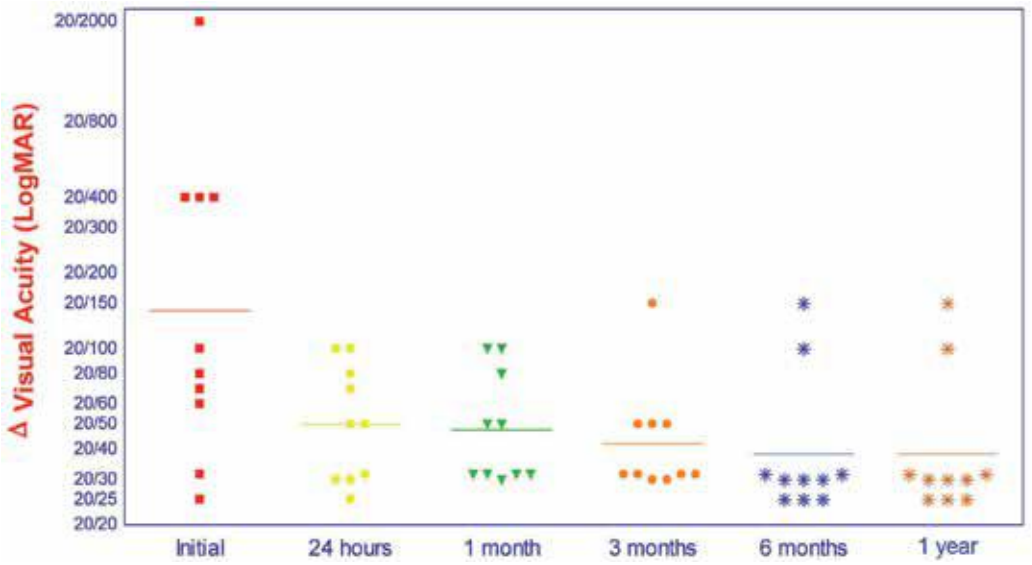

Fig. 6. Time Course of Visual Acuity (LogMAR) in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Asymmetrical Intacs ®

in order to compare each post-operatory time period. No significant statistical differences were seen.

In Figure 8 and 9 the evolution of astigmatism for the asymmetric and symmetric group was shown. With the application of one-way Anova, a significant statistical difference was observed in asymmetric group (p=0.031) while no significant statistical difference was found postoperatively (p =0.074) in symmetric group. The Bonferroni multiple comparison test

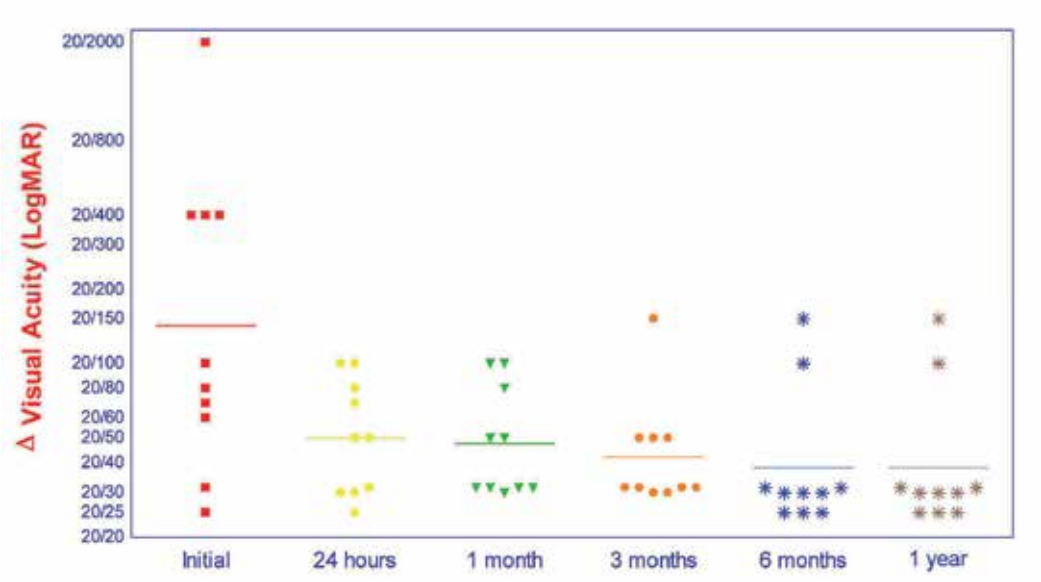

Fig. 7. Time Course of Visual Acuity (LogMAR) in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical Intacs ®

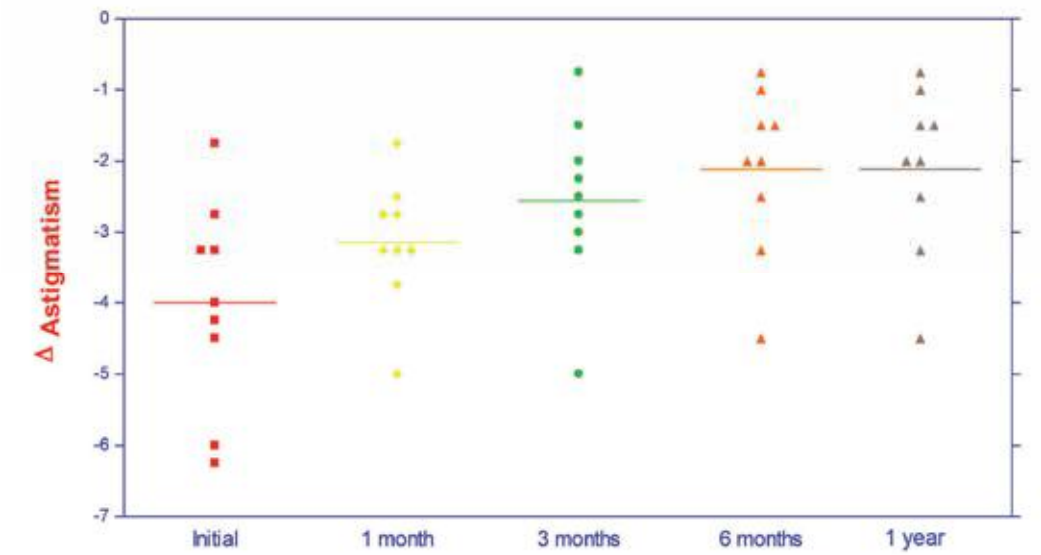

Fig. 8. Time Course of Astigmatism in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Asymmetrical Intacs ®

showed no significant statistical difference between initial and one month, and significant statistical differences between initial and three months and between initial, six months and one year respectively.

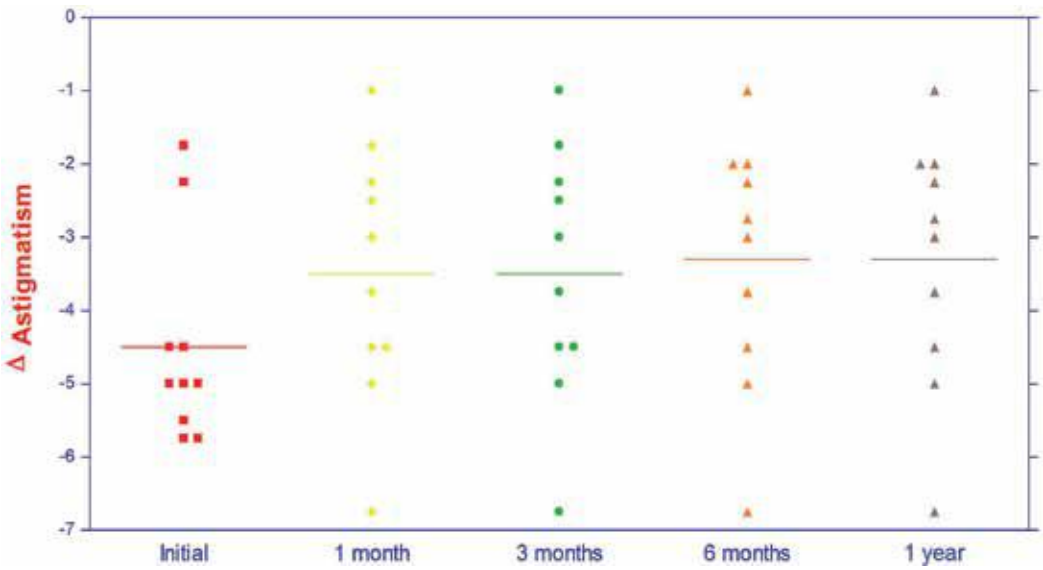

Fig. 9. Time Course of Astigmatism in Patients with Diagnosis of Pellucid Marginal Degeneration with Insertion of Symmetrical Intacs ®

Figures 10 and 11 analyzed the variation of spherical equivalent for the asymmetric and symmetric group. After applying one-way Anova, a significant statistical difference was observed in both groups (p=0.030; p=0.020). In addition we used the Bonferroni multiple comparison test in order to compare each time period and thereby established that the only difference was between initial and first month postoperatively in asymmetric group and initial with six month and first year in symmetric group.

In Figure 12 the evolution of flat keratometry in the asymmetric group is graphed. After the application of one–way Anova, a significant statistical difference was evidenced (p=0.005). We then applied the Bonferroni multiple comparison test in order to compare all the postoperative time periods. The difference found was observed in the comparison between the initial with three months and the initial with six months. No difference was found upon comparing initial with one month, nor when comparing the various time periods after initial (one month, three months, and six months) respectively. No significant statistical difference was observed in symmetric group (p=0.543) figure 13.

In Figure 14 the variation in steep keratometry in the asymmetric group was observed. After applying one-way Anova, a significant statistical difference was observed (p=0.003). In addition we applied the Bonferroni multiple comparison test in order to compare each time period, and the only difference found was when comparing initial with one month.

In Figure 15 we observed the evolution of steep keratometry in the symmetric group. No significant statistical difference was found when one–way Anova was applied (p=0.080).

With respect to the variation in visual acuity (log mar), astigmastism and spherical equivcalent, when both groups were compared with the student's t test, no significant statistical difference was found between them (p=0.366; p=0.412; p=0.344 respectively). Figure 16, 17 and 18.

5.1 Results in asymmetric group

At the end of follow-up period (one year), mean UCVA was 0.22 log mar, ±0,04 (20/30) (95% IC=0.13-0.30). Statistically significant differences were noted throughout the follow-up period ($p < 0.0001$)

Astigmatism value at final follow-up was -2.11D ±0.39 (95% IC= -5.25 – 0.55). P values at all of the postoperative follow-up periods were statistically significant (p=0.001). The maximum improvement in astigmatism was at three months postoperative.

Spherical equivalent mean value was -1.57D ± 0.62 (95% IC=-3.08- 0.06). The changes in mean spherical equivalent during the follow-up period were statistically significant (p=0.030) with maximum improvement at one month postoperative.

Keratometry flat meridian was 40.79D±0.63 (95% IC= 39.33- 42.25). All the changes in mean readings in flat keratometry were statistically significant (p=0.005). Maximum improvement was between three and six months postoperative.

Keratometry steep meridian was 44.51D±1.06 (95% IC= 42.07 – 46.96). The changes in mean readings in steep keratometry were statistically significant (p=0.003) with maximum improvement at first month.

5.2 Results in symmetric group

Mean UCVA was 0.28 log mar, ±0.09 (20/40) (95% IC=0.09-0.48). Statistically significant differences were noted throughout the follow-up period ($p < 0.0003$)

Astigmatism value at final follow-up was -3.30D ±0.54 (95% IC= -4.53 – 2.07). At first year, the difference was not statistically significant (p=0.074).

Spherical equivalent mean values were -0.58D ± 0.40 (95% IC=-1.49 – 0.33). The difference was statistically significant (p=0.020) with maximum improvement at six months postoperative.

Keratometry flat meridian value was 42.12D±0.50 (95% IC= 40.98- 43.25). At first year, the difference was not statistically significant (p=0.543).

Keratometry steep meridian was 45.07D±0.48 (95% IC= 43.98 – 46.15). At first year postoperative the difference was not statistically significant (p= 0.080).

5.3 Comparing results of both groups

Initial visual acuity values were not statistically different between both groups (p=0.550).

Astigmatism initial values were not statistically significant between both groups. (p=0.456). Spherical equivalent values were not statistically significant between both groups (p=0.914). Keratometries (flat and steep) meridian initial values were not statistically significant between both groups (p=0.905 symmetric group), (p=0.972 asymmetric group).

UCVA was not statistically significant between the groups (p=0.366). The difference of final post-op values in astigmatism for the groups was not statistically significant. (p=0.412). The difference of spherical equivalent values at six months post-op between the groups was not statistically significant (p=0.344). The difference of keratometry flat values at six months post-op between the groups was significant (p=0.025) with a better result in the asymmetric group. Keratometry steep values at one year postoperatively in both groups were not statistically significant. (p=0.647).

6. Discussion

Pellucid marginal degeneration (PMD) is a disease with a complicated prognosis in patients who are intolerant to contact lenses (10). Different procedures have been used to treat PMD with unpredictable results. Symmetric and asymmetric Intacs® segments are relatively new devices that reinforce the cornea through the arc-shortening effect of the corneal lamellae that produces flattening of the central cornea. The goal of using Intacs® for PMD is to reshape the cornea without removing tissue by lifting the inferior ectasia, flattening the soft ectatic corneal tissue and decreasing astigmatism. With this treatment, tissue and endothelium is maintained with the benefit that an additive surgical approach is used that adds rigidity and reinforces the ectatic cornea, flattening the central area, and positioning the optical zone in the center of the pupil. This procedure is also reversible. Mularoni et al. proposed a treatment with two asymmetric intracorneal segments in patients with intolerance to contact lenses and early and moderate PMD. Results were great improvement in UCVA, BSCVA and topographical findings (10). Colin J. and Malet F. implanted two symmetric Intacs® segments and followed the progress for two years post operatively obtaining favorable results. The findings in this study indicated that Intacs® segments are an effective long-term treatment for keratoconus and associated ectasia (21). Kymionis et al. reported a case of PMD treated with Intacs® symmetric

segments which reported an improvement in corneal topographic pattern. ICR insertion can reduce the corneal steepening and astigmatism associated with PMD (9). Rodriguez Prats et al. reported a reduction of steepening and astigmatism associated with PMD by implanting one inferior segment (17). Sharma M. and Boxer Wachler noted that placement of inferior segment Intacs® alone was more suitable than double segments Intacs® insertion for peripherally located cones (22). Alió et al found that by implanting either one or two segments produced a similar effect in the reduction of the refractive cylinder and the keratometric readings (19). Both methods have similar results especially when concerning the visual acuity.

In our study, we compared implanting two segments in an asymmetric group to implanting two segments in a symmetric group, with a slightly better result in UCVA in the asymmetric group. When we evaluated BCVA, UCVA, spherical equivalent, astigmatism and keratometric readings, the differences between preop and postop values in all parameters were significantly reduced in both groups with statistically significant differences.

We noted that when analyzing nomograms of the symmetric and asymmetric groups, there were no statistically significant differences when comparing the results of both procedures. This is mainly due to similar spherical equivalent and showed that both nomograms were effective. Both groups tolerated spectacles and contact lenses well after the procedures.

In the asymmetric group we implanted intracorneal segments that were thicker in the protrusion area and thinner in the flatter area, taking spherical equivalent into account. This could possibly have led to an overcorrection with the implantation of the thicker segment. When implanting thicker segments in the thinner protrusion area, great skill was used so as not to perforate the cornea or extrude the segment. In the symmetric group we implanted two same thickness segments, also dependent on spherical equivalent. In symmetric implantations there are more articles available that reported success in keratoconus and other ectasias. By implanting thinner segments in the protrusion area, undercorrection was a possibility. The advantage of implanting two segments was that corneal prolate is maintained.

Toric Intraocular Lenses for the Correction of Astigmatism

Milorad Milivojević,
Miroslav Vukosavljević and Mirko Resan
Eye Clinic, Military Medical Academy, Belgrade, Serbia

1. Introduction

Astigmatism can be corrected with:

1. Glasses and contact lenses
2. Excimer laser refractive procedures (LASIK, PRK)
3. Astigmatic keratotomy
4. Limbal or corneal relaxing and clear corneal incisions
5. Toric intraocular lens

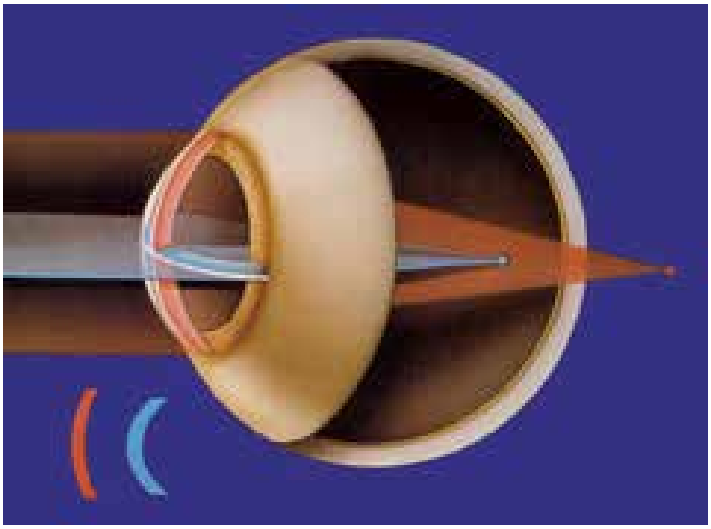

Fig. 1. Eye with astigmatism.

The ideal procedure for the correction of astigmatism should provide: precise and accurate adjustment, safety, predictable outcome, lasting effect and simplicity with an acceptable price. Conventional methods for solving problems such as glasses and/or contact lenses at the present time often do not meet the needs of patients. Whether it is the objective or subjective reasons for a large number of patients tend to avoid wearing glasses or contact lenses.

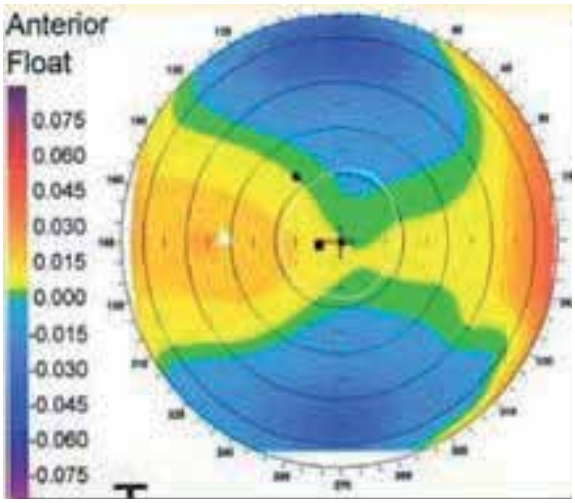

Fig. 2. The topography of corneal astigmatism.

Correcting corneal astigmatism during cataract surgery can increase spectacle independence. For the patient, this has economic benefits as well as desirable cosmetic and practical advantages. Spectacle correction of astigmatism creates meridional magnification, which when coupled with the associated back vertex distance produces retinal images that are asymmetrically magnified and distorted (1).

Company	Intraocular Lens	Range of Spherical IOL Power	Range of Cylindrical IOL Power	Range of Corneal Astigmatism Able to Correct	Percentage of Eyes Susceptible to Correction
Alcon	AcriSof Toric SN60T3/T4/T5 T6/T7T8/T9	+10.0 to +30.0(0.5)	11.5 to 6.0 (1.0)	1.0 to 4.2	34.2

Table 1. Range of spherical and cylindrical powers and corneal astigmatism capable of correcting for the toric IOL on the market (1).

According to the literature, it is estimated that 15 to 22.2% of patients who are candidates for cataract surgery have astigmatism greater than 1.50 D. This indicates that a large number of patients still has blurred vision after cataract surgery due to residual astigmatism and require operative correction of distance vision glasses or lenses. (2,3). Since the corneal limbal relaxing incision often have an unpredictable effect on the postoperative visual acuity, and the use of Excimer laser refractive surgery is often not feasible because of it is often contraindicated in elderly people, expensive procedure, requires high technological equipment and expertise of medical personnel. Toric intraocular lenses are the correction of choice for high levels of astigmatism. They promise a predictable method of astigmatic correction with minimal impact to the cornea. However, the effectiveness of a toric IOL is dependent on its orientation. (1,4)

2. Surgical aspects of implantation of toric intraocular lenses

Cataract surgery with implantation of toric intraocular lenses is identical to the normal procedure and requires no special training (4). The difference is reflected in the preoperative treatment, and in celebration of the cylinder axis, which is adjusted to the patient's eye. Toric IOLs need precise positioning to achieve optimal visual results. In accordance with the corneal measurements, reference markers on opposite sides of the pupil need to be established to demarcate the correct axis for IOL orientation. Eye rotation occurs in a supine position and so these markers need to be established pre-operatively. The slit lamp beam axis graticule can be dialed to the correct axis or a bespoke eyepiece graticule can be used to determine where to place the markers, which can be applied to the cornea or conjunctiva using ink or with scratches. Ink should be applied at the last possible minute as it can diffuse by 10° or disappear before implantation is complete. As an alternative, a Neodymium:Yttrium-Aluminum-Garnet (Nd:YAG) laser can be used to mark the cornea. It has been suggested that this improves the accuracy and definition of the markers. Specific toric axis marking instruments exist. One step methods, such as the Devgan Axis Marker (Accutome, Pennsylvania, USA) and the Gerten Pendulum Marker (Geuder, Heidelberg, Germany) are used pre-operatively to determine the required axis. They are dependent on a vertical head position when applied to the cornea. Two-step methods require marking the cornea at the zero and 180 degree positions pre-operatively and then aligning a degree gauge with these markings intra-operatively to establish the correct position (1). The iris architecture is intricate and full marking is done manually or by using the instrument in a sitting position (1,5). Another difference lies in the fact that the shaft of toric IOL to coincide with the axis of the cylinder, marked preoperatively. This is achieved by the end of the operation during the removal of viscoelastic. There are two main surgical factors that can influence IOL rotation. In the early post-operative period careful wound construction is essential. Following surgery, the IOP can fluctuate and in 6.3 per cent of patients, it drops to below 5 mmHg. It is important to emphasize that it is necessary to remove viscoelastic a rotation for maximum stability. Viscoelastic lag could lead to undesirable postoperative implant rotation, and therefore should be brought into question and the desired outcome (1).

Consideration of IOL haptic design is very important when trying to prevent postoperative lens rotation. Over time, the capsular bag contracts to enclose and secure the IOL, however,

before this contraction occurs there is potentfor rotation (6). To prevent rotation immediately after implantation, it is important to maximize the contact between the IOL haptic and the capsular bag. A polymethyl methacrylate (PMMA) IOL creates the most friction with the bag, followed by acrylic, with silicon causing the least (7). It is believed that if the implant rotates by more than 30 degrees postoperatively, the effect of cylindrical lenses is lost. The third difference relates to the calculation of the refractive lens, the strength and axis cylinder. As a rule, keratometry very carefully set manually, not automatic keratometer. Must also be taken into account and astigmatism, which will occur as a consequence of the main corneal incision. IOL manufacturers have developed calculators to determine the refractive power lens (as spherical and cylindrical components), and determine the shaft in which the implant should be placed. The data are entered to the calculator are manually specified value keratometry, spherical components required strength, where you are planning a major incision. These calculators are easily and freely available for use on the Internet (8).

3. The outcome of intraocular implantation of toric IOL

When it comes to the outcome of implantation of toric intraocular lenses, it is essential to assess the following parameters:

3.1 Rotational stability in capsular bag

3.1.1 Plate haptic IOLs

Plate haptic IOLs demonstrate excellent long-term stability. In comparison with open-loop haptics, plate haptic IOLs are not as susceptible to the effects of compression from the capsular bag.

The first commercially available toric IOL was the STAAR 4203TF (STAAR Surgical, Company, California, USA), which achieved FDA approval in 1998. It is a biconvex, silicone, plate haptic toric IOL, 10.8 mm in length, with two 1.15-mm positioning holes. The lens is available with a torus of either 2.00 or 3.50 D, which corrects levels of corneal astigmatism between 1.50 and 3.50 D. The lens demonstrates excellent long-term stability once fixation within the capsular bag has been established, 30 however, in the early postoperative period, the lens demonstrates a relatively high incidence of rotation. In its FDA trial, 24 per cent of the lenses rotated more than 10°, 12 per cent more than 20° and 8 per cent more than 30° (9).

The AT-TORBI (Carl Zeiss Meditec, Berlin, Germany) (previously the ACri comfort toric IOL) is an acrylic, bi-toric, plate haptic IOL, 11 mm in length, possessing two positioning holes on the haptic. It is a microincisional lens, and it can be inserted through a 1.5-mm incision. The AT-TORBI has a 6.0-mm optic, and can correct high levels of astigmatism, as it is available with a torus of 1.00 to 12.00 D in 0.50-D steps. Large-scale studies are required to demonstrate the effectiveness of this lens but early results are very promising. In a pilot study involving 21 eyes with 2.00 to 9.00 D of corneal astigmatism, only one lens rotated more than 5° between day one and six months post-operatively, with 76.1 per cent of these subjects achieving a postoperative uncorrected vision of 20/40 or better (10).

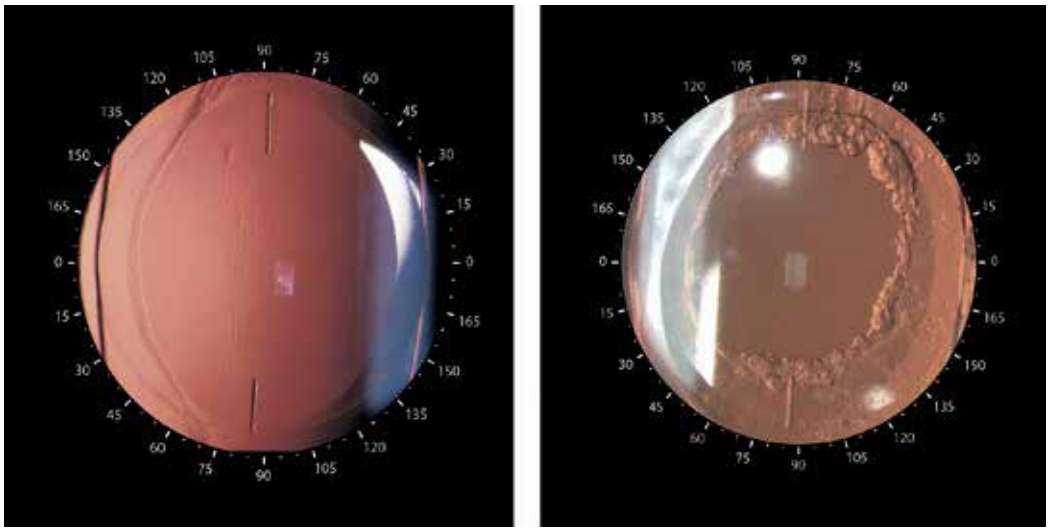

Fig. 3. Slit-lamp retroillumination photographs of a Staar toric intraocular lens with a superimposed digital protractor before (left) and after (right) a circular neodymium–yttrium-aluminum-garnet posterior capsulotomy (9).

Fig. 4. The ACri comfort toric IOL (10).

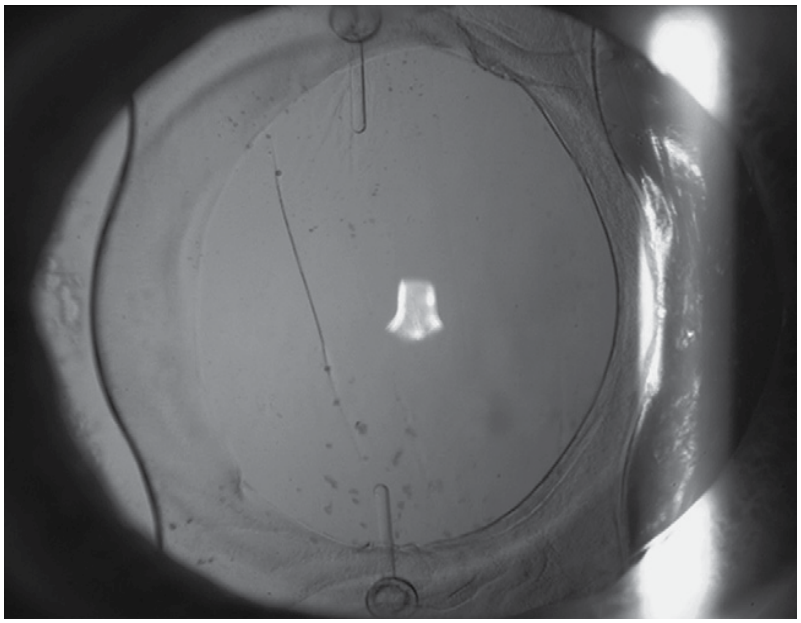

Fig. 5. The ACri comfort toric IOL in situ 3 months postoperatively (10).

3.1.2 Open loop haptic lenses

Open loop haptic lenses compared with previous models (plate haptic IOLs) demonstrate excellent early rotational stability in comparison to plate haptics. The longer loop haptics ensure immediate contact between haptic and capsular bag, maximizing friction in the early postoperative period, however, they are susceptible to late rotation caused by the compression of the capsular bag (11).

The AcrySof toric IOL (Alcon, Fort Worth, USA) is a single-piece acrylic toric IOL with open loop L-shaped haptics. It has a posterior toric surface with three available toric powers 1.50, 2.25 and 3.00 D. It is a 13mm in length with a 6.0mm optic. The AcrySof toric has demonstrated excellent rotational stability results. During its FDA trial, 81.9% of lenses rotated less than 5° and only 2.9% rotated over 10° and only 0.8% of these lenses were repositioned (2,8).

The Torica S (Human Optics, Erlangen, Germany) otherwise known as the Microcyl Toric 6116 (Human Optics), is a three-piece, silicon, Z-shaped open loop haptic toric IOL. It is 11.6mm in length with a 6.0mm optic. The Torica S has a novel haptic design with undulations designed to increase the friction between lens and bag. It has been reported that these undulations maintain the IOLs position but make it difficult to rotate the lens within the bag. To prevent the haptic undulations from causing trauma when rotating the lens, it is recommended that they are compressed against the optic and held away from the capsular bag until the lens is in the required position. In a study of 21 eyes (14 subjects) no lens rotated more than 5°(12).

Fig. 6. AcrySof toric IOL.

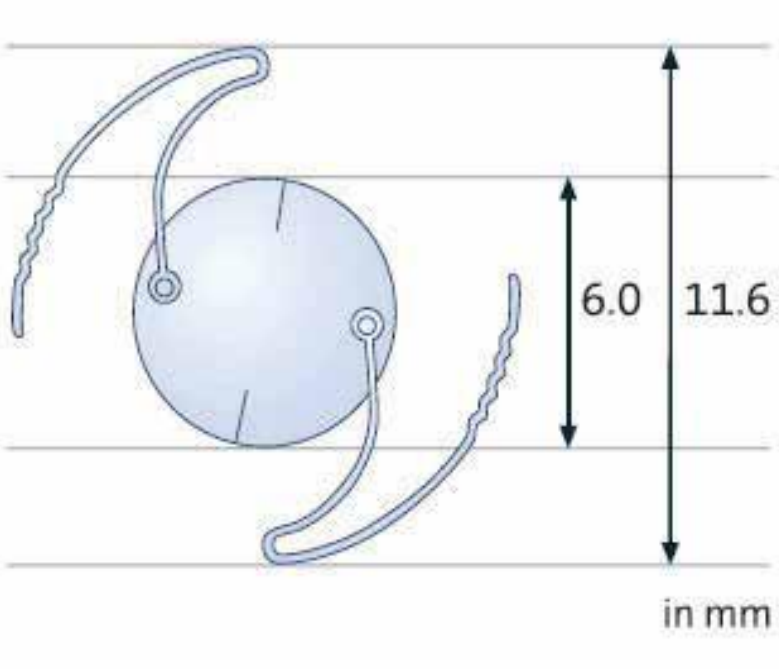

Fig. 7. The Torica-S IOL.

3.1.3 Closed loop haptics IOLs

Closed-loop haptics are a relatively new addition to the toric IOL market. These lenses are typically longer than the plate haptics, which should give good initial contact. The loops have a second insertion on the IOL that may resist capsular compression.

The T-flex toric (Rayner, Hove, UK) is a single-piece, acrylic, closed-loop haptic with anti-vaulting haptic technology. It is available in two sizes; the 573T has a 5.75-mm optic and 12 mm haptics, and the 623T has a 6.25-mm optic and 12.5 mm haptic. The anterior surface of the optic houses the toric surface, which is available with a torus of one to 11 D. The anti-vaulting haptic technology is designed to reduce the effect of compression using a lock and key system. Compression will push the outside of the haptic against the inner haptic, locking it into place. It has been reported that in a group of 10 subjects no lens rotated more than 5° between one week and two years after implantation (13).

Fig. 8. Rayner T-*flex*® Aspheric Toric IOL.

The Akreos (Bausch & Lomb, Rochester, USA) aspheric platform is a single piece acrylic, closed loop haptic IOL. It has a 6.0-mm optic and is 11 mm in length with a 360° square edge. The IOL is currently being assessed for its viability as a platform for housing a toric surface. A multicenter study has examined the rotational stability of the Akreos haptic housing from one day to six months post-operatively in 97 eyes. This lens was shown to be stable, as 96 per cent of the IOLs rotated no more than 5° and 99% no more than 10° (14).

Fig. 9. Akreos™ aspheric IOL.

Tsinopoulos and colleagues (15) reported a new procedure for intra-operative toric intraocular lens (IOL) axis assessment in order to achieve optimal implantation. IOL implantation procedure was directly recorded. An assessor estimated the angle formed by the marked 0–180 axis and the toric IOL axis after implantation with the use of the appropriate software. If IOL implantation was assessed to be inaccurate, the surgeon was advised to correct IOL positioning by rotating the IOL clockwise. The assessment procedure was repeated until accurate IOL positioning was achieved.

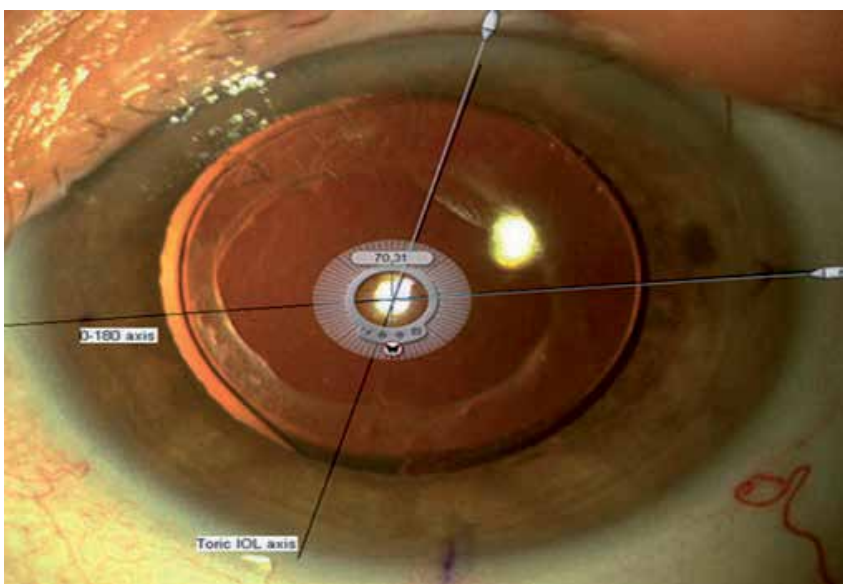

Fig. 10. Intra-operative toric implantation assessment with the use of the appropriate software (15).

3.2 The reduction of absolute residual astigmatism

The average absolute residual astigmatism after implantation of toric intraocular lenses is less than 0.55D. In patients who have significant astigmatism, and implanted them classic spherical lenses residual astigmatism is an average of 1.22D (1).

3.3 Uncorrected visual acuity at distance

Ninety-four percent of patients achieve visual acuity ≥ 0.5 with no correction, which is a remarkable result. Also, these patients have a greater vision improvement at all levels compared with patients who have conventional spherical lens. In 97% of patients whose toric lenses implanted in both eyes maximize distance vision without correction (1,2).

3.3.1 Stability and predictability of outcome

Patients who have significant astigmatism after cataract surgery have the option for correcting glasses or contact lenses. However, for many patients who expect excellent postoperative vision this is unacceptable solution.

Relaxing incisions that had previously been strongly represented in the correction of astigmatism now use fewer surgeons (40%) for the following reasons:

- Unpredictable results in a significant number of cases
- The problem of regression, astigmatism, especially in patients with severe preoperative astigmatism
- Inability to correct high astigmatism
- Paracentral incisions can correct high astigmatism, but more complications
- Healing of incisions can be problematic, since it is predominantly an elderly patient
- Patients with steep corneas and asymmetriastigmatism are not good candidates (1,16).

When speaking of the Excimer laser for the correction of astigmatism, the method is effective and safe, but laser is expensive and this way the correction is often unavailable for most patients (17).

3.3.2 Economic evaluation of toric intraocular lens

Pineda and colleagues (18) assessed the economic value of improved uncorrected visual acuity among patients with cataract and preexisting astigmatism treated with toric intraocular lenses (IOLs) compared with conventional monofocal IOLs. They concluded that toric IOLs reduce lifetime economic costs by reducing the need for glasses or contact lenses following cataract removal. These results can inform physicians and patients regarding the value of toric IOLs in the treatment of cataract and preexisting astigmatism.

Laurendeau and collegues (19) in their study concluded that bilateral toric IOL implants in astigmatic patients decreased spectacle dependence for distance vision and the need for complex spectacles. The economic consequences for patients depended on the national spectacle costs usually incurred after cataract surgery.

4. Conclusion

Toric intraocular lenses are accurate, reliable, predictable, permanently correcting astigmatism in cataract patients who are operated, while the flow of the operation is not extended, or require special training for surgeons already trained. Rotational stability of an IOL is the primary determinant of the refractive outcome. The surgeon should also keep in mind that the final outcome is very important and proper selection of patients, including patients with irregular astigmatism due to the scar tissue forming of the cornea, keratoconus, pellucid marginal degeneration, etc,. New available aspheric toric lens offer a better quality of vision postoperatively (reduction of spherical aberration, further improving contrast sensitivity, and uncorrected visual acuity at a distance). Toric IOLs reduce lifetime economic costs by reducing the need for glasses or contact lenses following cataract removal.

1. Introduction

1.1 Definition

Amblyopia in Greek is dullness of vision. It is defined as poor unilateral or bilateral visual acuity due to poor perception in the presence of normal appearing globe.[1] It is caused by poor visual perception during the critical postnatal period required for maturation of the visual pathways and cortex. Clear and corresponding image is required for visual system development in animals including primates.

1.2 Epidemiology

The prevalence of amblyopia in the general population is probably between 2 and 2.5%. The wider range of 1-4% reflects differences in the degree of amblyopia, the studied population and the location. These figures represent the average of the prevalence in the different studies. The frequency of disorder has a socioeconomic impact. These patients have a greater risk for legal blindness if the fellow eye develops a blinding condition or sustain trauma. Indeed, patients with amblyopia as monocular patients are at a greater risk for trauma in the fellow eye although their visual field may be full.

1.3 Development of the visual system

The postnatal visual system development differs in different animals. In humans, the visual acuity improves usually until the age of 5 and this reflects the maturation of both the retina and the visual pathways.[2] The most critical period for amblyopia is the first 2 to 3 years of life.[1] The sensitivity of the visual system to abnormal perception is decreasing gradually afterwards. One should distinguish between the period when amblyopia may develop, which is until 9 years of age (although in most patients, it appears by the age of 5) and the period in which it is treatable, probably until the age of 17.[3]

1.4 Classification

Amblyopia is a result of three mechanisms: deprivation (obscuration of the image on its way to the retina (i.e., ptosis and media opacities), strabismus and refractive (anisometropic

or isoamteropic) all causing blurred or non-corresponding images on the fovea.[1] The pathophysiology common to all of these is abnormal binocular interaction and/ or vision deprivation. Strabismic amblyopia occurs in the non-fixating eye and is always unilateral. It occurs in tropia and is more common in esotropia than in exotropia and indeed esotropia is neonatal while exotropia may be neonatal or acquired later in life. It is caused by signaling inhibition of the deviating eye to avoid confusion because of different foveal images between the eyes. Strabismic amblyopia is applied only to cases where the amblyopia is a result of strabismus and not vice versa. In refractive amblyopia, signaling inhibition of the blurred image occurs and in deprivation, there is usually no image. Anisometropia of +2.00, -3.00 and astigmatism of 1.5D or more are associated with amblyopia. The presence of astigmatism causes amblyopia in the astigmatic meridian called meridional amblyopia. Isoametropia of +4.00, -8.00 and astigmatism of 2D or more are associated with bilateral amblyopia. Lesser amount of hypermetropia than myopia is associated with amblyopia because the inability to focus images on the fovea at any distance. While strabismic amblyopia and most of the anisometropic amblyopia are unilateral, isoametropic and some of the deprivative amblyopia are bilateral. Deprivative amblyopia is usually the most profound and most resistant to treatment of all three forms of amblyopia. If it is present in the first 3 months, irreversible nystagmus develops. The unilateral cases are usually the worst.

2. Clinical manifestations

The visual acuity is poorer in the amblyopic eye than in the fellow eye or than in normal eyes and cannot be corrected to full with spectacles or contact lenses. A poorer visual acuity is considered if the visual acuity is less in two Snellen lines or more. Differences in one line may just be fluctuation and within the normal deviation and this is true not only for amblyopia but for all other instances as well. The subject uses the fellow better eye for fixation. The patient sees single signs on the Snellen chart better than several signs in a row (crowding phenomenon or abnormal contour interaction). This is caused by larger receptive fields (larger group of photoreceptors working as a single unit) and lateral inhibition by adjacent fields on the fixating field. Under dim light, the visual acuity decreases in both eyes but the visual acuity of amblyopic eye becomes similar to the normal eye. Thus the decrease in visual acuity is slower in the amblyopic eye than in a normal eye. The use of neutral density filters decreases the visual acuity in the amblyopic eye in much lesser extent compared with eyes with other diseases. In addition, amblyopic eyes have decreased contrast sensitivity, perception of brightness and have longer reaction time.

Other parameters are normal and similar to normal eyes including light perception (visual threshold) and visual field. An afferent pupillary defect is not supposed to occur but is a variable finding.

3. Treatment

Bilateral amblyopia is treated by eliminating the cause of blurred image (removal of the deprivation cause, strabismus surgery or refractive error correction). Unilateral amblyopia is treated similarly along with periodical patching or other penalization of the fellow sound eye. Penalization of the sound eye is usually performed by instilling once drop of atropine sulfate 1% one a day at bedtime. This causes cycloplegia and blurred image in the sound eye and forces the visual system of the amblyopic eye to act. Treatment should be initiated immediately when the condition is diagnosed. The elimination of the deprivative obstacle should be performed as early as possible (usually 2-3 weeks after birth). In strabismic

amblyopia, anti-amblyopic treatment is initiated when the condition is diagnosed long before the surgery for strabismus. The reasons for this are improving the possibility to gain binocular vision if visual acuity is improved, easiness to determine the fixation patters, and the strabismus serves as a reminder to the parents on the importance of treatment. Surgery is performed only after achieving alternating fixation and equal visual acuity.

The length of patching or other penalization depends on the severity of the amblyopia. It is increased in direct proportion with the degree of the amblyopia. The follow-up frequency is also increased as the length of patching increases. Amblyopia is more easily reversible if it occurs later (ages 6-9) than earlier in life. Improvement of visual acuity should be both in single and multiple signs on Snellen chart and should be permanent. However, regression may occur and requires re-treatment.

Occlusion may be for full-time (all the day) for several days with one day off, or part time (several hours per day). Full-time occlusion is preserved for severe amblyopia with no binocular vision such as deprivative amblyopia. Full-time occlusion should not exceed one week per one year of age. Part-time treatment is preferred according to the Pediatric Eye Disease Investigator Group (PEDIG) studies because it has a similar outcome as full-time occlusion with less risk for development of amblyopia in the normal fellow eye, especially in the presence of binocular vision and mild amblyopia. Six hours per day of occlusion are sufficient for severe amblyopia of less than 20/100 and 2-3 hours per day for moderate one (better than 20/100). Contact lenses may be employed in anisometropia of more than 3.00D to prevent aniseikonia. However, this is more demanding treatment. Bilateral amblyopia in isoammteropia is usually not treated with occlusion and improves slowly spontaneously once refractive correction has been applied. In all cases, it is essential to rule out the development of amblyopia in the sound eye during treatment.

Obtaining compliance is difficult especially at the beginning of the treatment. The compliance becomes better as visual acuity of the amblyopic eye improves. Children try to remove or pick through the occluder. Therefore, it is better to use eye drops as penalization or a skin sticker rather than a sticker to the eyeglass. A full cooperation is required from the parents. They should be insisting on meticulous treatment for the full period. It is best to occlude when the child is at home under supervision of the parents and to occlude when the child is performing near tasks such as reading or doing homework. A close follow-up is required to ascertain improvement in visual acuity of the amblyopic eye and prevention of developing amblyopia in the fellow eye. In general, the follow-up intervals are one week per each year of life (e.g., a 2-year-old child is followed every 2 weeks). The follow-up includes visual acuity in each eye with full cycloplegic correction after refraction. If the visual acuity decreases, the reason for it should be disclosed. If the correction is not sufficient, it should be adjusted accordingly. If it is sufficient, an adjustment of the anti-amblyopic treatment should be performed. The length of occlusion is gradually decreased if the visual acuity improves to the desired level and no regression is observed in follow-up visits. Occlusion is gradually tapered according to the patient's response. Gradual decrease in occlusion time has been demonstrated to be associated with less recurrence rate than abrupt determination. If regression is noted, the treatment is re-initiated and continued over the vulnerable period (up to the age of 17). Follow-up until the age of 17 is necessary even if the optimal results have been achieved. Recurrence occurs in up to 75% of the patients usually within the first 13 months.[4] If treatment has not been successful after several (usually 6) months, it may be abandoned and visual function will not improve thereafter.

In animal models, L-dopa and bicuculline have been demonstrated to reverse amblyopia.

However, they have not been used in humans because the first one showed only a temporary effect and the second can cause seizures.

4. Prevention

Prevention of amblyopia is of outmost importance. Screening of red reflex at birth should be done to all neonates. Screening programs at preschool and school children are also important.

5. Background

To date, no changes in gross anatomy of the eye were found in the human amblyopic eye. When optical coherence tomography (OCT) was employed to evaluate the overall macular thickness, volume and the retinal nerve fiber layer (RNFL) thickness, it was found that all were similar in one study between strabismic amblyopic and the fellow eyes in 14 patients.[5] Another study did report thicker RNFL in amblyopic eyes than in normal fellow eyes.[6] When the differences in RNFL thickness were compared between amblyopic eyes and normal eyes of other subjects, they were found to be statistically insignificant.[7] In this study, the foveal thickness in the amblyopic eyes was similar to normal control eyes ($p=0.551$), but the authors did not compare it with the normal fellow eye. It would be expected that any differences in the anatomy in vivo between amblyopic and normal eyes would be microscopic. One should also consider the reproducibility of the OCT and the normal variations between normal eyes at different ages. Therefore, to show differences, a comparison should be made first with the fellow normal eye in unilateral amblyopia.

We compared the foveal thickness of amblyopic eyes with the fellow normal eye by OCT. Furthermore, we compared the foveal thickness of amblyopic eyes that underwent successful occlusion therapy with amblyopic eyes refractory to treatment. Such a study has not been previously reported according to Medline® search. The rationale for the current study was that even if the gross anatomy is normal, subtle structural variations such as foveal hypoplasia might exist.

6. Methods

In a prospective study, we compared the foveal thickness of amblyopic eyes with the fellow normal eyes in unilateral strabismic and anisometropic amblyopia by OCT (spectral OCT/SLO, OTI, Ophthalmic Technologies, Toronto, Canada). The inclusion criteria included best-corrected visual acuity (BCVA) of 20/80 or less in the involved eye, BCVA of 20/25 or better of the fellow eye, normal eye exam of each eye and no explanation for the low visual acuity except for amblyopia, presence of one of the causes for amblyopia (anisometropia of more than –3.00D or more than +1.00D, or strabismus), no other ocular, neurologic or systemic disorders, and children between 4 and 10 years of age who can undergo OCT and be treated for amblyopia and that followed the treatment orders. All other patients were excluded from the study. Ocular and general medical history were obtained and the patients underwent a complete ophthalmic examination of each eye including visual acuity by Snellen charts, pupil reactions, slit lamp examination, dilated funduscopic examination with a slit lamp biomicroscopy and indirect ophthalmoscopy.

All eyes were analyzed by OCT. Measurement was performed at the thinnest point of the macular center, representing the fovea. Several topographic 3D, linear and radial scans were

obtained. The acceptance criteria of OCT included a central reflex, signal strength of at least 4 and standard deviation of the foveal thickness of less than 10% of the mean for each individual.

Amblyopic patients with refractive errors were treated by refractive full cycloplegic correction. Amblyopic patients with strabismus underwent strabismus surgery. All patients underwent occlusion (patching) therapy of the sound eye at least 6 for months and were followed according to previous recommendations.[3,8-10] Successful treatment was defined as an improvement in visual acuity in the amblyopic eye in at least 2 Snellen lines. The follow-up time ranged between 12 and 54 months.

Statistical analysis was performed with SPSS version 11.5 program (SPSS Inc., Chicago, IL, USA). Paired sample T-test was used for samples larger than 15 and Wilcoxon signed rank test was employed for smaller samples. Two-tailed $p<0.05$ was considered as statistically significant. Approval by the IRB/Ethics Committee was obtained and the patients' parents received a full explanation about the exam.

7. Patients

Nineteen children aged 4-10 with unilateral amblyopia were included. Ten patients had anisometropic (refractive) and 9 had strabismic amblyopia. Eight patients had successful occlusion therapy, while the other 11 had unsuccessful treatment.

8. Results

The foveal thickness in amblyopic eyes was 201±42 μm (average±SD) and in the normal fellow eyes 174±27 μm. The fovea was statistically thicker in the amblyopic eyes of whatever cause than in the normal fellow eye (p=0.011, paired sample T-test). The foveal thickness in eyes with anisometropic amblyopia (n=10) was 194±45 μm and in the fellow eyes of the same patients 167±23 μm (p=0.059, Wilcoxon signed rank test). The foveal thickness in eyes with strabismic amblyopia (n=9) was 210±39 μm and in the fellow eyes of the same patients 181± 30 μm (p=0.070, Wilcoxon signed rank test).

Eight (42%) of the 19 patients experienced improvement in BCVA after occlusion therapy. Six of the 8 had anisometropic and 2 had strabismic amblyopia. From the group of 11 (58%) patients that did not show improvement in BCVA, 4 had anisometropic and 7 had strabismic amblyopia (p=1.000). The foveal thickness in the patients who showed no improvement in BCVA after treatment was 216±41 μm and in their fellow eyes 176±31 μm (p=0.016, Wilcoxon signed rank test) (Table 1). In those who showed improvement, the foveal thickness in the amblyopic eyes was 181±36 μm and in their fellow eyes 171±21 μm (p=0.297, Wilcoxon signed rank test). Examples of the topographic 3-dimensional OCT maps of an amblyopic and normal fellow eye are seen in figures 1 and 2.

Parameter	Amblyopic eye	Fellow eye	P-value
Total (n=19)	**201±42**	**174±27**	**0.011**
Refractive (n=10)	**194±45**	**167±23**	**0.059**
Strabismic (n=9)	**210±39**	**181±30**	**0.070**
VA improvement (n=8)	**216±41**	**176±31**	**0.016**
No VA improvement (n=11)	**181±36**	**171±21**	**0.297**

9. Discussion

Amblyopic eyes are classically considered as having a normal structure.[1] The only changes that have been found were smaller parvocellular cells in layers II, III and V in the ipsilateral lateral geniculate body, layers I, IV and VI of the contralateral lateral geniculate body and reduction in the number of cells in the primary (striate) visual cortex V1 receiving input from the affected eye.[11,12] Reduction was noted in the number of cells receiving binocular input. An increase in the number of cortical cells responding to a contour orientation also occurs. Positron emission tomography demonstrated a reduced cortical activity under visual stimulation of the amblyopic eye.[13]

We found that in the amblyopic eyes the fovea was thicker than in the normal fellow eyes. This was common both for anisometropic and strabismic eyes. Our finding is supported by a recent study in 3,529 children aged 6-12 years that found thicker fovea in amblyopic eyes than in the normal fellow eyes by 5μm.[14] These and our results differ from a recent evaluation of the foveal thickness that did not show statistically significant differences ($p=0.551$) of the foveae in patients with unilateral anisometropic and strabismic amblyopia compared with normal subjects.[7] Nonetheless, the authors did not compare the amblyopic eye with the normal fellow eyes and therefore, did not have an internal control. The differences between our study and the previous one probably relate to variability of foveal thickness in different individuals and indeed such differences were found between different individuals in our study and therefore the standard deviation between different individual was quite high.

Careful review of the OCT images indicated that the foveal thickening was due to either thicker outer retinal layers or immature retinal tissue. The structural feature of the foveae in amblyopic eyes is hypoplasia similar to albinotic and nanophthalmic eyes.[15-18] The fovea is thicker and flatter in these eyes. Since there are no histologic preparations of the retina in amblyopic eyes, it is impossible to determine the exact composition of the foveal area. However, in oculocutaneous albinism the retinal tissue was intact and the Bruch's layer was thickened in one specimen.[19]

We found that amblyopic eyes refractory to occlusion therapy had thicker fovea than those of the normal fellow eyes, while the differences in thickness between amblyopic eyes that responded to treatment and the fellow eyes were insignificant. This finding could have been different if patients and their parents would not be cooperative. No previous study addressed this issue and therefore we cannot compare our data with previous ones.

In our study, patients with anisometropic amblyopia had not statistical significant success of the occlusion therapy compared with patients with strabismic amblyopia. The differences in foveal thickness in the amblyopic and the sound fellow eyes in each group were not statistically significant although they were marginal in the amblyopic eyes of the anisometropic group. The higher number of anisometropic patients that underwent successful occlusion therapy might explain this tendency. A larger population will be required to confirm if the foveal thickness differs in these two groups and if the type of the amblyopia is the cause for different foveal thickness rather than treatment success. The higher success of occlusion therapy in anisometropic amblyopia than in strabismic amblyopia might be related to the thinner foveae in anisometropic patients. Thicker foveae were found in strabismic than in anisometropic amblyopia in another study as well ($p=0.046$).[7]

In our sample, the foveae of the amblyopic eyes were thicker than in the fellow normal eyes except for one in which the thickness was the same and another 3 with thicker normal fovea. Two of these patients experienced an improvement in BCVA after occlusion therapy. If in all future patients, the fovea of the amblyopic eye will be thicker than in the fellow normal eye, the foveal thickness may serve as a prognostic factor for improvement after proper therapy. To validate this, more patients should be recruited and a scale should be established for the measures that may predict improvement or non-improvement. It is possible that there will be patients in whom the fovea in the amblyopic eye would be thinner than in the normal fellow eye and would not experience an improvement in BCVA after treatment. In such event, it may not be possible to predict the success of a treatment based on the foveal thickness at least in those patients.

In patients with bilateral amblyopia, measurements of each fovea and a comparison with normal foveae will be needed. In such cases, the differences might be subtle as after comparing unilateral amblyopic eyes with normal controls and prediction of successful treatment may be difficult. According to our findings, it might be worthwhile to create a database for foveal thickness in the normal population according to age, since the foveal thickness may change with age.[20] In addition, a correlation between BCVA and foveal thickness might be established as well.

OCT measurements in children are demanding because of inattention, especially in children under age 4. In addition, amblyopic eyes tend to fixate less and if nystagmus is present, clear images may not be possible to obtain, unless the eye is mechanically fixated. We should also consider the accuracy and reproducibility of the OCT. When assessing thin layers as in the fovea, if the accuracy and reproducibility are not perfect, subtle differences may not be measured accurately, even if the image resolution is of 2μm. For macular thickness, OCT was found accurate and reproducible[21] and it is expected that with better technologies including high-resolution Fourier-domain OCT, this problem will be solved.

It will be interesting to verify our results in amblyopic adults and to find what is the foveal thickness in children that had regression after treatment. The last and the most intriguing issue is whether treatment influences the foveal thickness. Since the fovea, as well as other structures such as the lateral geniculate body and visual cortex, continue to develop after birth (the "critical" period), it is tempting to hypothesize that in successful treatment, the foveal thickness might also change.

1. Introduction

In glaucoma, the most commonly used surgical options attempt to establish communication between the anterior chamber and the subconjunctival space, either by removing part of the trabecular meshwork and thus decreasing resistance to the passage of the aqueous humour or by means of drainage tubes that conduct the aqueous humour toward extraocular subconjunctival reservoirs. Trabeculectomy is still the most widely performed glaucoma procedure worldwide. Nevertheless, it creates an artificial pathway for drainage of aqueous that is less optimal than physiologic outflow and is associated with numerous short and long-term serious complications. Surgical alternatives, such as deep sclerectomy, are more demanding, longer and seem to be surgeon-dependent. Although they achieve a high level of hypotensive effect, these forms of surgery are not exempt from potential complications and are highly dependent on the inflammatory and healing response of the patient.[1] The use of antimetabolites to regulate this healing response is also linked to a higher rate of complications.[2,3,4,5,6]

The interest in new and possibly less invasive surgical techniques to lower intraocular pressure is growing. In particular, to avoid the eventual problems linked to surgical trauma to the conjunctiva and the ensuing inflammatory response, several new *ab interno* methods that attempt to achieve intraocular pressure control have been developed. Some of these methods are aimed at obtaining flow through Schlemm's canal, whereas others point to the possibility of obtaining flow from the anterior chamber to the suprachoroidal space. Gonioscopy is used in these *ab interno* procedures in order to visualize the site of implantation.

2. Visualizing the trabecular meshwork

Trabecular bypass surgery can be performed through the same incision used for phacoemulsification in cases of combined surgery, or by means of a paracentesis, when it is performed as a sole procedure. A temporal incision is warranted because of ease of patient's head positioning. Visualization of the angle using the goniolens should be practiced in cases prior to performing surgery, in order to learn the correct techniques.

In the case of phakic patients, the instillation of a miotic is recommended to minimize the risk of lens injury. If the procedure is carried out under topical anaesthesia it is advisable to introduce lidocaine 1% into the anterior chamber, because some of the surgical manoeuvres

can be uncomfortable for the patient. It is perfectly possible to carry out the surgery under topical anaesthesia with intracameral lidocaine; however, when performing the operation for the first few times, it may be advisable to use some form of locoregional anaesthetic (retrobulbar, peribulbar or sub-Tenon).

Once the incision has been made in the temporal cornea, the anterior chamber must be filled with a cohesive viscoelastic that makes it possible to enlarge the region of the angle where surgery is planned.

A perfect view of the trabecular meshwork and of the angle must be achieved. The most common error is failure to position the microscope and/or the patient adequately in order to obtain an adequate view of the trabeculum. The patient's head must be turned approximately 45° away from the surgeon. The microscope should be tilted approximately 30º towards the operating surgeon.

3. Specific devices and surgical techniques

3.1 iStent®

The iStent® trabecular micro-bypass (Glaukos Corporation, Laguna Hills, CA) is made of titanium and coated with heparin (Duraflo® powder). It is L-shaped and measures 1 mm x 0.33 mm, with a nominal snorkel bore diameter of 120 microns (fig.1). The iStent is designed to fit into Schlemm´s canal. The distal portion of the stent is bevelled and sharpened to facilitate penetration into the tissue of the trabecular meshwork. The external surface features three retention arches that impede the movement of the stent once it has been implanted. The implant weighs approximately 0.1 mg. It is delivered preloaded on an insertion device (fig.2) and it is implanted at the level of the trabecular meshwork with the aid of a Swan-Jacob type goniolens (fig.3). Two versions of the iStent are available; one for the right eye and one for the left eye. The difference lies in the orientation of the rails, designed to facilitate the penetration of the implant into the trabecular meshwork. The distal tip of the implant should point towards the patient's feet at all times.

Fig. 1. iStent® trabecular bypass

Fig. 2. iStent® trabecular bypass in iStent inserter

Fig. 3. Swan-Jacob goniolens

In all these techniques the patient is draped as for cataract surgery. Myosis is warranted if the surgery is not combined with phaco. Surgical steps are as follows:

1. A paracentesis is made generally using a 15 degree blade (fig.4).
2. If needed, the pupil is constricted with intracameral miotics and a cohesive viscoelastic is injected in the anterior chamber.
3. The tip of the stent, with the distal part parallel to the trabecular meshwork, should approach the trabecular meshwork at an angle of 15° to facilitate penetration of the tissue (fig.5). The stent should be placed parallel to the plane of the iris with the inner part covered by the meshwork and the lumen away from the iris. Excessive resistance indicates a path that is too perpendicular to the trabeculum or a wrong implantation site. Once the trabecular meshwork covers all of the implant, it should be released by pressing the applicator button. Only the proximal end of the stent should remain visible in the anterior chamber. The stent can be seated in its final position by gently tapping the side of the snorkel with the inserter tip. A small reflux of blood from Schlemm´s canal is common and reflects adequate positioning of the stent.
4. At the end of surgery, blood and viscoelastic are removed(Fig.6). The corneal incision can be hydrated if the paracentesis is not watertight.

Fig. 4. A paracentesis is performed temporally.

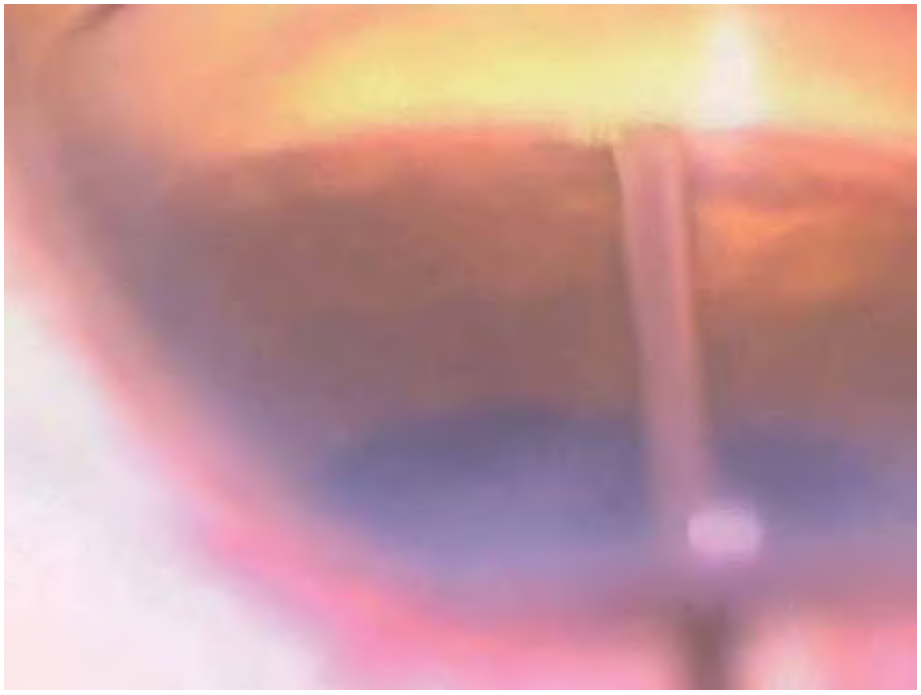

Fig. 5. The iStent is already half way within the trabecular meshwork.

Fig. 6. Residual blood and viscoelastic are washed and aspirated by the anterior chamber with a coaxial I/A tip - the same can be done using a bimanual technique.

The post-operative suggested treatment should be similar to what is commonly used by each surgeon for an uncomplicated phacoemulsification procedure. Generally anti-glaucoma drugs are discontinued post-operatively and reintroduced if the patient does not achieve the target pressure.

iStent *inject is a* second generation trabecular bypass device that is also designed to restore conventional outflow (fig. 7). Two stents come preloaded in a sterile disposable injector that is placed on the meshwork. A stent release button on the injector is used to release the stents one at a time into the proper position (approximately 2-3 clock hours apart (fig. 8).

This new mechanism of implantation allows for implantation of two stents without exiting the inserter from the eye.

Fig. 7. iStent® inject (image provided by Glaukos)

Fig. 8. iStent® inject inserter (image provided by Glaukos)

3.2 Trabectome

The Trabectome™ (NeoMedix Inc., Tustin, CA, USA) device consists of a disposable handpiece tip (19.5-gauge) that will fit through a 1.6mm corneal incision. The handpiece is connected to a console with irrigation and aspiration, and also to a simple electrocautery generator. The foot pedal controls the irrigation, aspiration and electrocautery ablation via a stepwise foot control similar to a phacoemulsification system (fig. 9).

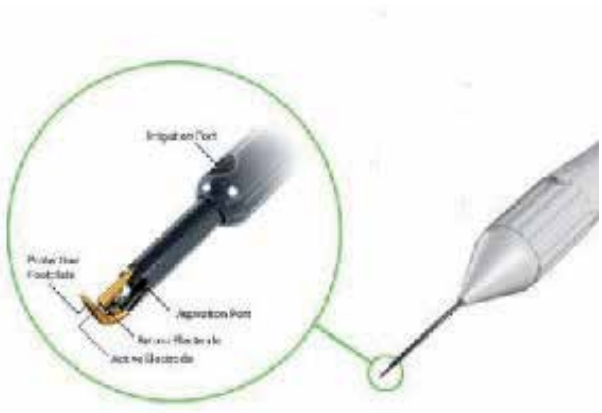

Fig. 9. Trabectome probe and tip

The tip of the handpiece is specially designed with an insulated footplate and is pointed for ease of insertion through the trabecular meshwork into Schlemm´s canal. The footplate is coated with proprietary multilayered polymer, which provides thermal stability, mechanical strength, biocompatibility and chemical resistance in laboratory testing. The aspiration port is in close proximity (approximately 0.3 mm) to the cautery electrode and serves to remove debris during ablation. The irrigation is 3 mm from the surgical site and serves the dual purpose of keeping the eye pressurized and further dissipating heat energy. Although the irrigation and aspiration system role is important, the high-frequency electrocautery generator system is the pivotal point of this technology. The generator is a modified 800 EU unit from Aaron/Bovie (St. Petersburg, FL, USA) and operates at a frequency of 550 kHz with adjustable power setting in 0.1-W increment up to 10 W (recommended range 0.5–1.5 W). The target tissue is disrupted and disintegrated by applying heat energy in bursts with a high-peak power and low duty cycle. This ablation approach equates to high-energy bursts, which are bunched into small increments with comparably long time intervals in between. As a result, disruption and disintegration of tissue is achieved rather than a thermal-cooking effect such as that seen in traditional cautery of blood vessels.[7,8]

Surgical steps: steps 1 and 2 are equal to the previous procedure, although a specially designed blade is provided by the manufacturer to obtain a water-tight paracentesis. A small paracentesis is more important with this procedure because during surgery the viscoelastic material is washed out by the water flowing through the tip of the instrument. 2) The tip of the footplate is inserted through the paracentesis aiming at the trabecular meshwork and then it is inserted through the trabecular meshwork into Schlemm´s canal . A foot switch activates the aspiration and electro-surgical elements that ablate and remove the strip of trabecular meshwork and Schlemm´s canal as the surgeon slowly advances the instrument along the meshwork in a clockwise and then counter clockwise direction using the insertion site as a fulcrum. A strip of trabecular meshwork and Schlemm´s canal spanning 80°–100° is ablated and removed under direct gonioscopic visualization. Intraoperative reflux of blood through the resulting cleft is desirable in this procedure and confirms appropriate ab interno "unroofing" of Schlemm's canal. 4) At the end of surgery any residual viscoelastic or blood present in the anterior chamber is removed. It is generally not necessary to hydrate the paracentesis.

The post-operative suggested treatment includes: antibiotics used for prophylaxis. Pilocarpine 2% qid should be used starting on the first post-operative medication and continued for a month. Lotemax is advised for three weeks and then tapered. Directly post-operative it is advised to continue the previous pre-operative anti-glaucomatous therapy, although prostaglandins should possibly be avoided. .Prof. Baerveldt recommends the eventual use of Latanoprost rather than other prostaglandins if they are absolutely necessary. Iopidine and Brimonidine can be used and are generally suggested. Anti-glaucoma medications can be reduced a month after surgery if target pressure is achieved.

3.3 Other procedures

Other approaches of gonioscopic surgery include the Ivantis method which simulates a short canaloplasty.

Two additional devices are aimed at improving flow of the aqueous humor from the anterior chamber to the suprachoroidal space. These are the Glaukos iStent *supra* and the Transcend Cypass. These devices will not be discussed, because the current data are less than one year post-operative.

4. Results

4.1 iStent

Numerous *in vitro* and *in vivo* studies support the stability, the effectiveness and the safety of the trabecular bypass iStent.

In 2004, Bahler demonstrated *in vitro* that the intraocular pressure was lowered after placement of a single stent, from 21.4 +/- 3.8 mm Hg to 12.4 +/- 4.2 mm Hg ($P < .001$).[9] This corresponded to an 84% increase in facility of outflow. Eyes receiving more than one stent had final IOP of 11.9 +/- 3.7 mm Hg. Nine eyes underwent sequential implantation of additional stents and seven of these had a further decrease of IOP (13.6 +/- 4.1 to 10.0 +/- 4.3; $P = .02$). This work suggested that bypass of the trabecular meshwork lowers IOP in cultured human anterior segments. One stent produced the greatest change in pressure. The sequential addition of more stents further lowered pressure in seven of nine eyes. Parallel to this study the founders/manufacturers of the iStent evaluated the stability of the implant on *ex vivo* eyes confirming that the L shape of the stent could not be moved even with strong traction on the stent itself.

A small clinical case series (n=6) reaffirmed the potential clinical utility of the current titanium version inserted *ab interno* and provided additional confirmation that the device stayed in place and continued to function to lower IOP with fewer medications through follow-up of one year.[10] All patients were seen day one, week one and at 1, 2, 6 and 12 months post-operatively. The mean pre-operative IOP of 20.2 ±6.3 decreased and stabilized at 14 to15 mm Hg with reduced medications out to one year. All devices remained in place and no complications were noted.

A larger prospective, 24-month, uncontrolled, multicenter, multicountry evaluation of 58 patients with uncontrolled primary open-angle glaucoma (including pseudoexfoliation and pigmentary) evaluated the effectiveness of the concurrent phacoemulsification and stent implantation.[11] Of the 48 patients in the per protocol population, 42 completed the 12

months follow-up. At baseline, mean (+/-SD) intraocular pressure (IOP) was 21.7+/-3.98 mmHg. At 12 months, mean IOP was reduced to 17.4+/-2.99 mmHg, a mean IOP reduction of 4.4+/-4.54 mmHg ($p<0.001$, 18.3%). At baseline, patients were taking a mean 1.6+/-0.8 medications. By 12 months, the mean number of medications was reduced to 0.4+/-0.62 ($p<0.001$). Half the patients achieved an IOP ≤ 18 mmHg and were able to discontinue hypotensive medication by the 12 month visit. The most commonly reported device-related adverse events were the appearance of stent lumen obstruction (seven eyes) and stent malposition (six eyes). None of the adverse events were deemed serious.

In 2010 Fea compared in a randomized study the results of phacoemulsification alone vs combined surgery (i.e. phacoemulsification and stent implantation).[12] The baseline IOP was similar in the two groups (combined group: 17.9 +/-2.6; control group: 17.3 +/-3.0 mm Hg) with a similar number of medications (2.,0 +/- 0.9 in the combined group and 1.9 +/-0.7 in the control group). Post-operative mean IOP at 15 months was 14.8 +/-1.2 and 15.7 +/- 1.1 respectively in the combined and in the control group ($p=0.031$). The author demonstrated that at 15 months the mean number of ocular hypotensive medications was significantly lower in the combined group (0.4 +/- 0.7 and 1.3 +/- 1.0, respectively; $P = .007$). Furthermore, after wash-out of ocular hypotensive medications, IOP was significantly lower in the combined group (16.6 +/- 3.1 mm Hg and 19.2 +/- 3.5 mm Hg). These results confirm the previous observation that IOP reduction could only partially be attributed to phacoemulsification and was in fact enhanced further by implantation of the iStent. The same author previously published a case report demonstrating the effectiveness of the procedure in one pseudophakic patient.[13]

More recently the effect of the iStent on flow was further elucidated by a fluorophotometic study by Fernandez-Barrientos et al.[14] Thirty-three eyes of 33 patients were randomized to either two stents and cataract surgery (n = 17, Group 1) or cataract surgery alone (n = 16, Group 2). Before surgery, flow and outflow facility were similar between Groups 1 and 2 (1.78 +/- 0.44 and 1.74 +/- 0.82 microL/min; $P = 0.18$; 0.12 +/- 0.03 and 0.13 +/- 0.06 microL/min/mm H; $P = 0.71$, respectively). At one year, outflow facility was significantly higher in the group with two stents (0.45 +/- 0.27 microL/min/mm Hg in Group 1 and 0.19 +/- 0.05 microL/min/mm Hg in Group 2; $P = 0.02$).

A larger prospective, randomized, open-label, controlled, multicenter clinical trial with a total of 240 eyes with mild to moderate open-angle glaucoma with intraocular pressure (IOP) ≤ 24 mmHg controlled on one to three medications compared the results of the patients who were randomized to undergo cataract surgery with iStent implantation (treatment group) or cataract surgery only (control).[15] The primary efficacy measure was unmedicated IOP ≤ 21 mmHg at one year. A secondary measure was unmedicated IOP reduction ≥ 20% at one year. Safety measures included best-corrected visual acuity (BCVA), slit-lamp observations, complications and adverse events. The study met the primary efficacy endpoint, with 72% of treatment eyes versus 50% of control eyes achieving the criterion ($P<0.001$). At one year, IOP in both treatment groups was statistically lower from baseline values. Sixty-six percent of treatment eyes versus 48% of control eyes achieved ≥ 20% IOP reduction without medication ($P = 0.003$). The overall incidence of adverse events was similar between groups with no unanticipated adverse device effects. This larger series not only further demonstrates the efficacy of the iStent in further lowering the intraocular pressure in patients undergoing cataract surgery, but also points out the safety of the

procedure. A longer post-operative follow-up through two years was reported more recently.[16] Best-corrected visual acuity of 20/40 or better was reported in 93% of treatment vs. 91% of control eyes at two years. Over the two year period, post-operative adverse events occurring at a level of 5% or greater included posterior capsular opacification (6% treatment vs. 10% control), elevated IOP (4% vs. 7%, respectively), visual disturbance (3% vs. 7%, respectively) and iritis (1% vs. 5%, respectively). Furthermore, in the treatment group, stent obstruction and malposition occurred in a small percentage of eyes (4% and 3%, respectively) and resolved shortly after occurrence (with or without treatment). The authors concluded that the overall long-term safety of iStents implanted during cataract surgery was similar to that of cataract surgery alone and that the adverse event/complication rate was low through the two year post-operative period.

4.2 Trabectome

The results obtained by the Trabectome can be summarized by a single paper which reports the experience of the Trabectome group. In this retrospective case series the authors reported their experience on follow-up through one year on 143 of 1127 Trabectome surgical procedures, including 102 through one year from 738 Trabectome-only and 41 through one year from 366 Trabectome-phacoemulsification surgeries[17]. It should be pointed out that many eyes at relatively high risk for filtering surgery failure were included after prior failed trabeculectomy or other previous surgeries were included in the study. Considering glaucoma surgery only: 273 underwent SLT, 170 ALT, 20 aqueous shunt surgery, 104 trabeculectomy, five prior Trabectome and five laser iridectomy.

Considering all cases, mean pre-operative IOP of 23.8 +/- 7.7 mm Hg decreased by 39% to 16.5 +/- 4.0 mm Hg at 24 months (n = 50). Intra-operative reflux bleeding occurred in 77.6%. Medications decreased from 2.8 to 1.2 by 24 months. Sixty-five patients (5.8%) had IOP elevation > 10 mm Hg above baseline on day one. Failure led to trabeculectomy in 5.9% (n = 67) and shunt installation in 1.6% (n = 18). Kaplan-Meier failure was defined across groups with at least two weeks follow-up as IOP > 21 mm Hg with or without medications and not reduced by 20% below baseline on two consecutive visits or repeat surgery. For Trabectome-only cases, mean preoperative IOP of 25.7 +/- 7.7 mm Hg was reduced by 40% to 16.6 +/- 4.0 mm Hg at 24 months (n = 46). No prolonged hypotony, choroidal effusion, choroidal haemorrhage or infections occurred. Failure led to trabeculectomy in 8.1% (n = 60) and shunt installation in 1.9% (n = 14). Medications decreased from 2.93 to 1.2 by 24 months. For Trabectome-phacoemulsification cases, baseline IOP of 20.0 +/- 6.2 mm Hg decreased at 12 months to 15.9 +/- 3.3 mm Hg (18%) (n = 45) and medications decreased from 2.63 +/- 1.12 to 1.50 +/- 1.36. Sixteen (4.4%) of 365 had prior failed trabeculectomy and 139 of 365 (38%) had prior laser trabeculoplasty.

Although the the large number of patients who underwent surgery of the study are very impressive, there are major limitations, including the retrospective nature and the fact that a very small number of procedures reported had been followed up postoperatively. Of the 738 patients who underwent only the Trabectome procedure, only 102 had a one year follow-up and of the 366 with combined surgery only 41 were followed up to one year. Furthermore, it is not clear if the patients with a longer follow-up and with available data include those high risk patients who were originally included in the study. If this is the case it would have been very important to analyse if there was any difference in terms of efficacy in the high versus low risk patients.

Recently, Knape and Smith[18] presented the case of a patient who had intra-operative blood reflux onto peripheral iris during trabeculectomy 11 months after Trabectome surgery. After having left the eye firm after surgery, the author did not report any other episode of hyphema during the following period. He hypothesizes that the absence of overlying angle structures, including the roof of Schlemm's canal, may have allowed blood to reflux into the angle and onto peripheral iris during a sudden decrease in intraocular pressure in trabeculectomy surgery. This self-limited episode suggests that the trabeculotomy remained patent, although the patient was not compensated and points out that further studies to assess the consequences of permanent trabecular meshwork tissue removal may be warranted.

More recently, Jea[19] reported on a cohort of patients and showed that a previously failed Trabectome surgery does not seem to impact the effect of subsequent trabeculectomy.

5. Complications prevention and treatment

Bleeding: bleeding with iStent, Trabectome or other trabecular bypass procedures is generally minimal, although aspiration of the blood in phakic eyes is suggested in order to allow proper visualization.. A very rare occurrence of more significant bleeding in the anterior chamber is generally due to damage of the iris either because the surgeon did not aim at the correct site or because involuntary movements occurred during surgery. The use of air or viscoelastics can stop the haemorrhage. It is generally advisable to postpone the trabecular bypass procedure if massive bleeding occurred previously because angle visualization can be difficult and because the source of bleeding and the effect on the angle structures are easier to visualize after the hyphema has cleared.

Malposition: the iStent may at times appear malpositioned. This does not preclude the implantation of another one provided the angle can be visualized. It is advisable to move at least two or three clock hours away from the previous implant to better visualize the meshwork.

Occlusion: occlusion of the Stent by a seemingly fibrinous plug can sometimes be seen during the postoperative follow-up. This may sometimes be eliminated by a single YAG laser spot.

Endothelial damage: although possible, it has never been reported with any of the procedures described.

6. Conclusions

The idea of approaching the surgery site *ab interno* is certainly appealing. The opportunity to perform a more standardized procedure and the opportunity to preserve the conjunctiva and the sites of eventual subsequent surgery are attractive. Furthermore, creating a direct communication between Schlemm's canal and the anterior chamber is a more physiological approach to IOP reduction with a lower rate of complications and a faster surgery compared to any other available approach.

Several studies pointed out the efficacy of the iStent in the reduction of IOP, although these studies were mainly performed in conjunction with cataract surgery. Nevertheless, there is strong evidence both *in vitro* and *in vivo* that the stent insertion actually facilitates outflow independent of the concurrent phacoemulsification. The procedure is safe and complications

are mainly limited to a small (and transient) blood reflux into the anterior chamber immediately upon insertion into Schlemm's canal. It should be noted, however, that all studies were performed in eyes with relatively low pre-operative IOP. At present there is no published evidence of the efficacy in patients with severe glaucoma nor what would be the impact in patients with higher baseline IOP.

Upon casual review of the number of cases reported by the papers on the Trabectome and the length of the follow-up, it may appear that the evidence of efficacy of this surgical method is more stringent. The net IOP reduction seems higher with the Trabectome compared to the iStent and patients at higher risk had been treated with this method. However, a more accurate analysis of the literature reveals that a very small number of patients have been followed for a reasonable amount of time. Futhermore, the ablation of part of the trabecular meshwork is certainly a more destructive procedure, although it seems that this fact does not impact upon the results of conventional surgery in the limited series followed for an adequate postoperative timeframe.

IOP outcomes with both approaches are usually in the mid-teens. Although mid-teens IOP might be adequate for initial and moderate patients, traditional filtering surgery with anti-fibrotic enhancement and bleb formation will probably remain the principal surgical approach to eyes with advanced glaucomatous optic neuropathy. Eventually more advanced patients may benefit from trabecular bypass surgery combined with hypotensive medications, but too little data are available at present to sustain this approach. Assuming ongoing clinical studies continue to be favourable, a strong argument can be made for use of these minimally invasive procedures which do not lead to bleb formation nor require anti-fibrotics, early in the glaucoma injury process, especially considering the difficulties of compliance with medical therapy. Neither of these procedures damages the conjunctiva superiorly, leaving surgical alternatives where necessary open. Furthermore, continued development of suprachoroidal stents (such as the iStent supra and the newer Transcend Cypass) may offer additional IOP lowering and thus serve a broader population of patients with more advanced disease.

Given that glaucoma is typically a chronic disease and that the introduction of these methods is relatively new, follow-up of the patients at the moment is limited to two years at maximum.

Trabecular surgery requires some learning curve to visualize the angle using a hand-held gonioprims and the diffuse illumination of the microscope gives a different appearance of the angle's structures as compared with slit lamp gonioscopy. Furthermore, the need for using a hand to hold the gonioprism makes any trabecular surgery strictly bimanual. During surgery, the implantation of the iStent is relatively easier compared with the Trabectome, because it does not need a continuous circumferential movement and because the chamber is well formed with viscoelastics. After the implantation of the device, the blood reflux in the anterior chamber is generally minimal with the iStent.

On the other hand, the Trabectome allows a visual feeling that the trabecular meshwork is ablated, whereas it is sometimes difficult to be sure of the correct iStent placement, especially when blood cannot be completely washed from the angle. Compared to trabeculectomy, additional costs with any device should also be considered. Furthermore at present only the Trabectome has been cleared by the FDA, although U.S. FDA approval of the iStent is expected in the near future.

A Novel Artificial Vitreous Substitute – Foldable Capsular Vitreous Body

Qianying Gao
State Key Laboratory of Ophthalmology, Zhongshan Ophthalmic Center, Sun Yat-sen University, Guangzhou, China

1. Introduction

The natural vitreous is a transparent, gelatinoid structure occupying four-fifths of the volume of the eye. It has a thin, membrane-like structure corresponding to the vitreous cortex that extends from the ora serrata to the posterior pole.[1] It is somewhat spherical but slightly flattened meridionally, and it has a cup-shaped depression in its anterior side. It consists of about 99% water by weight, collagen fibers (types II, V/XI, VI, and IX), hyaluronic acid, opticin, fibrillin, and hyaluronan, which can maintain a certain spatial relationship with dipolar water molecules.[1,2] However, very few cells are found in the vitreous body. These cells are mostly phagocytes that clear useless cellular debris and hyalocytes mainly found at the periphery and that produce hyaluronic acid and collagen. In human adults, the vitreous body has an approximate weight of 4 g, a density of 1.0053–1.0089g cm^{-3}, a refractive index of 1.3345–1.3348, and a PH range of 7.0–7.4. [3-5]

The physiological function of the vitreous body involves supporting adjacent posterior segment structures, providing an ocular refractive medium, and acting as a cell barrier to inhibit cell migration from the retina to the vitreous cavity.[6] With age, the natural vitreous body gradually shrinks and collapses during the course of syneresis. This phenomenon may eventually lead to posterior vitreous detachment and can play a crucial role in the formation of retinal breaks which result in rhegmatogenous retinal detachment if untreated.[7,8]

The removal of diseased vitreous bodies using pars plana vitrectomy combined with artificial vitreous substitutes can restore vision in many patients. These individuals include those affected by proliferative diabetic retinopathy, proliferative vitreoretinopathy, and endophthalmitis or patients otherwise regarded as hopeless.[9-11]

The vitreous body cannot regenerate, so the vitreous cavity must be filled with suitable artificial vitreous substitutes that will keep the retina in place and prevent phthisis bulbi. Artificial vitreous substitutes are one of the most interesting and challenging topics of research in ophthalmology.[2] A number of artificial vitreous substitutes, such as gas, silicone oil, heavy silicone oil, and hydrogels, have been used.[2,12]

There are three major categories of currently available gas vitreous substitutes: air substitutes, expansile gas substitutes, and Xenon. Gases are used for pneumatic retinopexy

and post-operative endotamponade. However, they are suitable only as short-term vitreous substitutes (Table 1).[13]

G	Molecular Weight	Purity (mol%)	Expansion Coefficient	Duration* (day)	Expansion Concentration (%)
Air	29	--	0	5-7	-
Xenon	131	99.995	0	1	-
SF_6	146	99.9	1.9-2.0	10-14	18
C_2F_6	88	99.7	1.9	10-14	-
C_4F_8	138	99.9	3.3	30-35	16+
C_3F_8	188	99.7	4	55-65	14

Table 1. Physical characteristics of gases as vitreous substitutes

In 1969, Norton et al. highlighted the advantages of clinical management with intravitreal air for the treatment of giant retinal tears.[14] However, the intravitreal longevity of air is only a few days[15] due to diffusion across the retina. The refractive index of the air (1.0008) is also incompatible with optically important tissues. Therefore, these issues limit the use of air. To date, air is mainly used in liquid–air exchanges during vitrectomy procedures.[16]

In 1973, Norton first experimented with sulphur hexafluoride (SF6) and found that the persistence of the gas and its expansile characteristics are superior to air. SF6 expands to twice its volume by dissolving nitrogen, oxygen, and carbon dioxide from the blood. It also stays in the vitreous cavity for about two weeks.[17] In 1980, Lincoff et al. proposed the use of perfluorocarbon gases[18]. These gases expand after intravitreal injection because of the diffusion of other gases from the blood stream. Perfluoropropane expands to four times its original volume by the fourth day after injection. It is also absorbed at a much slower rate than air or sulphur hexafluoride. To date, C3F8 is the agent of choice. Expansile gases last longer in the vitreous chamber than air, but they are spontaneously absorbed in 6 to 80 days and replaced by aqueous humor. Therefore, postsurgical removal is avoided if they cause certain concomitant complications.[19] However, they may induce lens opacification and usually result in a high intraocular pressure (IOP).[20,21] As with air, the refractive indices of gases are also lower (w1.17).[22]

Xenon was tested in rabbit eyes to evaluate its longevity in the vitreous cavity.[23] It is considered as the most promising gas with successful retinal reattachment in all cases. However, the major drawback is its rapid disappearance; almost 90% of Xenon disappears 3 h after introduction.[24]

Silicone oil is hydrophobic, viscous, transparent, and stable. It has a specific gravity of 0.97 g/mL and a refractive index of 1.4. Its viscosity is measured in centistokes and linearly varies with chain lengths and molecular weight. The 1,000 and 5,000 centistoke varieties are commonly used in clinics. The surface tension is approximately 40 mN/m. Introduced by Cibis in 1962,[25] silicone oil has been the most important adjunct for internal tamponade in the treatment of complicated retinal or choroidal detachment for the past five decades. It is

commonly applied for the treatment of superior retinal detachment through buoyancy force and high interfacial tension. It is the only substance currently accepted as a long-term vitreous substitute and is the preferred choice in complex retinal detachments, such as long-standing rhegmatogenous retinal detachment, traction retinal detachment, giant retinal tears, proliferative diabetic retinopathy, and severe endoophthalmitis involving the posterior segment.

However, the use of silicone oil has not always been successful. An anatomic success rate of around 70% has been reported,[19] with complications including cataract, keratopathy, anterior chamber oil emulsification, and glaucoma.[26] Several reports have demonstrated the migration of silicone oil droplets into the retina and the optic nerve. Others have shown the widespread loss of myelinated optic nerve fibers due to the oil's free-fluid characteristics within the eye.[27, 28]

Heavy oil, a solution of perfluorohexyloctane and silicone oil prepared as internal tamponade, has recently been used in retinal detachment surgery. However, it causes complications, such as emulsification and inflammatory reaction.[29] Some very recent results are encouraging,[30] but most clinicians are awaiting results from ongoing heavy silicone oil trials.[12]

Hydrogels and smart hydrogels seem to remain as the best candidates as long-term vitreous substitutes because they show excellent transparency and good biocompatibility. They can act as viscoelastic shock-absorbing materials, thereby closely mimicking the behavior of natural vitreous bodies. Hydrogels are networks of polymer chains that can contain over 99.9% water so they are hydrophilic and not flowable. Currently, a number of cross-linked polymeric hydrogels have been proposed, such as poly (vinyl alcohol) (PVA), poly poly (1-vinyl-2-pyrrolidone), poly (acrylamide) (PAA), and poly (ethylene glycol) (PEG).[2,12,31-34] Among these, the PVA and PAA hydrogels are the most promising candidates for long-term vitreous body replacement and are highly recommended for use. They show excellent biocompatibility, are biodegradable, and can closely mimic the physico-mechanical properties of natural vitreous bodies.[2] PEG is a synthetic water-soluble polymer that has been approved by the Food and Drug Administration (FDA) for use in a wide range of biomedical applications, including injectable hydrogels.[35] However, issues such as retinal toxicity, increased IOP, and formation of opacities still need to be addressed.[36] Fragmentation and changes in viscoelastic properties and resiliency after injection through a small-gauge needle have also been found in some types of hydrogels.[36, 37]

Smart hydrogels are a relatively new class of stimuli-sensitive hydrogels. They possess the common properties of conventional hydrogels, and they can respond to a variety of signals, including PH, temperature, light, pressure, electric fields, or chemicals.[38] Temperature-sensitive hydrogels, such as poly(N-isopropylacrylamide), the most extensively studied one, undergo sharp hydrophilic-hydrophobic transition in aqueous media at a lower critical solution temperature of 32 °C, which is close to the body temperature.[39] Generally, smart hydrogels appear promising, but they are still at an early experimental stage, and their long-term toxicity is unknown.[12] Therefore, despite half a century of research efforts to replace the vitreous body of the eye, an ideal and permanent vitreous body replacement has yet to be found.[40,41]

Current research on artificial vitreous bodies aims to determine ideal materials that are nontoxic and inert, thin and transparent, and have good water and oxygen permeability, high compatibility, and good elasticity[46] in order to mimic the natural vitreous perfectly. The materials must be hydrophilic and can form a gel within the vitreous cavity.[35] However, directly injected vitreous substitutes, like silicon oil and heavy silicon oil, often result in severe complications, such as intraocular toxicity, retinal cell proliferation, leakage into the anterior chamber, and difficulty of complete removal if emulsified with time, among others.

Inspired by the structure of the natural vitreous, we postulated a novel foldable capsular vitreous body (FCVB) to restore the shape and function of the natural vitreous body. The FCVB consisted of a capsule, drain tube, and valve. The capsule exactly mimicked the vitreous body using a computer. The intra-capsule pressure can be adjusted from the valve with a syringe, and there is a slice of anti-penetrating metal in the valve. Figure 1 and Table 2 show the images and parameters of the FCVB, respectively.[50] Silicone rubber elastomer has been used for tissue augmentation for many years, [43-45] so it was utilized to manufacture the capsule of FCVB. It showed good oxygen permeability, good mechanical and optical properties (Shore A hardness: 37.4°, tensile intensity: >5.86 MPa, elongation ratio: >1200%, tear intensity: 34KN/m, transmittance: 93%, Hazes<1%),[46] and good biocompatibility as shown in stable extracts experiment (no significant fever, good genetic safety, and no structural abnormality or apoptosis in the cornea, ciliary body, and retina over a six-month observation period).[50] After pars plana vitrectomy, the seamlessly connected FCVB was triple-folded and inserted into the vitreous cavity through a 3 mm × 1 mm scleral incision without air fluid exchange. Then an injectable medium, such as balanced salt solution (BSS) or silicone oil, can be injected into the capsule and inflated to support the retina. Through the tube–valve system, IOP can be adjusted by the volume of the injected medium. Similar to the glaucoma valve, the valve can be fixed onto the sclera surface. [46]

Component parts		Dimension (mm)	Permissible deviation (mm)
Capsule	Diameter	20.00	±2.00
	Rise of arch	2.00	±0.20
	Radius of curvature of fovea lentis	6.00	±0.50
	Chord length of fovea lentis	9.50	±0.50
	Optic part thickness	0.06	±0.02
Drain tube	Outside diameter	1.50	±0.20
	Inner diameter	1.20	±0.20
	Tube length	4.00	±0.50
	Vertical distance from the open end to the principal axis	7.99	±0.20
Drain valve	Top diameter	4.00	±0.20
	Bottom diameter	6.00	±0.20
	Total thickness	3.50	±0.20
	Puncture part thickness	2.00	±0.20
	Location hole diameter	0.50	±0.05

FCVB, foldable capsular vitreous body; BSS, balanced salt solution.
Note: The FCVB consisted of capsule, drain tube, and valve.The capsule was mimicking the vitreous body exactly by computer, and BSS was injected through the tube-valve system to inflate the capsule.

Table 2. Standard dimensions of the components of the human FCVB

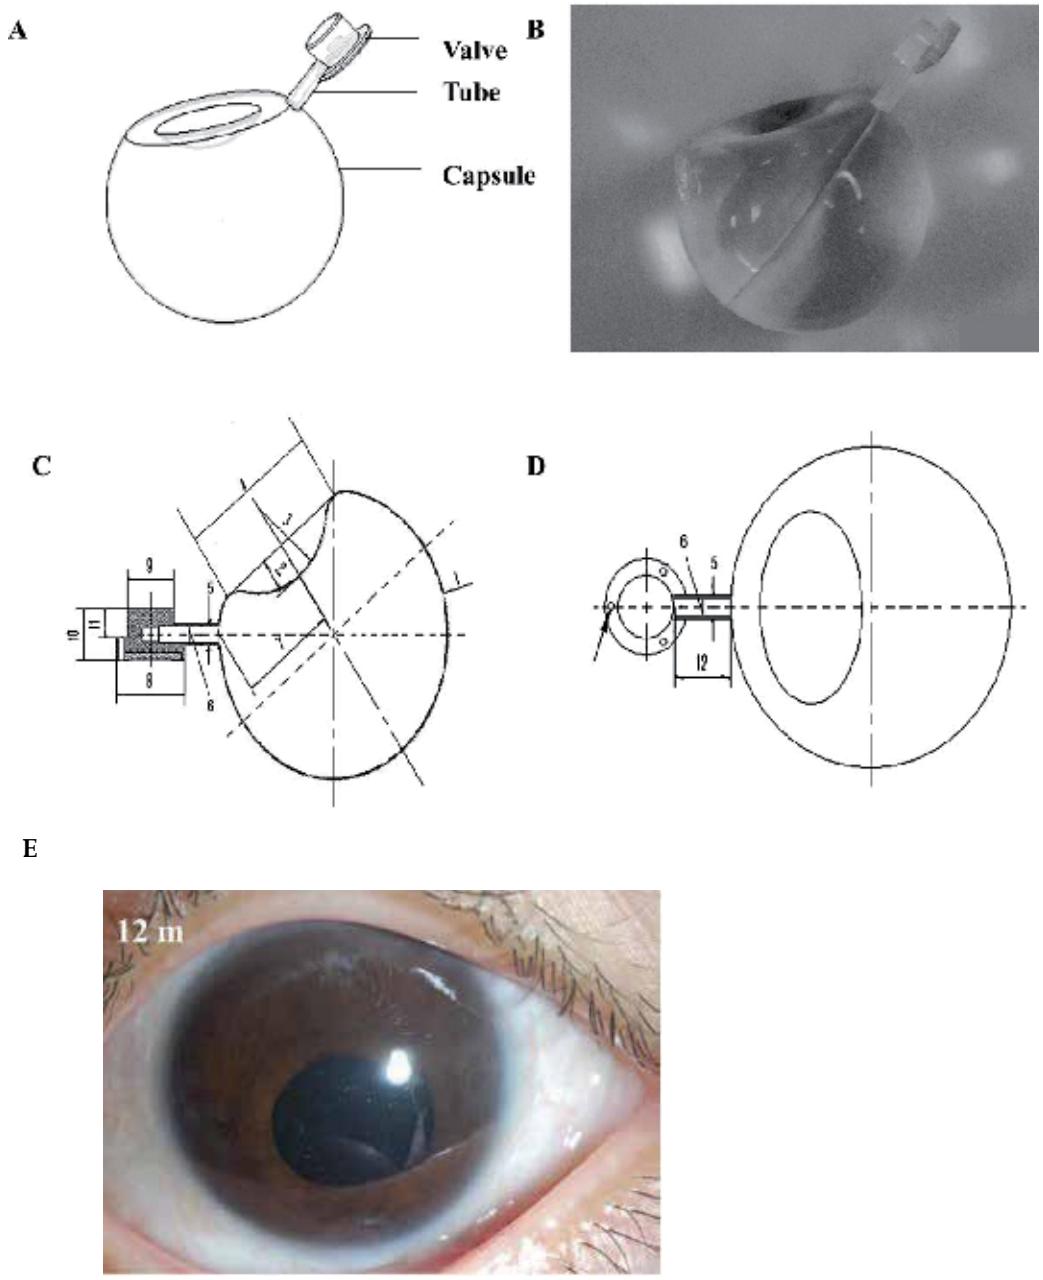

Fig. 1. The human foldable capsular vitreous body (FCVB) consists of vitreous-shape high molecular capsule, tube, and valve. The intra-capsule pressure can be adjusted from the valve with a syringe and there is a slice of anti-penetrating metal in the valve; the designed parameters finely mimic the vitreous shape of a human. (A) Illustration of FCVB. (B) Final sample of the FCVB (Outside the eye). (C) Side view of varied parameters. (D) Vertical view of varied parameters. (E) FCVB inside the eye (Twelve months after implantation).

Theoretically, a new artificial vitreous has the following advantages. First, it does not flow into the anterior chamber and subretinal regions or other sites. Second, it does not emulsify or damage the media over time nor cause it to be isolated in the capsule. Third, it has the capability to support discretionary retina using a 360-degree solid arc.

Developing an irregular vitreous-shaped thin capsule and smoothly connecting it to a very thin diameter tube and a pressure-control valve are very difficult. According to this hypothesis, a mirror steel mold is specially designed to fabricate FCVB using an injection-forming technology that would make the capsule, drainage tube, and valve of the FCVB seamlessly connected. The mold consists of an upper composite die, a lower composite die, and a core.[47] The core shape can be manipulated using a computer to match the human vitreous parameters. The capsular film is 60 μm thick, only one-third the thickness of the retina. In its natural shape, the human FCVB is somewhat spherical, but it is slightly flattened meridionally and has a cup-shaped depression anteriorly.

In the rabbit model of severe retinal detachment, the BSS-filled FCVB was found to mimick the morphology of the natural vitreous very closely and to restore its physiological functions, such as support, refraction, and cellular barriers, during a three-month observation period and without obvious complications. By contrast, the silicone oil control group showed obvious lens opacity, significant hyperopic shift, recurrent retinal detachment, preretinal membrane formation, and vitreoretinal traction.[48] The FCVB capsule can provide the detached retina with a platform to form a flat scar and a barrier to block cell migration from the retina to the vitreous cavity.

Interestingly, the BSS-filled FCVB very slightly changes the refraction compared with silicone oil and heavy silicone oil based on Gullstrand–Emsley and Liou–Brennan schematic eyes.[49] Reports from the State FDA in China show that FCVB has suitably mechanical, optical, and biocompatibility properties.[50] Its optical characteristics indicate that FCVB has high light transmission and laser irradiation stability.

In the early development of breast implants in plastic surgery, similar to current clinical vitreous substitutes, directly injectable materials were used. In fact, hydrophilic polyacrylamide gel (PAAG) was directly injected into the breast. This procedure was practiced widely in China and Eastern Europe in the 1990s. The breast implantation procedure was analogous to the use of silicone oil to replace the vitreous body. However, the injected PAAG was gradually found to induce severe complications, such as inflammation and infection, multiple indurations, hematoma, painful masses, and mastalagia. Currently, the direct injection of PAAG is prohibited, and it has been replaced with the use of capsule-like implants whose fluid substitute is contained in a thin, elastic capsule. This approach to implantation has shown clinical success.[51] In case of severe complications, as mentioned above, the implant can be completely removed without leaving behind residual fluid substitute. Apparently, the development of both artificial vitreous and breast substitutes shared a similar path, and both have suffered setbacks from the direct injection of the fluid substitute into the organ. Therefore, similar lessons can be learned, and the use of a capsule-type implant may be a good replacement for the use of the vitreous body.[46]

The use of FCVBs in the eyes is not yet a common practice worldwide. Therefore, an exploratory study of our new treatment for severe retinal detachment was conducted. The

detachment cannot be easily reattached with silicone oil tamponade, such as posterior scleral ruptures with large disruptions of the retina or severe scleral ruptures with retinal and choroidal detachments. It may also have rigid retinal redetachments or inferior holes occurring after silicone or heavy oil tamponade had been attempted. At Zhongshan Ophthalmic Center, 11 patients were implanted with FCVBs filled with BSS,[52] whereas 3 patients were implanted with FCVBs filled with silicone oil.[53] Patients with serious eye inflammation, with only one eye remaining, with silicone oil-filled eyes, with serious heart, lung, liver, or kidney dysfunctions, or have other diseases that make them unsuitable for inclusion were excluded from the research. Retinal reattachments were found by B-scan in 8 (73%) of the 11 eyes at the end of the three-month treatment time; leakage of FCVB caused failure in three eyes. The production method of FCVB was correspondingly revised, and this addressed the problem. No obvious inflammation was observed in any eye after FCVB implantation, and UBM showed that the FCVB did not crush the ciliary body. There was no obvious difference between the FCVB's spectral transmittance before implantation and after removal.[52] Overall, the results showed that FCVB is an effective and safe artificial vitreous body for severe retinal detachments. It can help avoid the complications induced by silicone oil, such as glaucoma, corneal keratopathy, and silicone oil emulsification during a 12-month implantation time.[53]

Current data have demonstrated the theoretical advantages of using FCVBs, as mentioned above. Even if an ideal injectable material can be found, the use of FCVB is necessary to the artificial vitreous body. It acts as a transporter that can be injected with media, such as BSS, silicone oil, heavy oil, and hydrogels. In the present research, BSS was injected into the capsule of FCVB after PPV, and it was demonstrated as a flexible, effective, and safe vitreous substitute over a three-month implantation period.[52] Further multiple-central clinical trials are in progress in China, and the encapsulation of silicone oil, heavy oil, or hydrogels in PPV eyes will be attempted. Some common substances are active, such as collagen, hyaloronic acid, water, and the natural vitreous that consists of approximately 99% water and 1.0% inorganic salts, organic lipids, and hyaluronan[1], so these are not recommended as encapsulated tamponades in PPV eyes.

In addition, tiny (300 nm) apertures (Fig.2)[54] exist in the capsule, so the FCVB can release dexamethasone sodium phosphate and Protein kinase Cα. It can also be used as an intravitreal drug delivery system in addition to serving as a vitreous substitute.[54,55] Therefore, without the need to change its chemical properties, FCVB may provide a common vehicle for different drug releases, including antibiotics, anti-proliferative agents, and vascular endothelial growth factor antagonists.

The present exploratory clinical study was not large enough to provide a definitive conclusion. Further, the effects of FCVB on the lens should be further evaluated because 10 of 11 eyes were aphakic, and only one eye was phakic.[52] Based on this trial, a nine-hospital clinical trial is currently in progress in China to ascertain FCVBs' safety and efficacy as a vitreous substitute. The FCVB produced by Guangzhou Vesber Co. Ltd. is still in the stage of clinical trial, so it is not commercially available.

FCVBs have some similarities to thin elastic capsule breast implants and tissue expander systems used in plastic surgery. However, they also have differences, which are as follows. (1) Production methods: FCVBs are formed by injection forming technology and have a US

patent, whereas capsule breast implants and tissue expander systems are made by dip forming for large balloons. (2) Sample size: Producing an irregular vitreous-shaped thin capsule and smoothly connecting it to a 1.2 mm diameter tube and a pressure-control valve are major challenges. However, capsule breast implants and tissue expander systems are large and easily made. (3) Implantation site: FCVBs are implanted into the vitreous cavity and come into contact with very tender tissues, such as the retina, ciliary body, lens, and anterior chamber. However, capsule breast implants and tissue expander systems directly come into contact with adipose tissues. Therefore, there are a number of safety issues in the use of FCVBs, which have to be addressed.

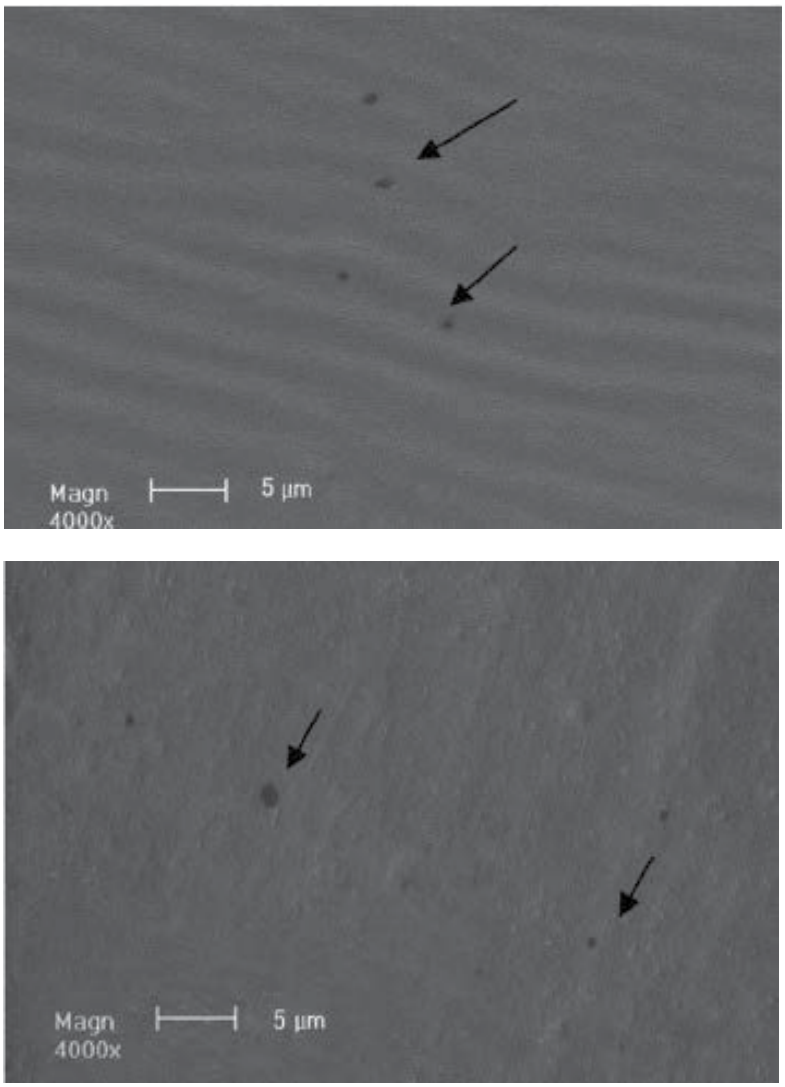

Fig. 2. Scanning electron microscope images of the capsule of the FCVB. Before implantation (**A**) and at the end of the observation time (**B**) 300-nm-mili apertures in the capsule were observed (*arrows*).

In conclusion, a new paradigm for the fabrication of a vitreous body substitute using FCVB was proposed in the current work. FCVB was established as an acceptable replacement as it closely mimics the morphology and restores the physiological function of the vitreous body. This idea provided us with a novel approach in researching on a new therapy strategy mimicking the natural vitreous that has been used for nearly half a century.

Endophthalmitis

Phillip S. Coburn and Michelle C. Callegan
University of Oklahoma Health Sciences Center, Dean McGee Eye Institute, Oklahoma City, Oklahoma, USA

1. Introduction

Endophthalmitis is an infection of the anterior and posterior segments of the eye resulting from the introduction of microorganisms following a surgical procedure (postoperative), traumatic penetrating injury (posttraumatic), or metastasis from an infection of a distant site in the body (endogenous). Endophthalmitis can develop into panophthalmitis if the infectious agent invades the cornea and sclera. The vast majority of cases of endophthalmitis result from intraocular surgical procedures, in particular cataract surgery (West et al., 2005). Over the past several decades, the number of postoperative endophthalmitis cases has risen steadily, owing to the increase in the number of invasive ocular surgeries performed (West et al., 2005). The etiological agents responsible for endophthalmitis include both Gram-positive and Gram-negative bacteria and fungi. Cases of post-surgical endophthalmitis are usually a result of the introduction of members of the normal microbiota of the eyelid and skin surrounding the eye, the most common cause being coagulase-negative staphylococci (CNS) (West et al., 2005). Cases of posttraumatic endophthalmitis are more frequently caused by environmental bacteria, the most common being *Staphylococcus aureus* and *Bacillus cereus* (Jonas et al., 2000; Meredith, 1999; O'Brien & Choic, 1995; Thompson et al., 1993). Frequent causes of endogenous endophthalmitis (EE) include *S. aureus*, streptococcal species, *B. cereus*, and Gram-negative bacteria including *Klebsiella pneumoniae*, *Escherichia coli*, and fungal agents such as *Candida albicans* (Greenwald et al., 1986; Jackson et al., 2003; Okada et al., 1994; Romero et al., 1999; Shammas, 1977; Shrader et al., 1990).

The clinical hallmarks of endophthalmitis are acute vision loss, severe ocular pain, periorbital swelling, hypopyon, proptosis, and the presence of white cells and flare in the anterior chamber and vitreous (Lemley and Han, 2007). The visual prognosis can vary widely depending on the infectious agent, ranging from mild inflammation and full resolution to devastating blindness and loss of the eye. Therapy for endophthalmitis caused by avirulent skin microbiota typically results in complete resolution and full vision recovery. However, posttraumatic or endogenous endophthalmitis caused by virulent pathogens may not respond to therapeutic intervention and result in partial to complete vision loss, and in some instances, evisceration or enucleation of the infected eye.

This chapter will present a summation of the latest findings of epidemiological studies and discuss current therapeutic modalities. Moreover, the bacteriology and the current state of knowledge regarding the pathogenesis and host/pathogen interactions will be explored.

Given that a number of detailed and authoritative reviews of endophthalmitis in general have been published in the last ten years, and given the paucity of reviews on endogenous bacterial endophthalmitis, this chapter will primarily focus on this route of endophthalmitis.

2. Endogenous endophthalmitis

2.1 Historical perspective

Endogenous or metastatic endophthalmitis results from microorganisms seeding the bloodstream from a distant focus of infection and invading the posterior segment of the eye via a compromised blood retinal barrier (BRB) (Arevalo et al., 2010; Greenwald et al., 1986; Jackson et al., 2003; Okada et al., 1994; Romero et al., 1999; Shammas, 1977; Shrader et al., 1990). While this form of endophthalmitis is rare, the potential for blindness in one or both eyes is high. To date, almost nothing is known about the pathogenesis of endogenous endophthalmitis (EE), even though this disease ranks as one of the most devastating infections of the eye. In the pre-antibiotic era, the majority of cases of endophthalmitis resulted in poor visual outcome. From 1944 to 1966, approximately 73% of endophthalmitis cases resulted in a final visual acuity of hand motion vision or worse. The clinical outcome of endophthalmitis improved somewhat upon the introduction of intravitreal antibiotics and vitrectomy (Neveu and Elliot, 1959; Peyman et al., 1978). Even after the introduction of intravitreal antibiotic therapy and vitrectomy, the visual outcome of EE has not improved significantly in over 50 years (Jackson et al., 2003). Morever, there is a paucity of information on the pathogenic mechanisms of this disease from both the causative agent and host perspectives. The majority of patients have an underlying condition and are immunocompromised (Jackson et al., 2003). The leading predisposing condition of EE is diabetes mellitus type 2, but intravenous drug abuse, immunosuppressive agents, malignancies, and AIDS are also underlying conditions (Arevalo et al., 2010). Symptoms of EE typically include ocular pain, blurring or loss of vision, purulent discharge, and photophobia. EE may present as focal white nodules on the lens capsule, iris, retina, or choroid, or as a ubiquitous inflammation of multiple ocular tissues resulting in purulent exudate throughout the globe. In addition, inflammation can spread to involve the orbital soft tissue (Arevalo et al., 2010).

EE was first identified and described by the German pathologist Rudolf Ludwig Karl Virchow in 1856 (Virchow, 1856). While the causative agent was not identified, it may have been bacterial. In 1894, German ophthalmologist Theodor Axenfeld reported in a treatise on endogenous endophthalmitis that the majority of cases involved only one eye and were a result of the deposition of septic emboli in the uvea (Axenfeld, 1894). However, in one-third of cases, both eyes were affected and infection was selectively localized to the retina. Axenfeld postulated that although bacteria were found in all branches of the carotid and ophthalmic arteries, the predilection for the retina was probably due to the smaller size of the retinal capillaries and „the presence of areas of disease in the capillary walls favoring the lodgment there of micro-organisms“ (Tooker, 1938). Collins and Mayou (1925) further speculated that „the retina becomes infiltrated with polymorphonuclear leukocyes, which make their way inward, collecting in large numbers between the retina and the hyaloid membrane and in the neighboring vitreous“. Axenfeld noted in his writings that approximately one-third of patients with EE also had endocarditis, and that the vegetations were the likely source of bacteria infecting the eye. In 1916, a case of unilateral EE in a 19 year-old soldier with cerebrospinal meningitis was described (Weakley, 1916). Gram-negative diplococci, presumably *Neisseria*

meningitidis, was cultured from both the cerebrospinal fluid and from the anterior chamber of the left eye. The patient was treated with repeated injections of antimeningococcus serum into the spinal column, which resulted in complete resolution of the meningitis. Interestingly, infection and inflammation of the affected eye was also resolved, leading the case author to speculate that the antiserum therapy may have contributed to the rapid clearance of the infection. Regardless of whether the antiserum had any effect on clearing the infection, the patient retained only perception of light visual acuity (Weakley, 1916). In 1938, Tooker described a case of unilateral EE in a patient that was readmitted to the hospital after having undergone ear surgery (Tooker, 1938). The left eye was severely inflammed and visual acuity was perception of light only. Blood cultures were positive for staphylococci and the patient expired from septicemia three days following readmission. An autopsy revealed bronchial pneumonia, vegetative endocarditis, and abscesses in the kidneys, spleen, and liver. Examination of the left eyeball revealed two primary foci in the retina and ciliary body. Tooker concluded that staphylococcal emboli lodged in the retinal and ciliary capillaries, entered the vitreous chamber, and induced a robust inflammatory response. Tooker reported that the patient had been in excellent condition prior to the ear surgery, blood glucose levels were normal, and no other underlying condition was present. It is therefore possible that a systemic inflammatory response induced a breakdown in the blood retinal barrier allowing staphylococci to invade the vitreous humor.

Even after the introduction of antibiotic therapy, visual outcomes following EE remained poor. Walker and Fenwick (1962) reported a case of fulminate bilateral endophthalmitis following streptococcal septicemia. In spite of aggressive treatment with systemic steroids, hydrocortisone ointment, and local and systemic antibiotics, vision in the right eye was perception of light, and in the left was count fingers. More recently, Jackson et al. (2003) reviewed 267 cases of EE and found that the visual prognosis was uniformly poor. These authors offered a number of possible explanations for the poor visual outcome of EE, including misdiagnosis owing to the fact that EE may mimic other ocular conditions, the rapid progression of the disease, and the failure to recognize the overlap between ocular and systemic infection (Jackson et al., 2003). Since the earliest reports of EE, little progress has been achieved in improving the visual prognosis of this disease. This highlights the necessity for studies to characterize the factors that contribute to the pathogenesis of EE, both from the host and the bacterial perspectives.

2.2 Epidemiology and bacteriology

Current epidemiological studies indicate that EE accounts for approximately 2 to 15% of all cases of infectious endophthalmitis (Arevalo et al., 2010; Puliafito et al., 1982). The often poor visual outcome and potential for bilateral blindness make EE one of the most destructive and devastating ocular infections. In recent reviews of cases of bacterial EE, 41% of cases resulted in a final visual acuity of count fingers or better, 26% of infected eyes lost all useful vision, and 29% required enucleation or evisceration (Greenwald et al., 1986; Jackson et al., 2003; Shammas, 1977). The vast majority of infections are unilateral, with disagreement among studies as to whether there is a predilection for the right or left eye (Arevalo et al., 2010; Greenwald et al., 1986; Jackson et al., 2003; Okada et al., 1994). Bilateral infections occur in approximately 25% of patients with EE (Arevalo et al., 2010). As stated earlier, over 50% of EE patients have an underlying medical condition, with diabetes being

the most prevalent. Additional populations at risk include immunocompromised patients, patients with prolonged indwelling devices, and intravenous drug abusers. Sources of infection include suppurative liver disease, endocarditis, urinary tract infection, and meningitis (Jackson et al., 2003). Virtually any organism that can infect the bloodstream has the capability to cause EE, but frequent causes include opportunistic and environmental pathogens such as *Staphylococcus aureus*, *Streptococcus sp*., *Clostridium septicum*, coagulase-negative *Staphylococcus*, *Bacillus cereus*, *Listeria monogocytogenes*, *Escherichia coli*, *Klebsiella pneumoniae*, *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Neisseria meningitidis* (Arevalo et al., 2010). However, *S. aureus* and *K. pneumoniae* dominate as bacterial causes of Gram-positive and Gram-negative cases of EE, respectively.

S. aureus is a Gram-positive bacterium found as a member of the normal microbiota of skin and mucosa, but can cause a variety of systemic, skin, and deep tissue infections and is a leading cause of contact lens-associated corneal infections (Callegan et al., 1994; Callegan et al., 2002b). The association between *S. aureus* EE and the prolonged use of indwelling prosthetics has been reported in diabetics and patients with other underlying immunocompromise with increasing frequency (Jackson et al., 2003; Major et al., 2010; Ness and Schneider, 2009; Nixdorff et al., 2009; Okada et al., 1994). *S. aureus* causes the majority of the cases of EE in Western countries and Europe (Ho et al., 2011). The emergence of lineages resistant to methicillin in the 1960s has prompted a public health crisis due to the difficulty in treating methicillin-resistant *S. aureus* (MRSA) infections and the increasing trend of infection among individuals with fully competent immune systems. MRSA infections may be community acquired (CA) or healthcare-associated (HA), with CA-MRSA being easier to treat but considerably more virulent. Coinciding with an increase in the prevalence of MRSA strains is an increase in MRSA ocular infections (Blomquist, 2006; Major et al., 2010). Recently, Ho et al. (2011) described a series of 7 patients (8 eyes) from a single institution that were diagnosed with EE caused by MRSA. Treatment of these cases consisted of intravitreal tap and injection of vancomycin and ceftazidime, as well as intravenous vancomycin. While retinal detachment occurred in 6 of 8 eyes, most of the patients experienced improved visual acuity from initial presentation, and only one eye lost all vision and required enucleation. Previous reports found that only 23.5% of cases of MRSA EE resulted in a visual acuity better than 20/200, whereas these authors found that 37.5% of eyes showed a final visual acuity of better than 20/200 (Ho et al., 2011). The authors contend that the higher than usual retinal detachment rate observered in their study might have been due to the higher than normal time between onset of EE and presentation, generally a mean time of 3.5 to 7.1 days versus a mean time of 17 days in their study (Ho et al., 2011).

K. pneumoniae is responsible for the majority of cases of EE due to Gram-negative bacteria and is the leading cause of EE throughout East Asia (Arevalo et al., 2010). Similar to MRSA, *K. pneumoniae* represents a therapeutic challenge due to increasing rates of acquisition of antibiotic resistance determinants. Although *K. pneumoniae* is found in the environment and as a commensal member of the gastrointestinal tract microbiota, it is also a frequent cause of healthcare-associated infections such as pneumonia, bacteremia, and urinary tract infections (Chang et al., 2002; Chuang et al., 2006; Fang et al., 2004; Fung et al., 2002;). *K. pneumoniae* has become the leading cause of pyogenic liver abscess in patients in Taiwan and other countries in the Far East (Chang et al., 2000; Wang et al., 1998), and reports of *K. pneumoniae* EE resulting from septicemia following pyogenic liver abscesses in diabetics are increasing (Chang et al., 2002; Chen et al., 2004; Chuang et al., 2006; Fang et al., 2004; Fung et al., 2002;).

In a case review of 18 patients with EE in Korea, Chung et al. (2011) also reported a close association between diabetes and infection with *K. pneumoniae*, and these factors were linked to a poor visual prognosis. These findings highlight the necessity for increased scrutiny of diabetic patients that present with ocular symptoms.

2.3 Diagnosis and therapeutic modalities

Early diagnosis and the initiation of treatment are critical to controlling infection and improving the visual prognosis of EE. Diagnosis of EE is difficult to establish based on clinical presentation alone because of the nonspecific nature of the symptomology. Diagnosis is usually based on clinical presentation and additional methods such as fundoscopy, ultrasonography, optical coherence tomography, and magnetic resonance imaging (Jackson et al., 2003). When EE is suspected, cultures of blood, vitreous and aqueous humor, and Gram stains are criticial for confirmation (Arevalo et al., 2010). Symptoms of systemic disease may also be useful in diagnosis, however only 57% of patients with EE manifested systemic signs of infection (Okada et al., 1994). Moreover, EE might be missed in patients with systemic infection until ocular pain and vision loss are experienced. Therapy for diagnosed bacterial EE consists of administration of systemic antibiotics such as third generation cephalosporins, vancomycin, and aminoglycosides (Lemley and Han, 2007). Fourth generation fluoroquinolones are also used at the discretion of the physician (Lemley and Han, 2007). Therapy also consists of intravitreal injection of 1 mg vancomyin per 0.1 ml for Gram-positive and 2.25 mg ceftazidime per 0.1 ml for Gram-negative pathogens and/or the aminoglycoside amikacin (0.4 mg). Jackson et al. (2003) reported in a literature review that vitrectomy is beneficial in cases of severe EE caused by highly virulent organisms and increases the likelihood of a better visual outcome by threefold. Vitrectomy is also indicated for cases of EE complicated by retinal detachment (Arevalo et al., 2010). As stated earlier, however, the visual outcome of EE has not improved in over 50 years. The lack of clinical improvements in EE is likely due to the lack of a reproducible animal model in which to study this disease; a disease model would be beneficial in terms of therapeutic testing and analysis of pathogenesis.

2.4 Pathogenesis

EE is one of the most frequently blinding intraocular infections, however little is known about the interplay of host and bacterial factors that contribute to the development of this disease. Moreover, the pathogenic mechanisms underlying the migration of bacteria toward and into the eye, inflammation, and vision loss have not been addressed. It is also unknown as to why diabetes is a common predisposing condition, although there are a number of possible explanations. Diabetes compromises the eye both immunologically and architecturally, resulting in changes that may weaken the ability of the eye to exclude organisms during systemic infection. One of the most serious and common complications among diabetics, specifically those with type 2 diabetes, is diabetic retinopathy (Aiello et al., 1998; Engler et al., 1991). During the progression of diabetic retinopathy, the vasculature, glia, and neurons of the retina are affected. The initial changes that occur within the retinal vasculature are the death of pericytes and thickening of the basement membrane, which lead to capillary leakage and occlusion. These changes ultimately result in macular edema, formation of new vessels, and neuroretinal degeneration (Asnaghi et al., 2003; Fong et al., 2003; Martin et al., 2004; Neely and Gardner, 1998; Qaum et al., 2001; Takeda et al., 2001).

Increases in vascular endothelial growth factor (VEGF) and the cytokines interleukin (IL)-1β, IL-6, IL-8, and tumor necrosis factor alpha (TNFα) in diabetic retinas contribute to angiogenesis and to breakdown in the BRB, implying an association with inflammation in the disease process (Jo et al., 2010). Intercellular adhesion molecule 1 (ICAM-1) and CD18 are upregulated and contribute to increased leukocyte adhesion to the endothelial wall. This is turn results in endothelial cell injury and death (Funatsu et al., 2005; Miyamoto et al., 1998; Miyamoto et al., 1999; Schroder et al., 1991). Elevated expression of matrix metalloproteases in the retina may also facilitate increases in vascular permeability and degradation of tight junction complexes, leading to BRB dysfunction (Giebel et al., 2005). Retinal pigment epithelia (RPE) and vascular endothelium, barrier cells of the BRB, also undergo changes in hyperglycemic environments *in vitro* and *in vivo*, including increases in VEGF that may contribute to vascular permeability (Amrite et al., 2006; Losso et al., 2010). The deterioration of the BRB during the development of diabetic retinopathy may allow pathogens to more readily invade the interior of the eye and might partially explain the link between diabetes and an increased risk of acquiring EE. Unfortunately, a clinical link between patients with diabetic retinopathy and EE has not been reported, only speculated. Retinal vascular permeability is not the only change occurring in a diabetic individual. Diabetes also compromises the innate immune response and depresses the ability to clear infections in general. Polymorphonuclear leukocytes (PMN) are of critical importance in clearing pathogens from the bloodstream and in the eye during acute bacterial endophthalmitis (Callegan et al., 1999; Ramadan et al., 2006; Ramadan et al., 2008; Wiskur et al., 2008). These important cells are impaired in diabetics. PMN defects in chemotaxis, phagocytosis, and bactericidal activity have been reported in the context of diabetes (Delamaire et al., 1997; Walrand et al., 2004) and PMN from diabetic mice and humans are incapable of phagocytizing and killing both *S. aureus* and *K. pneumoniae* (Lin et al., 2006; Park et al., 2009). These defects in the ability of PMNs to clear bacteria that are destined to cross a compromised blood retinal barrier may also contribute to the development and pathogenesis of EE, but this has not been scientifically analyzed.

Virtually nothing is known about the bacterial factors that contribute to the pathogenesis of EE. *S. aureus* and *K. pneumoniae* possess a repertoire of factors with demonstrable roles in the virulence of these species in a number of animal models of infection, however it is currently unknown if they contribute to the pathogenesis of EE. *S. aureus* expresses a number of adhesins, including the fibronectin binding proteins FnbpA and FnbpB (Green et al., 1995), the fibrinogen-binding proteins ClfA and ClfB (McDevitt et al., 1994), and the collagen binding protein Cna (Patti et al., 1992) that have been shown to mediate attachment to extracellular matrix and plasma proteins, a crucial first step in initiating infections. *S. aureus* synthesizes alpha-toxin, a cytolysin shown to be important in corneal infections (Callegan et al., 1994) and endophthalmitis (Booth et al., 1998; Callegan et al., 2002b). *S. aureus* also secretes a host of other secreted cytolytic toxins including the beta-, gamma- and delta-toxins, and Panton-Valentine leukocidin (Plata et al., 2009) that may contribute to structural damage within the eye, or in the case of Panton-Valentine leukocidin (PVL) have either anti- or pro-inflammatory effects. PVL lyses neutrophils at higher concentrations but is a potent stimulator of the release of proinflammatory cytokines such as IL-8 at lower concentrations (Otto, 2010). Some strains of *S. aureus* are also encapsulated, rendering them resistant to phagocytosis and more virulent in animal models of sepsis (Luong and Lee, 2002; Thakker et al., 1998). Most clinical isolates of *S. aureus* produce either Type 5 or Type 8 capsular polysaccharide (Roghmann et al., 2005). The capsule of *S. aureus* may afford a survival

advantage and prevent clearance from the bloodstream as well as the vitreous humor, especially in diabetics with impaired clearance mechanisms.

K. pneumoniae produces at least five major virulence factors that contribute to the pathogenesis of infection and include capsular serotype, hypermucoviscosity phenotype (HMV), lipopolysaccharide (LPS), siderophores, and pili. However, nothing is known about their potential contribution to EE pathogenesis. There are 77 capsular serotypes, however serotype K1 predominates among bacteremia, liver abscess, and EE isolates in Taiwan (Fung et al., 2002). Capsule production is likely to impede clearance of *K. pneumoniae* from the bloodstream and from the eye. The HMV phenotype is enriched among highly virulent, invasive strains of *K. pneumoniae*, especially those causing EE (Fang et al., 2004; Fang et al., 2007; Fung et al., 2002; Karama et al., 2008; Keynan and Rubinstein, 2008; Lee et al., 2006). Strains that express this phenotype possess a thick, viscous capsule-associated mucopolysaccharide web (Wiskur et al., 2008). Two commonly studied genes are associated with HMV: *magA* (mucoviscosity-associated gene A), which encodes a 43 kd outer membrane protein that has not been characterized (Fang et al., 2004), and *rmpA* (regulator of the mucoid phenotype A), a regulatory gene that controls the synthesis of the extracapsular mucopolysaccharide (Nassif et al., 1989). It has been shown that HMV confers resistance to serum killing and phagocytosis, and contributes to virulence in mice (Fang et al., 2004). *magA*- transposon mutants, which lost the HMV phenotype displayed serum sensitivity, became phagocytosis susceptible, and were avirulent in a mouse model (Fang et al., 2004). *magA* was located within a 35-kb locus containing 24 open reading frames (ORFs) with homologies to genes involved in exopolysaccharide biosynthesis or export and glycosylation (Chuang et al., 2006). This locus may represent a novel pathogenicity island responsible for the hypervirulence seen with certain *K. pneumoniae* pathogenic strains (Chuang et al., 2006). HMV+ *K. pneumoniae* are the most common cause of EE in Southeast Asia, with cases of EE caused by HMV+ *K. pneumoniae* on the rise in Western countries (Keynan and Rubinstein, 2008; Lederman and Crum, 2005). Our laboratory has previously shown that the HMV phenotype contributes to the pathogenesis of experimental *K. pneumoniae* endophthalmitis. In this model, an HMV+ strain caused significantly greater inflammation and greater loss of visual function than an HMV- strain following direct injection of bacteria into the vitreous (Wiskur et al., 2008). Further, the HMV+ strain was not readily cleared from the eye in this model (Wiskur et al., 2008). More recently, the *magA* gene was directly linked to the pathogenesis of EE in experimental *K. pneumoniae* endophthalmitis. Hunt et al. compared a wildtype HMV+ *K. pneumoniae* strain with an isogenic mutant defective in the *magA* gene, and found that mice infected with the *magA*- strain showed a significantly improved visual outcome relative to mice infected with the wildtype strain (Hunt et al., 2011). These results clearly demonstrate a role for the HMV phenotype in *K. pneumoniae* endophthalmitis. As this direct injection model circumvents systemic infection, it remains to be seen whether the HMV phenotype is important for crossing the BRB and establishing EBE.

The lipopolysaccharide O side chain has been shown to confer serum resistance to *K. pneumoniae* by preventing the deposition of complement components on the bacterial cell membrane and the ensuing complement-mediated cell lysis (Tomas et al., 1986). It is therefore possible that *K. pneumoniae* LPS from cells migrating near the BRB might elicit increases in permeability in the retinal vasculature that result in leakiness, facilitating entry into the eye. Metrickin et al. (1995), demonstrated that *E. coli* LPS induced a dose-dependent breakdown of the BRB. The siderophores enterobactin and aerobactin could also potentially be involved. While enterobactin is synthesized by nearly all isolates of *K. pneumoniae*,

aerobactin is less frequently detected (Podschun et al., 1993). However, only *K. pneumoniae* isolates with capsular serotype K1 or K2 that produced aerobactin were more virulent (LD_{50} $<10^3$ cfu), and transfer of the genes necessary for synthesis of aerobactin into an avirulent strain increased the virulence by 100-fold (Nassif and Sansonetti, 1986). *K. pneumoniae* produce two types of pili or fimbriae, type 1 and type 3, that mediate attachment to epithelial cells. The type 1 fimbrial adhesion gene *fimH* was shown to be enriched among blood isolates (Yu et al., 2006), and the type 3 fimbrial adhesion protein MrkD has been demonstrated to contribute to virulence by binding to epithelial cells of the urogenital, repiratory, and gastrointestinal tracts (Sebghati et al., 1998), and the type 3 fimbrial shaft protein MrkA is required for biofilm formation on intravenous and urinary catheters and human extracellular matrix (Jagnow and Clegg, 2003; Langstraat et al., 2001). It is conceivable that these pili mediate adherence to structures in the eye and aid in the establishment of EE. However, as for all of the above discussed factors, no studies have been conducted evaluating the importance of these virulence traits to EE pathogenesis due to the lack of a well-characterized animal model of this disease.

3. Postoperative endophthalmitis

Postoperative endophthalmitis is the most common type of endophthalmitis and most frequently occurs following cataract surgery, with 90% of cases occuring following this procedure (Lemley and Han, 2007). The rates of postoperative endophthalmitis have been increasing over the past several years, owing to increases in the number of cataract surgeries and other types of intraocular surgeries performed. This raises concerns due to the ever-growing population of the elderly that require cataract surgery. Millions of cataract surgeries are performed each year. Fortunately, the rate of occurrence of post-cataract endophthalmitis remains low, ranging between 0.06% and 0.25% (O'Brien et al., 2007; West et al., 2005). Among the types of cataract surgeries performed, phacoemulsification accounted for approximately 48% of the postoperative endophthalmitis cases, while 38.5% and 6.6% of cases followed extracapsular or intracapsular extraction, respectively (Ng et al., 2005). Postoperative endophthalmitis can occur after other types of surgery such as secondary intraocular lens placement, pars plana vitrectomy, penetrating keratoplasty, and even after corneal suture removal (Lemley and Han, 2007).

Fig. 1. Acute endophthalmitis caused by *Staphylococcus aureus* in a 43-year-old patient 3 days following a triple surgical procedure (penetrating keratoplasty, cataract extraction, and posterior chamber intraocular lens). Note the hypopion in the anterior chamber. The vitreous was also involved. Reproduced with kind permission from Dr. Rumelt

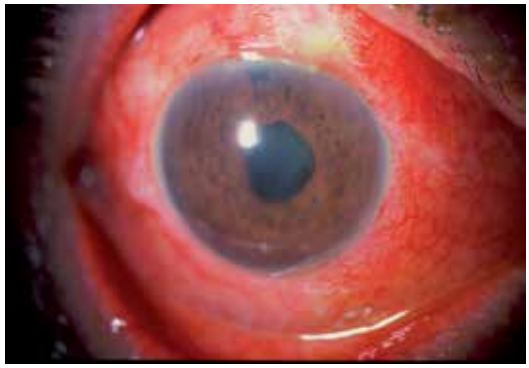

Fig. 2. Bleb-associated endophthalmitis due to *Streptococcus pneumoniae* in the right eye of a 63-year-old patient, 2 weeks after trabeculectomy. Note the whitening of the filtering bleb due to inflammatory infiltrate. There was also inflammation of the anterior and posterior segment. The earliest sign of endophthalmitis is infiltration of the bleb by inflammatory cells, and when the anterior and posterior segments are still normal, this is defined as "blebitis". Reproduced with kind permission from Dr. Rumelt

Preventative measures consist of prophylactic intracameral antibiotics or prophylactic subconjunctival antibiotic injection following cataract surgery (Kelkar et al., 2008). Patients with acute postoperative endophthalmitis generally present between 1 to 2 weeks following surgery. Endophthalmitis has also been reported to occur after intravitreal injection of anti-VEGF agents for the treatment of age-related macular degeneration (AMD). While the rate of endophthalmitis following intravitreal injection of these agents is equivalent to that of postoperative endophthalmitis following cataract surgery, approximately 0.16%, the increasing number of elderly patients requiring this type of therapy is a significant cause for alarm (Gragoudas et al., 2004).

Endophthalmitis must be distinguished from sterile inflammation following surgery. Diagnosis is established by visual acuity measurements, fundoscopy, and ERG, followed by microbiological evaluation of aqueous and vitreous samples (Lemley and Han, 2007). Gram-positive bacteria are the leading cause of postoperative endophthalmitis cases, with coagulase-negative staphylococcal (CNS) isolates being the most common, causing 47–70% of all postoperative endophthalmitis cases (Han et al., 1996). *S. aureus* account for approximately 10%, *Streptococcus* species for 9%, *Enterococcus* species for 2.2%, and Gram-negative bacteria for approximately 6% (Han et al., 1996). Fortunately, postoperative endophthalmitis caused by CNS is relatively mild and is more easily resolved with antibiotic and anti-inflammatory therapy (Josephberg, 2006). The visual prognosis is generally favorable, with 84% of cases resulting in at least 20/100 visual acuity, and 50% of these cases resulted in 20/40 visual acuity (Josephberg, 2006). Less virulent bacteria such as *Propionibacterium acnes* and CNS, and the fungal organism *Candida parapsilosis* are the most common causative agents of chronic endophthalmitis (Lemley and Han, 2007). Patients with this form of endophthalmitis typically present several months following surgery (Lemley and Han, 2007). Postoperative endophthalmitis caused by *S. aureus*, species of streptococci, enterococci, *Bacillus,* and Gram-negative bacteria can cause a more explosive and fulminant infection. The visual outcome of severe infections is uniformly poor, with only 30% of eyes attaining 20/100 visual acuity (Josephberg, 2006). The primary treatment is typically a single

intravitreal injection of antibiotics consisting of 1.0 mg vancomycin per 0.1 ml, and 2.25 mg ceftazidime per 0.1 ml or 400 µg amikacin per 0.1 ml. Fourth generation fluoroquinolones can also be employed because of their broad spectrum of activity and usefulness against Gram-negative bacteria. Vitrectomy and corticosteriod therapy are are often advocated as adjunct treatment modalities (Lemley and Han, 2007), however corticosteriod treatment is still considered controversial.

4. Posttraumatic endophthalmitis

Posttraumatic endophthalmitis is a complication of a penetrating injury to the eye and is not as frequent as postoperative endophthalmitis. However, the rate of infection is higher and the visual prognosis is poorer following penetrating injury to the globe than following surgical procedures. The infection rates following traumatic injury to the globe range from 3% to 17% (Meredith, 1999; O'Brien and Choi, 1995; Thompson et al., 1993). The rates increase substantially when a foreign body remains in the globe and range from 11 to 30% (Boldt et al., 1989; Brinton et al., 1984; Thompson et al., 1993). Other risk factors include age greater than 50 and a more than 24 hour delay prior to presentation (Thompson et al., 1993). Those patients who presented for intraocular foregin body removal greater than 24 hours following injury were approximately 4-fold more likely to acquire endophthalmitis (Thompson et al, 1993), highlighting the necessity of seeking immediate medical attention following penetrating injury. Staphylocci and *B. cereus* rank as the number one and two causes, respectively, and together account for 95% of cases (Das et al., 2005; Lemley and Han, 2007).

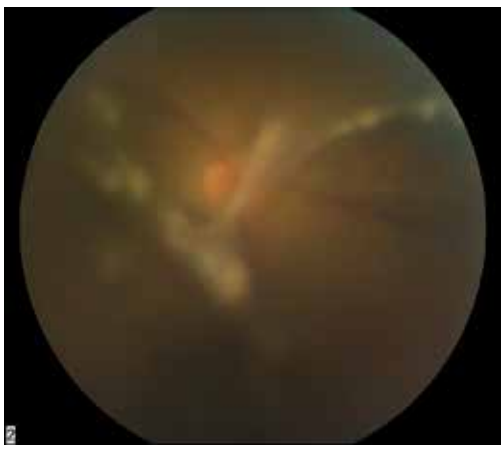

Fig. 3. Fundoscopic exam of a patient with *Staphylococcus aureus* endophthalmitis after a penetrating ocular injury. The findings of endophthalmitis in the vitreous may include not only flare and cells, but also fibrin in various degrees of organization. Organization to fibrotic bands may results in traction retinal detachment due to contraction of such bands. Reproduced with kind permission from Dr. Rumelt

B. cereus is ten times more likely to be the causative agent of posttraumatic than postoperative endophthalmitis, especially in cases involving organic or soil-contaminated

intraocular foreign bodies (Das et al., 2005). Other causative agents include CNS, streptococcal species, clostridial species, fungi, and protozoa such as acanthamoeba (Lemley and Han, 2007; Rumelt et al., 2001).

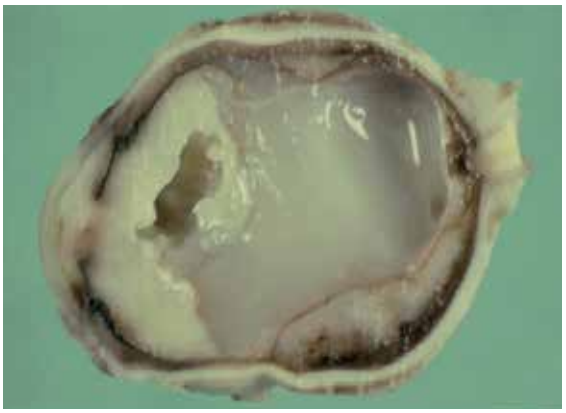

Fig. 4. Gross pathologic specimen of the globe affected by *Pseudomonas aeruginosa* endophthalmitis. The patient lost his vision in the eye and it became a blind, painful eye that underwent enucleation. Note the massive necrosis of the ocular tissues. Reproduced with kind permission from Dr. Rumelt

Fig. 5A. Endophthalmitis caused by the gas-forming bacterium *Clostridium bifermentans*. The endophthalmitis was caused following ocular penetrating injury be a soiled-contaminated foreign body. Note the brownish discoloration of the conjunctiva and a subconjunctival gas bubble. The patient was treated with intravenous and intravitreal panicillin and clyndamycin, but lost his vision despite the treatment. Reproduced with kind permission from Elsevier, Inc., in Rehany U, Dorenboim Y, Lefler E, Schirer E. Ophthalmology. 1994;101:839-42.

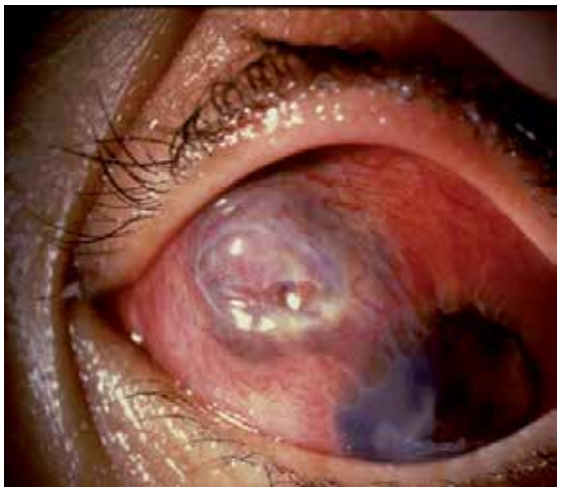

Fig. 5B. The same patient as in 5A a few days later. Note that the conjunctiva has become necrotic, the color became purple, and the gas bubble ruptured. Reproduced with kind permission from Elsevier, Inc., in Rehany U, Dorenboim Y, Lefler E, Schirer E. Ophthalmology. 1994;101:839-42.

When penetrating injury occurs, the foreign body should be removed as soon as possible, especially when the material is organic or soil contaminated due to the potential for *B. cereus* contamination (Lemley and Han, 2007). In some cases, for example where the foreign body is inert glass and is located in a sensitive position such as the retina, it may not be desirable to remove the object. Even relatively minor injuries to the eye can result in severe endophthalmitis with devastating outcomes. Cases have been described following penetrating injury to the eye due to orthodontic headgear (Blum-Hareuveni et al., 2006). Diagnosis of posttraumatic endophthalmitis is established by visual acuity tests, slit-lamp examination, and ophthalmoscopy, as well as computed tomography and ultrasound (Lemley and Han, 2007). For posttraumatic endopthalmitis, treatment consists of administration of intravitreal 1 mg vancomycin per 0.1 ml, 2.25 mg ceftazidime per 0.1 ml or 400 μg amikacin per 0.1 ml (Lemley and Han, 2007). Even with early therapy, the outcomes are often poor due to the potential virulence of the infecting bacterium and the explosive inflammatory response.

5. Experimental endophthalmitis and the roles of bacterial and host factors

A rabbit model of experimental endophthalmitis has been used to assess the contribution of both bacterial and host factors to the development of endophthalmitis. This model mimics the infection course after introduction of bacteria directly into the posterior segment of the eye that would occur following a surgical procedure or penetrating injury, but does not allow for the analysis of host immunological status and bacterial factors that contribute to the development of EE. This model system allows intravitreal injection across the pars plana of low inocula that allow the bacterium under study to adapt to the intraocular environment of the eye and replicate (Booth et al., 1995; Booth et al., 1997; Callegan et al., 1999a; Jett et al., 1992; Sanders et al., 2010; Sanders et al., 2011). Depending on the infecting organisms, infection symptoms in the rabbit model develop over a period ranging from 6 hours to 3

days, and a number of infection parameters can be repeatedly monitored and quantitative data obtained. Parameters that can be monitored include ocular inflammation, fibrin deposition, electrophysiologic measurement of retinal function, and bacterial growth and distribution. Infiltration of inflammatory cells can be quantified by slit lamp biomicroscopy in which progressive inflammation is scored in different anatomical locations within the eye (Callegan et al., 1999a). Inflammation and fibrin deposition can be qualitatively assessed by analysis of thin-section histopathology. Retinal damage as a result of the production of toxin by the bacterium under study or by bystander damage due to PMN activity in the eye can be measured by electroretinography (ERG). Using the rabbit model, Callegan et al. (1999a) found that supernatants from from *B. cereus* and *S. aureus* caused retinal damage and were highly inflammogenic, suggesting that secreted toxins are of primary importance to the pathogenesis of endophthalmitis. Callegan and colleagues did not find individual roles for the *B. cereus* membrane damaging toxins hemolysin BL, phosphatidylinositol-specific phopholipase C, and phosphatidylcholine-specific phospholipase C in this model, however, other toxins controlled by the global regulator *plcR* were found to contribute to pathogenesis of experimental *B. cereus* endophthalmitis (Callegan et al., 1999b; Callegan et al., 2002a; Callegan et al., 2003). The *S. aureus* alpha- and beta-toxins, but not the gamma-toxin, were shown to make an important contribution to endophthalmitis (Booth et al., 1998; Callegan et al., 2002b). Isogenic mutants deficient in each of the toxin-encoding genes were compared in this model. Injection of rabbit eyes with the gamma-toxin deficient mutant had no impact on retinal function when compared with the wildtype strain. However, the alpha- and beta-toxin deficient mutants were attenuated when compared with the wildtype. After 2 days, rabbit eyes infected with the alpha- or beta-toxin deficient mutant showed 40% and 60% retinal function retained, respectively, as compared with 20% retained in rabbits infected with the wildtype strain. Moreover, a cumulative effect was observed as a result of inactivation of all three toxin loci on retention of retinal function (Callegan et al., 2002b). This model has also been used as a sensitive measure of the contribution of enterococcal virulence factors to pathogenesis. Jett et al. (1992) demonstrated that the course and severity of disease was significantly determined by the *E. faecalis* biocomponent cytolysin. The cytolysin destroyed the neural tissue of the retina and its architecture over a period of 24 – 72 hours. The toxicity to retinal tissue was not attenuated by either antibiotic and/or anti-inflammatory therapy when infection involved a cytolytic strain, although an isogenic, non-cytolytic infection completely resolved when both of these treatments were provided 24 h postinfection. These studies showed not only the contribution of the cytolysin to the pathogenesis of enterococcal endophthalmitis, but also the importance of inflammatory sequelae. Engelbert et al. (2004) demonstrated that the *E. faecalis* gelatinase and serine protease in concert contributed to pathogenesis in this model as double mutants in these genes were significantly attenuated when compared to the single mutants. Callegan et al. (1999a) also utilized this model to implicate the contribution of bacterial cell wall components in inciting an inflammatory response during endophthalmitis. Injection of metabolically inactive bacteria or cell wall sacculi elicited significant intraocular inflammation. The rabbit model has also been used to implicate the *Streptococcus pneumoniae* capsule in the pathogenesis of endopthalmitis (Sanders et al., 2011). Infection with an isogenic unencapsulated *S. pneumoniae* mutant strain resulted in significantly lower slit lamp examination scores, significantly greater retinal function, and significantly less neutrophil infiltration into the eye compared with the wildtype parental strain in this model. Moreover, they demonstrated the efficacy of immunizing with the *S. pneumoniae* pneumolysin in

protecting the eye from retinal damage during *S. pneumoniae* endophthalmitis (Sanders et al., 2010). In summary, the rabbit model of experimental endophthalmitis has proven invaluable in assessing the role of bacterial virulence factors and identifiying potentially new therapeutic targets.

More recently, a mouse model of experimentally induced endophthalmitis has been employed to explore various aspects of disease development, course, and outcome. As with the rabbit model, infection parameters can be qualitatively and quantitatively measured including bacterial growth, ocular inflammation, and retinal function. Ocular inflammation can be qualitatively assessed via thin-section histopathology as well as quantified by slit-lamp biomicrosopy and indirect measurements of PMN influx by a myeloperoxidase ELISA (Ramadan et al., 2006). As stated earlier, Wiskur et al. (2008) implicated the HMV phenotype in the persistence of *K. pneumoniae* in the eye by comparing the bacterial growth of an HMV+ to that of an HMV- strain after intravitreal injection of 100 CFU. The HMV- strain did not grow to the same level as the HMV+ strain and were cleared with 27 hours. HMV+ infected eyes underwent phthisis within 24 hours. This study provided evidence that the HMV phenotype makes an important contribution to *K. pneumoniae* endophthalmitis pathogenesis. As discussed above, Hunt et al. (2011) confirmed these findings using a *magA*-mutant of *K. pneumoniae* in the mouse endophthalmitis model. *S. aureus* cell wall teichoic acids have also been shown to contribute to the pathogenesis of endophthalmitis and that inhibitors of cell wall teichoic acid synthesis might serve as candidates for therapy of *S. aureus* endophthalmitis in this model (Suzuki et al., 2011).

An important aspect of the murine model of experimental endophthalmitis is that factors of the host immune system can be assessed by comparison of the infection course in genetic knockout mouse strains with that in wildtype strains of the same genetic background. Ramadan and colleagues (2006) showed that as early as 4 hours post-injection with *B. cereus*, significant decline in retinal function and PMN infiltration were observed, which coincided with an increase in the proinflammatory cytokine TNF-α. In TNF-α knockout mice, *B. cereus* replicated more rapidly, retinal function declined more sharply, and fewer PMN infiltrated the eye. These findings illustrate the power of this model in allowing the repeated measurement of multiple infection parameters and showed that damage to the retina occurred earlier than was previously thought. Furthermore, the necessity of TNF-α in PMN recruitment and control of *B. cereus* replication was established. Engelbert and Gilmore (2005) used C3 and FasL knockout out mice to dissect components of the innate immune and ocular immune privilege systems in controlling *S. aureus* endophthalmitis. The infection course in C3 knockout eyes followed a similar course to their wildtype counterparts, suggesting that complement does not play a significant role in ocular defense against *S. aureus* infection. On the other hand, the membrane-bound Fas ligand (FasL), which functions to maintain the immune privilege status of the eye by inducing apoptosis in infiltrating inflammatory cells, was found to be criticial in bacterial clearance. Mice deficient in FasL were unable to control *S. aureus* infection after injection of an inoculum that is cleared in wildtype mice (Engelbert and Gilmore, 2005). The host heat shock protein alphaB-crystallin was shown to be upregulated in the retina and prevent apoptosis and retinal damage during murine *S. aureus* endopthalmitis (Whiston et al., 2008). These authors found that mice deficient in the production of this molecular chaperone displayed increased retinal apoptosis and damage, and that *S. aureus* produced a protease capable of cleaving this

protective protein. Finally, Kumar et al. (2010) suggested that the host toll-like receptor (TLR) 2 is involved in controlling infection by *S. aureus* in this model by showing that pretreatment of mice with intravitreal injections of the TLR2 ligand Pam3Cys reduced bacterial load when compared with mock-injected animals. In summary, the murine model of experimental endopthalmitis has proven to be invaluable in analyzing both host and bacterial factors that contribute to this disease. The growing number of available genetic knockouts in components of the innate and adaptive immune systems and the relative ease of use will continue to make the murine model key to understanding the complex interplay between host and bacterial factors during the initiation, course, and resolution of endophthalmitis.

6. Conclusions

Endophthalmitis remains a relatively rare infection, but the potential for vision loss and/or blindness is significant. The potential for poor prognosis, which depends on the causative organism and the immune status of the patient, remains high despite antibiotic and surgical intervention. Research on the contribution of bacterial virulence factors has implicated both secreted toxins and proteases, capsules, and the intraocular host response to bacterial cell wall components in the pathogenesis of experimental *B. cereus, S. aureus, E. faecalis, S. pneumoniae,* and *K. pneumoniae* endophthalmitis. Moreover, components of the host inflammatory response and mediators of ocular immune privilege have been shown to play critical roles in controlling experimental *B. cereus* and *S. aureus* endophthalmitis. Virtually nothing is known about the contribution of bacterial or host virulence factors to the development of EE. The fact that visual prognosis of EE and other types of bacterial endophthalmitis caused by pathogenic organisms remains uniformly poor highlights the need for continuing research on the interactions between the offending pathogen, the internal structures of the eye, underlying disease state and the immune response.

Retinal Detachment – An Update of the Disease and Its Epidemiology – A Discussion Based on Research and Clinical Experience at the Prince Charles Eye Unit, Windsor, England

Irina Gout, Faye Mellington, Vikas Tah,
Mahmoud Sarhan, Sofia Rokerya, Michael Goldacre and Ahmed El-Amir
Oxford University
England

1. Introduction

Retinal detachment is a potentially blinding condition. It is caused by separation of neurosensory retina from the underlying retinal pigment epithelium. Despite treatment advances, functional results remain poor (with only 42% achieving 6/12 vision and only 28% if the macula is involved). There are three distinct types of retinal detachment: rhegmatogenous (RRD), tractional and exudative. For the purpose of this chapter we will focus on RRD.

RRD demonstrates wide geographical variation with incidence reported between 6.3 and 17.9 per 100, 000[1] with 7300 new cases estimated annually in the UK[29]. Risk factors include myopia, increasing age and certain vitreoretinal conditions. Horseshoe tears, giant tears and round holes have been shown the most common along with lattice degeneration[7].

Vitreoretinal traction is responsible for most RRD. As the vitreous becomes syneretic (liquefied) with age, a posterior vitreous detachment (PVD) occurs. In most cases, the vitreous separates from the retina without any sequelae. However, in certain eyes, strong vitreoretinal adhesions are present and the occurrence of a PVD can lead to a retinal tear; then, fluid from the liquefied vitreous can enter the sub-retinal space through the tear, leading to a retinal detachment.

Several studies have investigated the epidemiology and risk factors associated with RRD. These differ in their methodology making comparison of data difficult [1,2,4,6,11,29]. RRD incidence varies with ethnicity and is strongly associated with increasing age, myopia and certain vitreoretinal degenerations including lattice degeneration and round holes. Abnormal vitreoretinal adhesions, which may be visible or invisible, are present in many eyes. Among the visible ones are lattice degeneration and cystic retinal tufts. When a PVD occurs and encounters such an area, a retinal tear may form. Due to changes in cataract surgery trends, the proportion of pseudophakic retinal detachment presenting to specialised

centres appears to be increasing. The incidence is lower in phacoemulsification than extra and intracapsular cataract extraction.

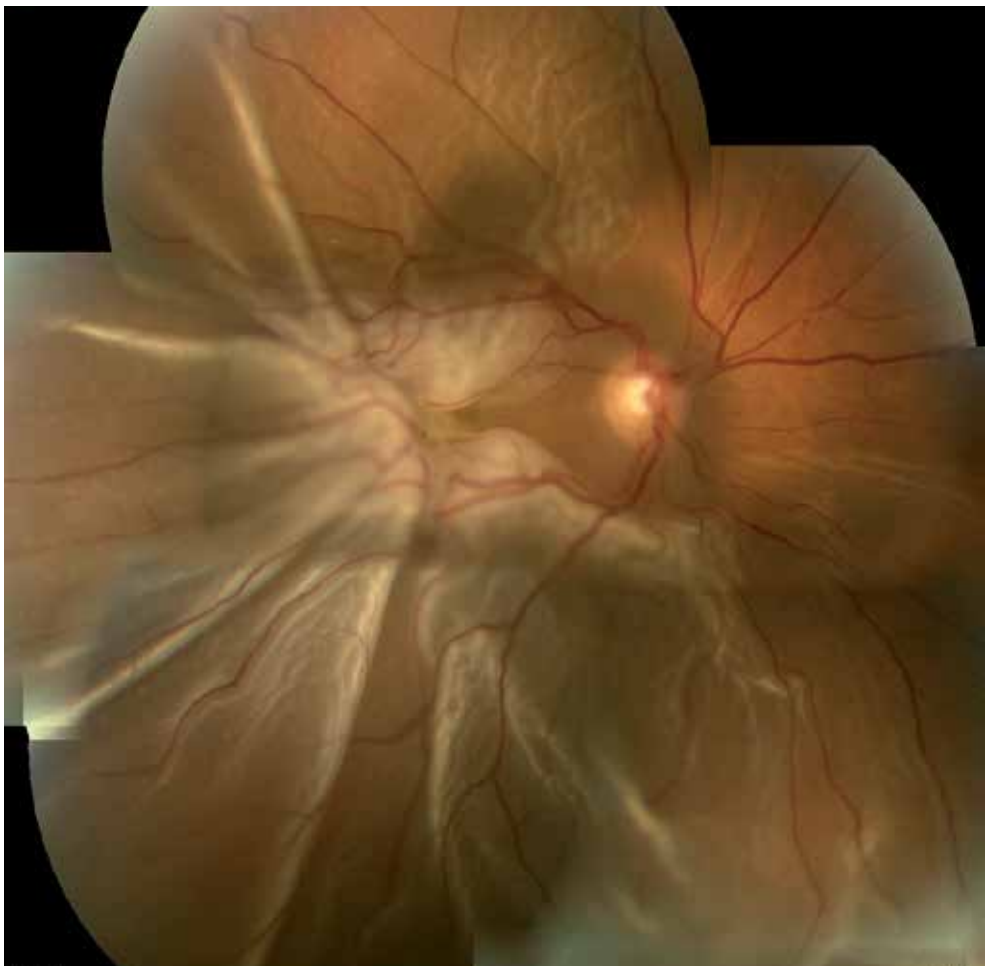

Fig. 1. Retinal detachment

Obtaining an accurate estimate of rhegmatogenous retinal detachment incidence in England and associated risk factors is essential in understanding the healthcare burden related to this disorder. We investigated the epidemiology of rhegmatogenous retinal detachment and associated clinical features by analysing routinely collected hospital statistics for England, using the Hospital In-patient Enquiry (HIPE) and Hospital Episode Statistics (HES) from 1968 to 2004, and for the Oxford National Health Service Region using the Oxford Record Linkage Study (ORLS) from 1963 to 2004. A literature review is also presented.

Fig. 2. Retinal break

2. Methods

At the start date for our national analysis, 1968, national hospital statistics for England were collected as the HIPE. This system ceased in 1985 and was replaced, though not until 1989 by HES. Both HIPE and HES are statistical databases of demographic, medical and administrative information about each episode of hospital care. HES include data on all ''day cases'' or office procedures, as well as patients admitted for overnight stay, whereas the HIPE did not include day cases.. The Oxford Record Linkage Study (ORLS) was also used for all patients treated in the Oxford Regional Health Authority area.

The International Classification for Disease (ICD) by the World Health Organisation was used to identify rhegmatogenous retinal detachment. The codes included ICD-7 (1955) code 386, ICD-8 (1965) code 376, ICD-9 (1977) codes 361.0, 361.1, 361.8 and 361.9, ICD-10 (1992) codes H33.0, H33.2, H33.4 and H33.5.

National HES for England were analysed to produce a geographical profile of hospital admission for retinal detachment by the Local Authority (LA) between 1998 and 2005. The data were used to construct a map showing the person-based admission rate per 100 000 resident population for each LA, expressed as an average annual rate. The LAs were arranged into quintiles: the fifth of LAs with the lowest rates are shown with the lightest colour, and the fifth of LAs with the highest rates are shown with the darkest colour.

The association with affluence was studied using the Index of Multiple Deprivation score for 1998-2005 (n= 57,949) as a measure of deprivation levels. The study population was split into quintiles from least deprived to the most deprived. Standardised admission ratios and 95% confidence intervals were calculated to evaluate statistical significance. Seasonal

variation by monthly analysis was studied for detachment surgery from 1989-2006 (n=169,417).

The datasets were anonymised; approval to analyse them in a programme of research undertaken by the Unit and affiliated University, was obtained through the NHS Central Office for Research Ethics Committees (reference 04/Q2006/176).

3. Incidence

The English National and ORLS admission rates for retinal detachment surgery were just over 10 episodes per 100 000 population in the late 1960s. They rose nationally steadily, but gradually, to around 22 episodes per 100 000 population by 2004.

The ORLS data show rates based on the number of people admitted to hospital for retinal detachment surgery as well as the number of episodes of care for surgery (episodes of separate admission or transfers within an admission, or both). The scale of multiple admissions per person was small, although an increase in multiple recording is evident in recent years as seen in the recent divergence between the rates for episodes and people (figure 3). The figure confirms that the increase in hospital episodes in the 1990s represents an increase in the number of people treated (all RRD admissions were operated). It also shows more accurately than the English figures (which omit data for 1986–8) that the start of rapid increase in surgery was about 1989–90.

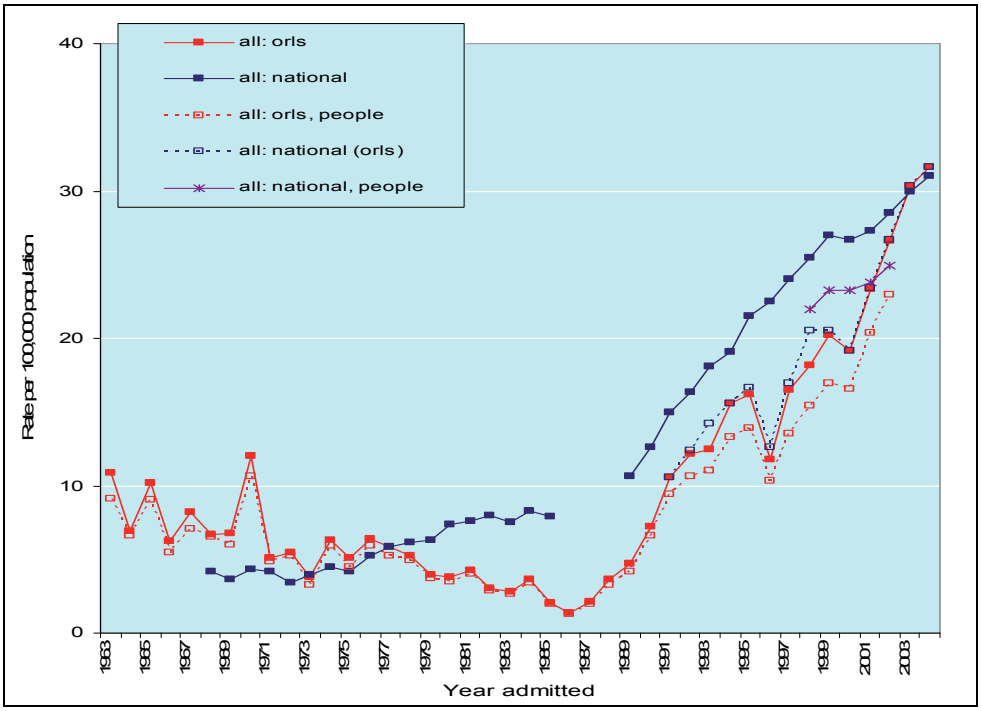

Fig. 3. Hospital admission rates 1963-2004 for Retinal surgery for ORLS and National data measured as episodes and people per year, male and female, all ages, all sources of admission, any mention

The reported annual incidence of rhegamatogenous retinal detachment in other studies around the world varies from 4-17.9 per 100 000 population [1,2,4,8,10,12,13,32,38]. Studies with small sample size, potential for sampling error and varied methodologies underlie these different results.

4. Geographic variation

The people rate for the national data is at its peak at 16 per 100,000 in 2004. There is a suggestion that the rate has reached its peak as the rate fluctuated between15-16 per 100,000 from 1998 to 2004. The people rate for the Oxford data continues to show a rise to 20 per 100,000 in 2004. This can be explained by the fact that Oxford remains a tertiary referral centre for retinal detachment and serves patients from outside the region and so the service throughput may not represent the local population. Bilaterality was not investigated but most series support a bilateral rate of retinal detachment of between 5-15%.

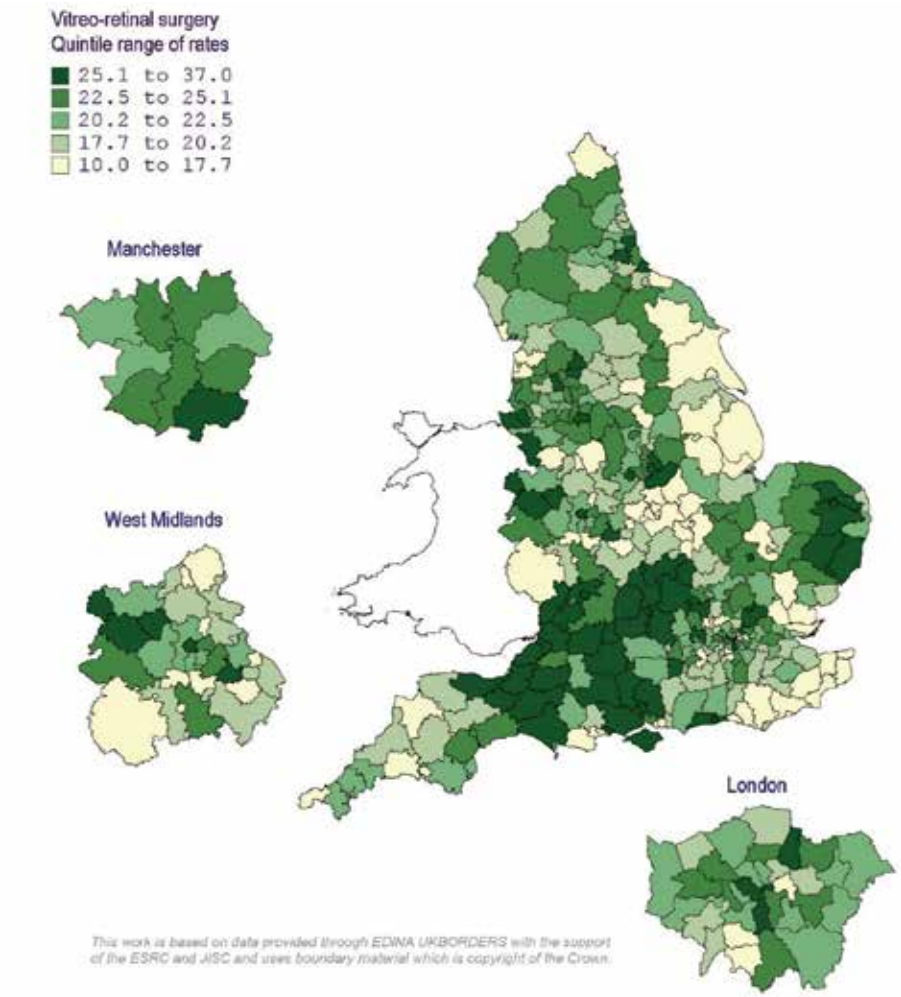

Fig. 4. Vitreo-retinal surgery: males and females indirectly standardised rate per 100 000: each local authority in England any mention of operation: 1998/99 to 2004/05

Figure 4 shows a geographical profile of the annual rate of retinal detachment surgery by LA. LAs showed a wide variation in rates of retinal detachment surgery, ranging from 7 to 23 people per 100 000 population. This reflects the relative infancy of retinal surgery service provision in comparison to cataract surgery for example and highlights the need for more service provision for patients in England.

5. Age distribution

The prevalence of PVD increases with age; occurring in 11% of 60-69 year olds, 46% of 80-89 year olds and occurring earlier in myopes. The highest incidence rate of detachment was found in the 70-74 age group with rates of 60 per 100,000. The incidence rate in under 20 year old females was the lowest noted; <3 per 100,000. The bimodal distribution with a secondary peak in younger ages (24-30 years) reflects the highly myopic group.

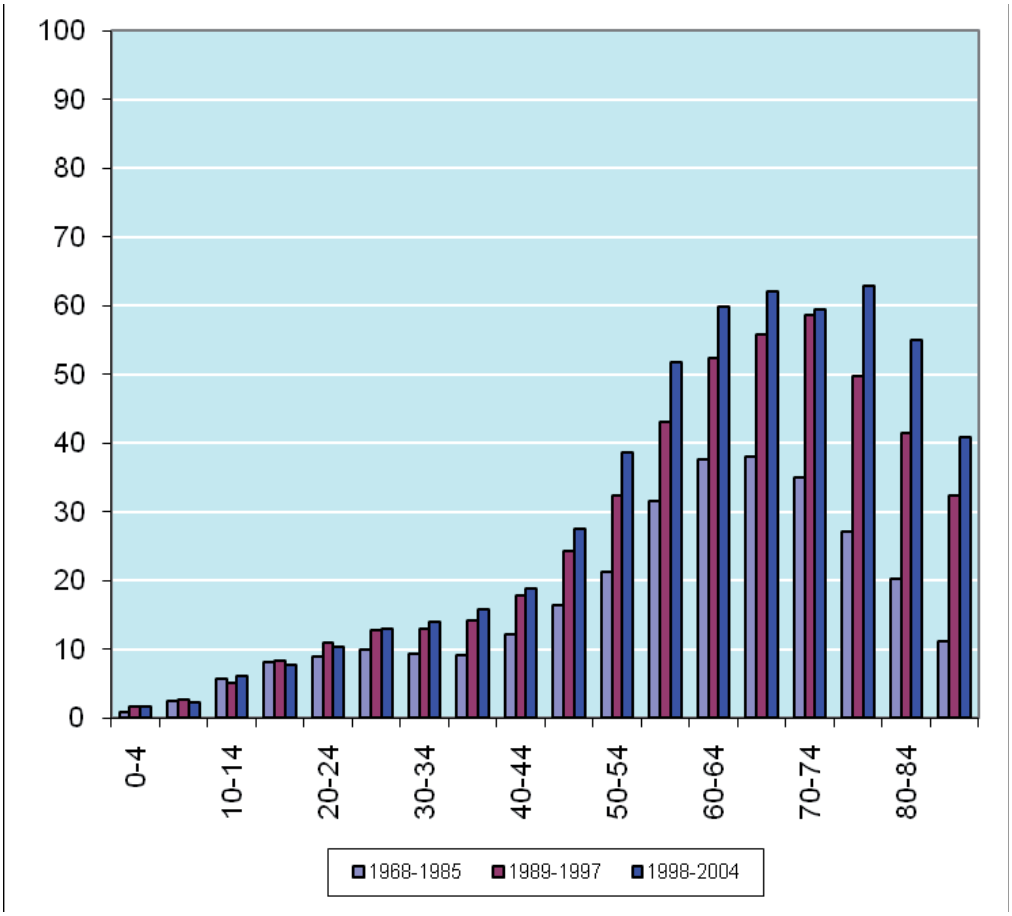

Fig. 5. Admission rates for retinal detachment per 100,000 population: all sources, males, National data

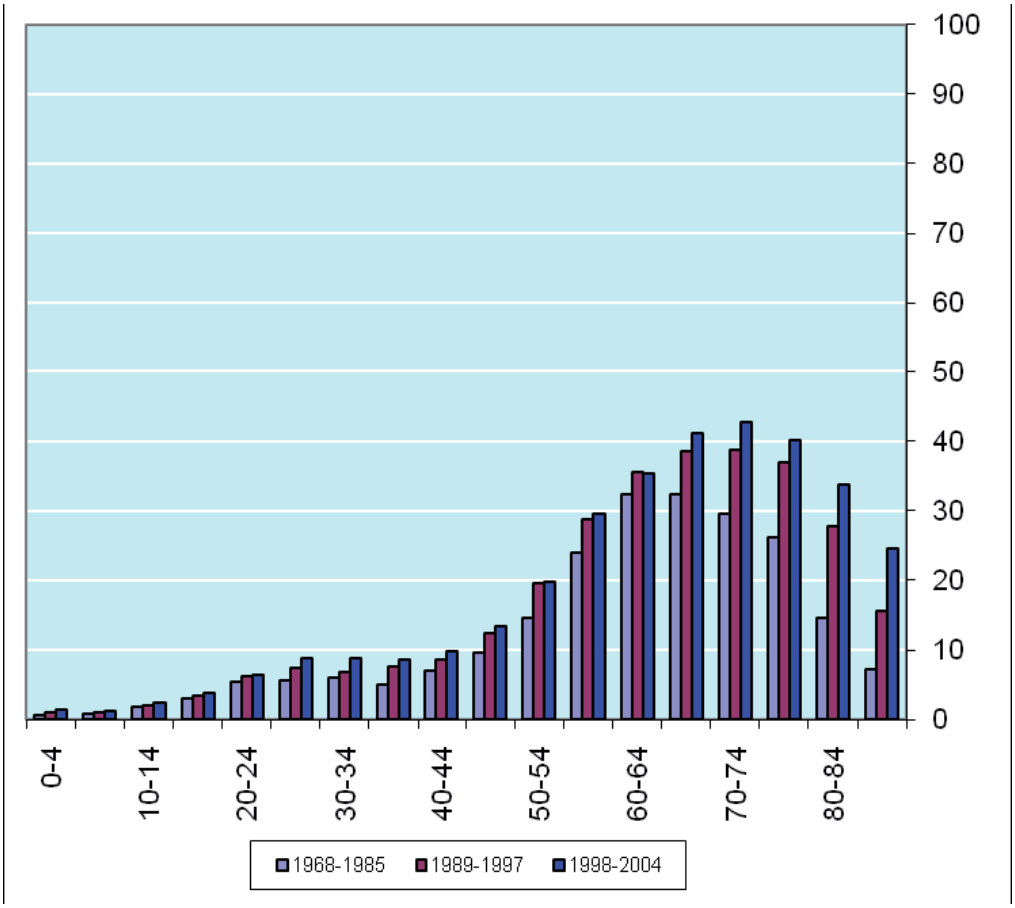

Fig. 6. Admission rates for retinal detachment per 100,000 population: all sources, females, National data

6. Gender

Figures 5 and 6 presents national and ORLS admission rates for retinal detachment surgery analysed by age and sex, and over three time periods (1968–1985, 1989–1997 and 1998–2004) for men and women separately. Three contrasting time periods were selected: one relatively long historical period, when rises in rates were fairly modest, and two more recent periods, when rises were more evident. Over these time periods, the rate of retinal detachment surgery shows a bi-modal distribution with peaks at the 24-30 and 70-74 age groups for both men and women. There was a 6 times higher risk in the 70-74 age group for both males and females. The rate of retinal detachment surgery for all age groups shows a 1.5 times male preponderance.

While some reports indicate a sex distribution corresponding with that of the general population, most indicate a male preponderance[2-6]. This may be related to an inherent gender risk, though an increased rate of ocular trauma may be contributory. Furthermore, the higher proportion of myopia in young males may partly explain this.

In a prospective study which involved 1130 cases of RRD in Scotland over a 2-year period from 2007-2009, Mitry *et al*., reported that PVD -associated RRD showed a male preponderance of 61.7% male vs. 38.2% female (P<0.001). Notably, 1 in 10 cases were associated with a recent history of ocular or head trauma.[7] The underlying sex distribution could not account for this gender discrepancy but higher rates of traumatic RRD or an inherent increased risk in men may be influential.[8]

Exclusion of traumatic retinal detachments from analysis may negate or even reverse gender differences in RRD incidence. The Beijing Rhegmatogenous Retinal Detachment Study Group prospectively reviewed 528 patients diagnosed with RRD from October 1999-September 2000. It reported a greater incidence of RRD in males (8.98/100000 population; 95% CI 8.07 – 10.13 in males, and 6.78/100000 population; 95% CI 5.97 – 7.76 in females). However, on subgroup analysis, although there was a greater incidence of traumatic RRD in males, there was no significant difference between males and females in nontraumatic, phakic, aphakic and pseudophakic retinal detachments.[11] A Swedish retrospective study of 590 cases of RRD over a 10-year period from 1971 to 1981 reported a higher incidence of non-traumatic RRD in females.[12] However in another large retrospective case-control study (1032 cases from 1995 to 2001), the male predominance persisted even after excluding trauma-related RRD, with a reported 2.15 odds ratio for male gender.[13]

The sex difference, that is a higher incidence of RRD in men, also appears to apply to retinal detachment incidence after cataract surgery. A small retrospective study from Olmstead County, Minnesota, found that men were 2.9 times more likely to have a retinal detachment after cataract surgery than women (P<0.001; 95%CI 1,8-4.4).[14]

Other possible explanations include increased myopia and axial length in men, as well as gender differences in the anatomy of the vitreoretinal base. [15, 16] Myopia is a well-known risk factor for retinal detachment and an increase in axial length is significantly associated with an increased risk of RRD.[17-19] Axial length is related to height and men tend to be taller than women.[20] Anatomical differences in the vitreoretinal base (with males having larger eyes hence longer vitreous chambers as described in 1912 by Salzmann's Anatomy and Histology of the Human Eyeball) can be in the form of greater migration of the posterior vitreous base towards the retina in males as reported by Wang et al, in their study of donor eyes.[21] This may predispose males to retinal breaks after PVD, either from greater dynamic vitreoretinal traction and/or an increase in vitreoretinal irregularities of the posterior border.

7. Cataract extraction and other ophthalmic operations

Cataract operation is the most common ophthalmic surgical procedure worldwide. Even with the best technique and in healthy eyes this procedure is associated with an increased risk of retinal detachment. There is a higher rate of PVD after cataract extraction and a lower hyaluronic acid concentration causing vitreous collapse **5**. Increased rates of cataract surgery (phacoemulsification, internal and external capsular cataract extraction) and higher life expectancy may also contribute to retinal detachment. The cumulated six year risk of detachment after cataract surgery is increased by a factor of 6 to 8, increasing linearly for 20 years[22].

The risk is increased if there are complications during cataract surgery. There is a statistically significant higher incidence of RRD after posterior capsule rupture and anterior vitrectomy than after uncomplicated phacoemulsification, 16% versus 0.75% according to one study[23].The estimated risk of retinal detachment after cataract surgery is 5 to 16 per 1000 uncomplicated cataract operations[24].The risk may be much higher in those who are highly myopic, with a frequency of 7% reported in one study[25].Young age at cataract removal further increased risk in this study. A vitreo-retinal centre in London analysed cases of rhegmatogenous retinal detachment in 1980 and again in 1999 finding that pseudophakia rose from 0.8% to 24%. This may explain the steady rise in retinal detachment we found as shown in figure 7 in England over the last 4 decades. Most series report that about 50% of RRD occur during the first year following cataract surgery. Long term risk of retinal detachment after extracapsular and phacoemulsification cataract surgery at 2, 5, and 10 years was estimated in one study to be 0.36%, 0.77%, and 1.29%, respectively[26].

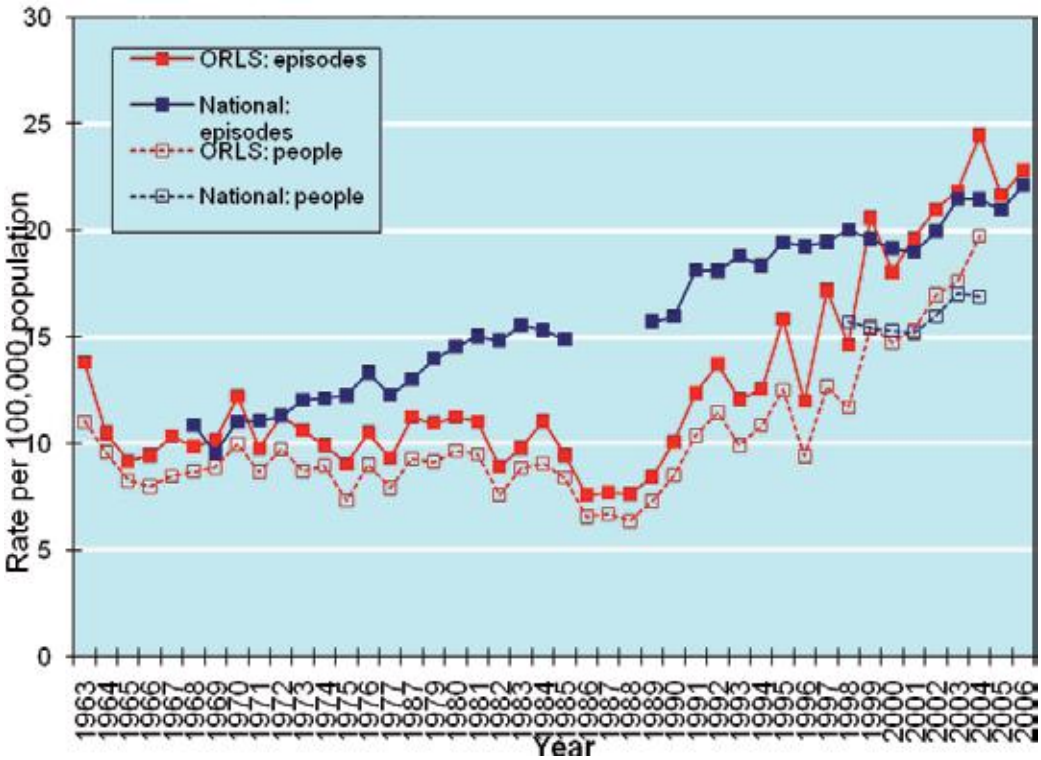

Fig. 7. Hospital admission rates (per 100,000 population) for retinal detachment: National & ORLS data 1963-2004(06) measured as episodes and people per year, all ages, males and females, all sources, any mention

The exact mechanism contributing to retinal detachment related to cataract surgery is not fully known, however several hypothesis have been postulated. It is well known that

cataract extraction alters the physiology of the eye. Removal of a larger cataractous lens in aphakia or its replacement with a smaller lens implant in pseudophakia is responsible for the anterior shift of the iris lens diaphragm resulting in a relative increase in volume of the vitreous cavity. The removal of the lens and its anterior capsule also disturbs the diffusion barriers and results in a more liquefied vitreous with a reduced hyaluronic acid content . This is associated with a higher rate of PVD. Direct evidence between cataract surgery and PVD comes from a recently published study from New Zealand [33]. The study showed that among 149 patients aged 50 to 60 years who underwent unilateral cataract surgery, the incidence of PVD after five years was 51 per cent in the treated eyes, compared to only 21 per cent in their unoperated fellow eyes. Other possible mechanisms leading to a retinal detachment have been implicated to be the inflammatory vitreoretinal adhesions and retinal breaks caused by surgical trauma.

ND:Yag capsulotomy following cataract operation carries a potential to induce PVD, and thereby cause a retinal detachment [23]. The risk factors include myopia, lattice degeneration and retinal detachment in the fellow eye. No relationship has been established between energy application and incidence of retinal detachment. According to one study the incidence of RD following Nd:YAG laser capsulotomy was 0.82% , with a mean time of 32 months between cataract surgery and capsulotomy and 13.5 months between capsulotomy and RD.[23]

The incidence of retinal detachment following penetrating keratoplasty is variable, dependent on whether the eye is phakic or pseuphakic or whether the procedure has involved vitreous manipulation. Several series report 2.4-6.8% of cases with RRD[28]

Intravitreal injections have entered the therapeutic arena recently and remain a potential threat to causation of a rhegmatogenous retinal detachment. Iaterogenic retinal tears and rips due to misdirected needles can cause retinal detachment, however most studies have documented that this risk is low. A consecutive, interventional, multicenter case series measured the incidence of RD in patients receiving intravitreal anti-vascular endothelial growth factor. During 36 consecutive months the incidence rate of RRD was 0.013% (5/35 942) (1 per 7188 injections)[29] .

8. Affluence

Socio-economic deprivation plays a major role in health and disease, but its role in retinal detachment in England has not been studied. Figure 8 shows the study population being split by Index of Multiple Deprivation (IMD) scores into quintiles from the least deprived (group 1) to the most deprived (group 5). As shown by the standardised admission ratio (with lower and upper 95% CIs) there is a gradient with deprivation score showing a significant relationship, though not strong, between affluence (least deprived) and retinal detachment surgery. There's about a 10% difference between the least deprived quintile and the most deprived (n= 57,949).

The Scottish Retinal Detachment Study Group, based on 12 months prospective research between 1 November 2007 and 31 October 2008, assessed 572 patients diagnosed with primary retinal detachment[29]. They came to the conclusion that retinal detachment is twice as common among the more affluent than those living in areas of deprivation. This might be as those in poorer areas may present later if at all to medical services and the more affluent tend to have greater myopic prevalence.

IMD Group	Index of Multiple Deprivation Score	No. of LA's	Observed	Expected	o/e	SAR	Confidence Interval (Lower)	Confidence Interval (Upper)
1 Least Deprived	8,26	71	9924	9150,1	1,09	108,5	106,3	110,6
2	12,69	70	9867	9615,1	1,02	102,0	100,0	104,0
3	17,13	70	9585	9793,4	0,98	97,9	95,9	99,9
4	22,92	70	11701	11903,7	0,98	98,3	96,5	100,1
5 Most Deprived	33,35	71	16932	17486,6	0,97	96,8	95,4	98,3
Total			57949	57949,0		100,0		

Fig. 8.

High myopia is one of the risk factors in patients with retinal detachment. It was documented that there is an association of short sightedness with intelligence quotient (IQ) and thus higher income and socio-economic status[31,32]. Saw et al. report the association between retinal detachment and educational achievement in a study of 1204 school children aged 10 to 12 in Singapore. Using the nonverbal Raven Standard Progressive Matrix test Intelligence Quotient they concluded that non-verbal IQ is a strong risk factor for myopia[32]. Higher prevalence of myopia in the most affluent quartile could explain the increased incidence in this group.

However, we cannot exclude the possibility that affluence is associated with some other, hitherto undefined, risk factor such as genetic factors. The latest evaluation by the Scottish Retinal Detachment Study Group investigated the influence of genetic predilection on primary RRD in 2011. They show a doubled risk of the condition in those having an affected sibling[33]. Whilst ethnicity could not be studied we know that the incidence of retinal detachment is lower in Asians and in Blacks[34].

As the risk of retinal detachment has direct connection with the most affluent group of population, there are implications for service planning, as there is likely to be a greater need for vitreoretinal services in wealthier areas.

9. Seasonality

Seasonal variation in RRD incidence has been widely reported. Most studies describe a summer peak and winter trough; others vice versa and some no seasonal variation at all[35-39]. This is likely attributed to increased sun exposure and outdoor activities in summer[36].

Figure 9 shows that the rate of retinal detachment surgery is higher in summer peaking in July with the lowest rates being in January-February. This pattern is most striking in males under

40 in whom there is relatively lower presentation in winter (lower incidence in December-February). The association with season was statistically significant at the level of p=0.01.

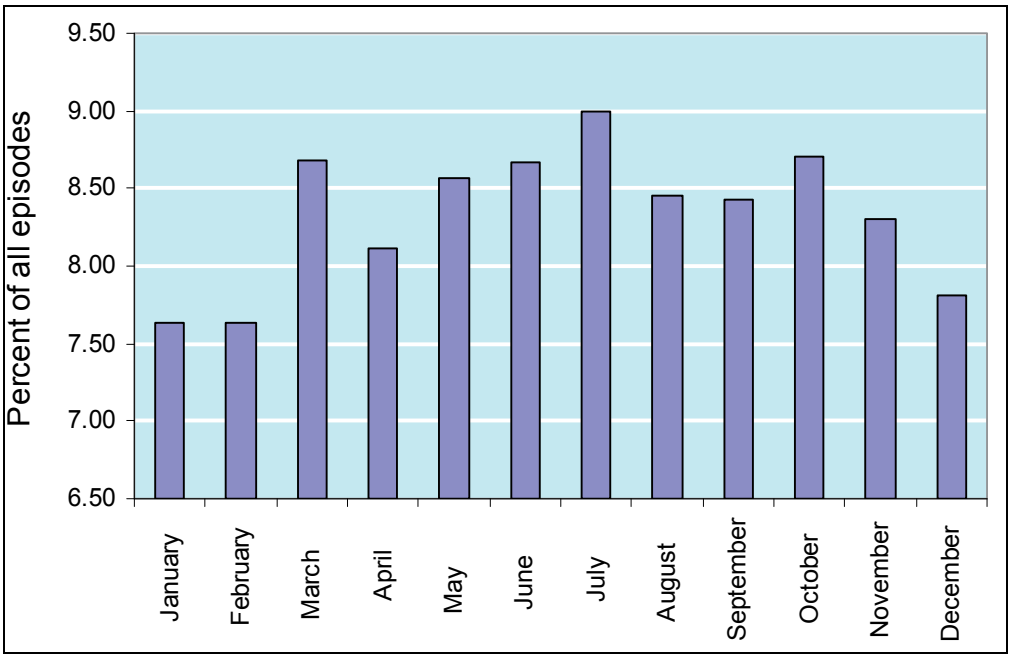

Fig. 9. Retinal detachment: monthly percentages of all FCEs, National data, male and females, any mention 1989-2006

We found a statistically significant summer peak and winter trough at the level of p=0.01 (n=115,450). The effect of light and temperature on the vitreous has been implicated. This study showed that the seasonal variation was most striking in younger males suggesting another association other than the season itself. Could this subgroup of patient be more active during the summer months and be more likely to experience trauma and PVD formation?

In a large retrospective review of 2314 patients with primary RRD in Germany, Thelen *et al*. (1997) reported a significant mid-summer peak incidence (n in July = 228) and winter trough (mean n December to January = 161) with a difference of 36% between the two periods. They noted a close correlation between seasonal incidence of RRD and seasonal incidence of light hours per day and considered a potential role of light-induced changes on vitreoretinal adhesion.[35]

Mansour *et al.* (2009) retrospectively reviewed the charts of 211 patients undergoing idiopathic RRD repair in one referral centre in Lebanon over a 13-year period. They reported a significant ($P<0.05$) increase in RRD in spring and summer compared to autumn and winter (56% vs. 44%). Interestingly, there was a significantly younger age of onset of RRD in the warmer months (47 vs. 54, $P= 0.007$).[36]

In contrast, a retrospective evaluation of RRD in Kuwait from 1981 to 1987 reported a peak incidence in winter (with the highest level in November) and a trough in the summer months.[38] These findings have not been replicated elsewhere.

Studies reporting no apparent seasonal variation in RRD incidence include the large prospective population-based study by the Beijing Rhegmatogenous Retinal Detachment Study Group. There were no seasonal differences in incidence even after further classification of retinal detachments into blunt traumatic, aphakic and pseudophakic and non-traumatic phakic.[39]

Possible explanations for seasonal variation in RRD incidence include: variations in light and temperature affecting vitreous structure, and increased outdoor activity and consequent trauma during periods of longer daylight hours and warmer weather [35].

Posterior vitreous detachment (PVD) is widely accepted as a contributory factor in RRD. Mitry *et al.* (2011) found that more than 85% of RRDs are associated with PVD and associated tractional retinal tears.[40] The influence of climatic variables namely seasonality, air temperature, solar radiation and humidity on PVD rates was elegantly evaluated by Rahman *et al.* (2002).[41] They retrospectively reviewed 567 patient records diagnostically coded as PVD in the Oxford Eye Casualty over a 2-year period. They excluded cases with a precipitating cause for PVD such as blunt trauma, retinal vascular disease and diabetes, and looked for a correlation between ambient temperatures, humidity and solar radiance and PVD incidence. Interestingly, they found no statistically significant difference in the total numbers of new patients attending the Eye casualty over the summer months compared to winter (912 from April to September vs. 839 October to March). They did however note a strong association (P= 0.035) between weekly average air temperatures and PVD incidence. Air temperatures of the previous week also correlated positively with PVD incidence (P = 0.028). The higher the average air temperature the higher the weekly rate of PVD. As such, increased physical activity and dehydration associated with higher ambient temperatures may alter vitreous structure and thereby increase the incidence of PVD and, in turn, RRD. Further investigation into the role of increased temperature on the biochemical structure of the vitreous and retinal detachment rates is needed.

10. Conclusion

The data on overall incidence of RRD worldwide has been inconsistent. The incidence varies with the population studied and is limited by study design and inclusion criteria. Few recent estimates of incidence have used large samples sizes. These studies show national data and provides longitudinal information, a more inclusive estimate of incidence and its' variation over time.

The highest annual incidence of RRD in England is in the 70-74 year age group with a secondary peak in young myopes and a higher overall incidence in males. Retinal detachment is correlated with affluence and season in England and there is geographic variation. This data sheds light into understanding the epidemiology of RRD in England. This would be particularly useful in designing and developing vitreo-retinal services to meet local needs.

11. Clinical features and management summary

Patients perceive flashing lights and floaters acutely. It probably arises from the mechanical stimulation of vitreoretinal traction on the retina. Floaters are opacities in the vitreous cavity that cast a shadow in the patient's visual field. Cobwebs are caused by condensation of the collagen fibers. Floaters can also indicate fresh blood due to the rupture of a retinal vessel

during an acute PVD. Patients often describe a black curtain (visual field defect) once the subretinal fluid accumalates. When the macula becomes detached (ie, extension of subretinal fluid into the macula), the patient experiences a drop in central vision.

Cell and flare may be seen in the anterior chamber and the intraocular pressure is usually lower in the affected eye. Pigment in the anterior vitreous ('tobacco dusting' or a Shaffer sign) is usually present and this represents release of retinal pigment epithelium through the retinal break. Once the retina becomes detached, it assumes a slightly opaque color secondary to intraretinal edema. It has a corrugated appearance and undulates freely with eye movements unless severe proliferative vitreoretinopathy is present.

Patients with a RRD should be referred to a vitreoretinal specialist immediately. Regardless of the surgical technique chosen, the surgical goals are to identify and close all the breaks with minimum iatrogenic damage. Closure of the breaks occurs when the edges of the retinal break are brought into contact with the underlying RPE. This is accomplished either by bringing the eye wall closer to the detached retina (using a scleral buckle) or by pushing the detached retina toward the eye wall (intraocular tamponade with a gas bubble or silicone oil). Sealing of the breaks is accomplished by creating a strong chorioretinal adhesion around the breaks; this may be completed with cryotherapy or laser photocoagulation.

Scleral buckles usually are made of solid silicone and silicone sponges. Indirect ophthalmoscopy is used to localize all the breaks. Once the breaks are localized, they are usually treated with cryotherapy. A buckling element is chosen and sutured over the breaks. The drainage of the subretinal fluid is a controversial topic among vitreoretinal specialists. The retina can be reattached by either technique and the technical details are outside the remit of this chapter.

Currently, many surgeons use pars plana vitrectomy surgery (PPV) to treat primary uncomplicated retinal detachments. A central core vitrectomy and removal of the vitreous from the margins of the breaks is the next step. Drainage of subretinal fluid through a break internally is then performed. Intraocular tamponade with either gas or silicone oil is chosen according to the surgeon's preference. The advantages of gas are that it has a higher surface tension than silicone oil and it dissipates on its own. The disadvantage is that it expands with changing atmospheric pressure. Patients with an intraocular gas bubble should not fly. Transconjunctival and suture-less small-gauge vitrectomy has gained popularity in the past few years. 23 and 25 gauge systems have several potential advantages over traditional 20-gauge vitrectomy including improved patient comfort, faster wound healing, decreased inflammation, less conjunctival scarring, and a decrease in surgical time in opening and closing.

More than 90% of RRD cases can expect anatomical success with reattachment following one operation. Further surgery is required in the failed cases.

Retinal Vascular Occlusions

Mario Bradvica, Tvrtka Benašić and Maja Vinković
University of Josip Juraj Strossmayer, Medical School Osijek, University Hospital Osijek
Croatia

1. Introduction

Retinal vascular occlusions are serious diseases and significant causes of blindness that include arterial and venous obstructions. The causes, pathogenesis, clinical characteristics, prognosis, and response to therapy are influenced by the location of the occlusion in the retinal vasculature and by the extent of retinal nonperfusion.

The hallmark of clinical presentation in the retinal occlusive disease is painless loss of vision, which can be asymptomatic, gradual with only mildly reduced visual acuity, or sudden and reduced to counting fingers depending on the extent of the irrigation area of the affected vessel. The clinical presentation aids in distinguishing the type of the occlusion, which may be classified according to the anatomical site of the occlusion.

2. Retinal Artery Occlusion

Retinal artery occlusion (RAO) represents an ophthalmologic emergency. In 1859, von Graefe first described central retinal artery occlusion (von Graefe, 1859). Retinal artery obstruction may be classified as follows: central (CRAO), affecting the retinal vessel at the optic nerve, hemicentral (occasional, only when one of the two trunks of the CRA is occluded) (Akkoyun et al., 2006; Karagoz et al., 2009; Schmidt & Kramer-Zucker, 2011), branch (BRAO), obstruction distally to the lamina cribrosa of the optic nerve, cilioretinal (CLRAO) and central sparing cilioretinal artery (Hayreh, 2011). Obstructions more proximal to the central retinal artery, in the ophthalmic artery, or even in the internal carotid artery, may produce visual loss as well. More proximal obstructions usually cause a more chronic form of visual problem—the ocular ischemic syndrome often associated with occlusive carotid disease (Kearns & Hollenhorst, 1963).

Central retinal artery occlusion results in sudden visual loss and is therefore one of the most important topics in ophthalmology. Branch retinal artery occlusion causes sudden segmental visual loss and may recur to involve other branch retinal arterioles. Amaurosis fugax is a common transient acute retinal ischemic condition. Acute retinal arterial occlusive disorders together comprise one of the major causes of acute visual loss (Hayreh, 2011). Only anecdotal reports have described spontaneous recovery of vision, and case series have shown only up to 14% of spontaneous recovery (Atebara et al., 1995).

The majority of retinal arterial obstructions are either thrombotic or embolic in nature (an embolus is visible only in 20% of the patients with branch or central retinal artery occlusion)

(Rumelt & Brown, 2003). Arterial occlusions in the eye are almost always due to microembolism and the major source of microemboli is the plaque(s), which may be present with or without any significant carotid artery stenosis. Thus, absence of significant stenosis of the carotid artery does not necessarily rule out the carotid artery as the source of microembolism (Hayreh et al., 2009).

Immediate intervention improves chances of visual recovery, but even then, the prognosis is rather poor, with only 21-35% of eyes retaining useful vision (Jain & Juang, 2009), because it dominantly depends on the type of the occlusion (Hayreh & Zimmerman, 2005). Although restoration of vision is of immediate concern, retinal artery occlusion is a forerunner for other systemic diseases that must be evaluated promptly. Establishing of the cause of obstruction is essential. In case of giant cell arteritis causing occlusion immediate treatment is urgent.

2.1 Epidemiology

Central retinal artery obstruction (CRAO) is a rare event – it has been estimated to account for about 0.85 in 100,000 per year (Jain & Juang, 2009). The mean age at onset is about 60 years, with a range from the first to the ninth decade of life (Duker, 2003). Bilateral obstruction occurs in 1-2% of cases (Brown, 1994). CRAOs account for 58% of acute RAOs, BRAOs for 38%, and cilioretinal artery occlusions (CLRAOs) (Jain & Juang, 2009). There are discrepancies among authors regarding the prevalence of men over women. Some advocate the ratio 2:1 (Duker, 2003) whereas the others found slightly more frequent occurrence in men (Hayreh et al., 2009). A large case series documented that approximately one fourth of patients with CRAO had a form with the cilioretinal sparing (Brown & Shields, 1979). The incidence of CLRA occlusion (CLRAO) varies in different studies from none to 32% (Justice & Lehmann 1976), which would be the most acceptable data, because the incidence was calculated by reviewing stereoscopic color fundus photographs as well as FA; the incidence of CLRAO is in direct proportion with the presence of cilioretinal artery in the population. FA is the most reliable way to ascertain the true incidence because the CLRA dyes concurrently with the filling of the choroid and usually before the start of filling of the CRA. The arteries occurred bilaterally in 14.6% (Justice & Lehmann, 1976).

Multiple studies have shown increased mortality in patients with retinal arterial emboli (Bruno et al., 1995; Ho et al., 2008; Lindley et al., 2009). The frequency of retinal emboli increases with age and are more common in men than in women. Bilateral are rare, although multiple emboli in a single eye may be seen in up to one third of cases. They are associated with the presence of carotid artery disease (CAD), hypertension, smoking, and possibly diabetes (Wong & Klein, 2002). The large Beaver Dam Eye Study calculated the prevalence of retinal arteriolar emboli of 1.3% in the population ranged from 43-86 years, and the 5-year incidence of 0.9%, the 10-year incidence of 1.5% for the same population, and also confirmed a significantly higher hazard of dying from a stroke in people with retinal emboli (Klein et al., 1999; Klein et al., 2003).

Debate exists in the literature on the prevalence and etiology of neovascularization (NV) following CRAO. The reported prevalence varies from 2.5% to 31.6%. Studies have reported prevalence of 18.2% of neovascularization and 15.2% of neovascular glaucoma (NVG) (Duker et al., 1991; Rudkin et al., 2010). In branch retinal artery occlusion, the incidence is

even rarer. Neovascularization is more likely to occur in persons with concurrent diseases and not CRAO per se, as with diabetes, severe carotid artery disease or generalized atherosclerosis (Hayreh & Podhajsky, 1982). Clinical cases have been reported in which neovascular glaucoma developed after branch retinal artery occlusion (Brown & Reber, 1986); most probably they are a result of later complete CRAO rather than pure BRAO.

2.2 Pathophysiology and histology

Visual loss from retinal arterial occlusion (RAO) occurs from the loss of blood supply to the inner layer of the retina. Blood supply to the retina originates from the central retinal (CRA) and the cilioretinal (CLRA) artery. The primary source of blood supply to both arteries - the ophthalmic artery (OA), usually the first intracranial branch of the internal carotid artery (ICA), does not always originate from the ICA; the most common abnormal origin is the middle meningeal artery (Hayreh, 2011; Morandi et al., 1998). The central retinal artery arises independently in 37.5% from the ophthalmic artery, in 59.5% by a common trunk with one or another posterior ciliary artery (PCA), and extremely rarely with other branches of the OA. Numerous anastomoses are established by the branches of the CRA with other branches of the OA, mostly pial. The study showed that these pial anastomoses were usually large enough to establish a variable amount of collateral circulation in the eye having an occlusion of the CRA. This was also demonstrated by fluorescein fundus angiography (FA) (Hayreh, 2011; Hayreh & Weingeist, 1980). The central retinal artery supplies the retina as it branches into smaller segments upon leaving the optic disc. The so-called "branch retinal arteries" are in fact arterioles after the first branching in the retina which don't have either an internal elastic lamina or a continuous muscular layer (Hayreh, 2011). A retinal vascular bed does not own any anastomoses; it is end-arterial system. The cilioretinal artery belongs to the PCA system; it usually originates from the peripapillary choroid or directly from one of the PCAs and supplies the part of the macular retina. The CLRA has a characteristic hook-like appearance at its site of entry into the retina at the optic disc margin, usually on the temporal side. Branch retinal artery occlusion (BRAO) occurs when the embolus lodges in a more distal branch of the retinal artery. BRAO typically involves the temporal retinal vessels and usually does not require treatment, unless perifoveolar vessels are threatened (Ho et al., 2008).

Acutely, obstruction of the central retinal artery results in inner retinal layer edema and pyknosis of the ganglion cell nuclei. Ischemic necrosis results and the retina become opacified and yellow-white in appearance. The opacity is most dense in the posterior pole as a result of the increased thickness of the nerve fiber layer and ganglion cells in this region. The opacification takes as little as 15 minutes to several hours before becoming evident and resolves in 4-6 weeks. Furthermore, the foveola assumes a cherry-red spot because of a combination of 3 factors: (i) the intact retinal pigment epithelium and choroid underlying the fovea, (ii) the foveolar retina is nourished by the choriocapillaris, and (iii) the thinnest NFL at this location. The late stage shows a homogenous scar replacing the inner layer of the retina. Pigmentary changes are typically absent since the retinal pigment epithelium remains unaffected (Kearns & Hollenhorst, 1963).

It has been shown experimentally on animal studies that the retinal damage is irreversible after 105 minutes of completely occluded circulation, but may recover at 97 minutes (Hayreh et al., 2004), and the treatment instituted at any time beyond 4h after the onset of

CRAO cannot have any scientific rationale for improvement of vision. However, complete occlusion or retinal artery circulation in humans is rare with retinal artery disease; thus, retinal recovery is possible even after days of ischemia (Brown & Magargal, 1988). Controversy exists regarding the optimal window of treatment in humans, but the conservative approach involves treatment up to 24 hours (Kearns & Hollenhorst, 1963).

The retinal artery could be occluded due to embolism, vasoobliteration (atherosclerotic plaques, giant-cell arteritis and other types of vasculitis) and vascular compression (a retrobulbar mass - hematoma, neoplasm, retrobulbar injections may lead to an optic nerve and central retinal artery compression) (Korner-Stiefbold, 2001), angiospasm, hemodynamic or hydrostatic arterial occlusion (Hayreh, 2011). By far the most common cause of nonarteritic RAO is the embolism. Emboli are usually of three types: cholesterol - Hollenhorst plaque, platelet-fibrin, calcified, and occasionally myxomatous, or bacterial. The incidence is 74%, 15.5% and 10.5% for the first 3 types, respectively (Arruga & Sanders, 1982). They are mostly of carotid and/or cardiac origin (Korner-Stiefbold, 2001). The major source of embolism in the carotid arteries is plaque (66%), whereas a significant carotid stenosis (>50%) accounts for only 30% of cases (Hayreh et al., 2009; Korner-Stiefbold, 2001; Younge, 1989). Statistically, Caucasians, when compared to African Americans, have significantly different incidence of ICA stenosis, which is 41% and 3.4% for the each group, respectively (Ahuja et al., 1999). A significant stenosis of the extracranial internal carotid artery is the most common identified condition associated with retinal and ocular ischemia (Biousse, 1997; Mizener et al., 1997; Sharma et al., 1998). It represents the hemodynamic cause, and, especially if associated with nocturnal arterial hypotension, can lead to transient CRAO (Hayreh & Zimmerman, 2005). The sources of emboli in heart are valvular lesions, patent foramen ovale, myxoma and endocarditis (Mangat, 1995; Reese & Shafer, 1978; Schmidt et al., 2005; Sharma et al., 1997). It must be remembered though, that the absence of any abnormality on color Doppler ultrasound or echocardiography does not exclude carotid artery or the heart as the source of microembolism, because of the test-resolution and location of the plaque/stenosis.

Animal studies have shown that, serotonin in atherosclerotic vessels produces vasospasm of the central retinal artery (CRA) and/or posterior ciliary artery (PCA) in various combinations (but not vasospasm of the arterioles in the retina). It is postulated that in some atherosclerotic individuals this mechanism may play an important role in the development of ischemic disorders of the retina and optic nerve head (ONH), including amaurosis fugax, CRA occlusion and anterior ischemic optic neuropathy, and possibly also glaucomatous optic neuropathy, particularly in normal tension glaucoma (Hayreh, 1999).

Central retinal arterial occlusions could be divided into permanent or transient; arteritic (usually gigantocellular arteritis) or nonarteritic occlusion. The transient is the nonarteritic and could occur due to (i) transient impaction of an embolus, (ii) fall of perfusion pressure in the retinal vascular bed below the critical level (night arterial hypotension, hypovolemic shock, hemodialysis, spasm of CRA, marked carotid artery disease, ocular ischemia, or a rise of intraocular pressure because of orbital swelling, acute angle-closure glaucoma, neovascular glaucoma (NVG) with ocular ischemia), and (iii) vasospasm of the atherosclerotic lesions (induced by the platelet-aggregation plaque secreting serotonin) (Hayreh, 2011).

Branch arterial occlusion is usually due to embolism and occasionally vasculitis. It could be recurrent (Barak et al., 1997; Beiran et al., 1995; Beversdorf et al., 1997; Johnson et al., 1994). Most of these cases probably have Susac's syndrome (autoimmune endotheliopathy leading to encephalopathy, BRAO and hearing loss) (Susac et al., 2007). The etiology of this syndrome is still unknown, but the prognosis is good in most cases. Spontaneous resolution usually occurs, but early treatment minimizes the risk of sequelae (Van Winden & Salu, 2010).

2.3 Causes

Embolism of the carotid artery and the heart are the most common causes of retinal artery obstruction. Carotid artery disease causes retinal arterial occlusion by three mechanisms: embolism, hemodynamic changes in significantly stenosed carotid artery, and arterial spasm. The major source of emboli is plaques in the carotid arteries, and much less frequently stenosis. According to some studies, hemodynamically significant carotid artery stenosis was found in about 18%of patients with acute RAO (Sharma et al., 1998) and as previously mentioned, Hayreh et al. suggest that the presence of plaques on Doppler color imaging is of more value in determining the cause of acute occlusive event rather than the embolus itself (Hayreh, 2005). The probable cause is the microembolism, which may not produce hemodynamically significant stenosis recordable on Doppler color imaging but may indeed account for the retinal artery occlusion. As shown in the study, carotid Doppler and/or angiography showed the presence of plaques in 71% in CRAO and 66% in BRAO (Hayreh et al., 2009). The fluctuation of hemodynamic factors, especially drops in blood pressure in nocturnal hypotension along with significant stenosis of the carotid artery may be responsible for transient retinal artery occlusion (Hayreh & Zimmerman, 2005; McCullough et al., 2004). Based on experimental studies on animals, the investigators have introduced the possible role of serotonin, released by platelet aggregation on atherosclerotic plaques in the carotid artery, causing transient vasospasm of the central retinal artery and thus potentially inducing retinal artery occlusion and retinal ischemic disorders.

Systemic cardiovascular diseases have a well known association with retinal arterial occlusive disease in elderly people (Sharma, 1998). Therefore, a careful history should include identifying the possible underlying causes such as arterial hypertension, diabetes mellitus, hyperlipidemia, carotid artery disease, coronary artery disease, cerebrovascular disease and symptoms suggestive of temporal arteritis. Cigarette smoking has been described significantly more common among these patients than in the general population. In patients with no obvious systemic risk factors and especially in subjects under the age of 40, the other causative options should be considered, which include systemic vasculitis, blood dyscrasias, drug abuse, hypercoagulabile states, infective diseases, migraine and prolonged direct pressure to the globe in unconscious patients (Brown et al., 1981; Graham, 1990; Greven et al., 1995).

Coagulopathies from sickle cell anemia or antiphospholipid antibodies are more common etiologies for CRAO in patients younger than 30 years of age and the proposed mechanisms involve increase in coagulation factor or platelet activity, thrombocytosis, interaction of lupus anticoagulant and anticardiolipin antibodies with phospholipids as well as the deficiencies of protein C and S and resistance to activated protein C (Comp & Esmon, 1984; Love & Santoro, 1990; Palmowski-Wolfe et al., 2007; Vignes et al., 1996). Increased levels of homocysteine have been linked with higher incidence of occlusive vascular incidents damaging the vascular

endothelium and thus increasing atherosclerotic changes and the formation of blood cloths. Therefore, in cases of suspected homocystinuria or heterozygosity for homocystinuria an oral methionine loading test may be performed since this state may be preventable by taking appropriate vitamin supplements (Boers et al., 1985; Weger et al., 2002; Wenzler et al., 1993). In cases of clinical suspicion, the HIV testing may be indicated since there have been case reports of CRAO or BRAO associated with HIV infection (Conway et al., 1995). A variety of other diseases, including systemic lupus erythematosus, polyarteritis nodosa, dengue fever, West Nile virus, sickle cell disease, Takayasu's arteritis, after smallpox vaccination, Churg-Strauss syndrome, ocular Behçet's disease, Fabry's disease, Susac'c syndrome, and head injury may present with retinal occlusive disorders. It is necessary to exclude these states if there is a young person with sudden loss of vision, fundoscopic findings of arterial occlusion, central or branch, and no obvious identifiable systemic risk factors as above mentioned. In conclusion, arterial occlusive disease of the retina is the result of either arteriosclerotic thrombosis, embolic impaction (predominantly atheromatous plaques of carotid bifurcation, or the internal carotid artery, but also consisting of different material – fat, parasites, talc, air), vasculitis, vasospasm or systemic hypotension. These numerous potential causes mandate often time-consuming and expensive lab tests, and sometimes a causative management of the underlying disease. The possible causes and underlying states associated with retinal arterial occlusion are incorporated in Table 1.

2.4 Clinical presentation

2.4.1 Symptoms

The main presenting symptom of the arterial occlusive disease is loss of vision, usually monocular, which may be sudden (seconds to minutes) blurring, decrease or total loss of vision. The extent of visual loss depends on the type of the occlusion. In central artery occlusions, visual loss is central and dense. In branch artery occlusions, visual loss may go unnoticed if only a section of the peripheral visual field space is affected. Various types of the retinal artery occlusion have different degree of visual acuity (VA) drop; CRAO characterizes severely decreased VA (counting fingers to light perception); BRAO has VA 20/20 to counting fingers; VA in cilioretinal occlusion ranges from 20/30-20/60; CRAO with cilioretinal sparing has VA 20/30 to hand motion, depending on the amount of the papillomacular bundle supplied by the patent vessel; combined CRAO and CRVO have VA counting fingers to light perception (Rumelt S, Brown GC, 2004). The patients with CRAO without cilioretinal sparing rarely regained any useful vision (Brown & Shields, 1979).

Pain accompanying the visual loss is unusual and usually denotes associated ocular ischemic syndrome (Werner et al. 1994). Rarely, in cases associated with arterial spasm, a relapsing and remitting course of visual loss precedes central retinal artery obstruction. Amaurosis fugax precedes visual loss in about 10% of patients involving transient loss of vision lasting seconds to minutes, but which may last up to 2 hours (Brown, 1999). The vision usually returns to baseline after an episode of amaurosis fugax.

2.4.2 Signs

In CRAO, the first signs are afferent pupillary defect on the affected side and segmental arterial blood flow ("box- carring"), which appear immediately at the occlusion and are

accompanied by the various degree of diminished visual acuity. Later signs are retinal opacification and cherry-red spot and optic disc pallor, attenuation of the retinal arteries, arterio-arteriolar collaterals or neovascular glaucoma (as a complication). Von Graefe was the first one who described typical fundoscopic findings associated with occlusion of the central retinal artery: whitish, edematous retina attributable to infarction, especially at the posterior pole where the nerve fibre layer and ganglion cell layer are the thickest (Beatty & Au Eong, 2000). As these layers are absent in the fovea, the underlying choroidal vascular bed can be seen in this area, thus giving rise to the classic cherry-red spot (Fig. 1.). In the presence of a patent cilioretinal artery, the retinal region served by the unobstructed vessel is not involved (Fig. 2.). Disc pallor and retinal vascular narrowing are characteristic of the late stage of CRAO. The characteristic of BRAO is retinal edema in the distribution of the affected vessel only (Fig. 3.). Obstruction of a cilioretinal artery, or even a macular branch arteriole, gives cloudy, edematous appearance of the macula and affects central vision. In acute stage, the arteries appear thin and attenuated while cherry red spot and ground glass appearance may take hours to develop. In severe blockages, both veins and arteries may manifest "box-carring" or segmentation of the blood flow.

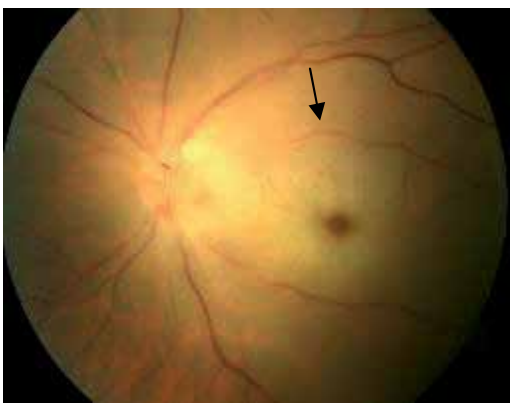

Fig. 1. Central retinal artery occlusion, note foveal cherry red spot and ground glass appearance of the macula (arrow)

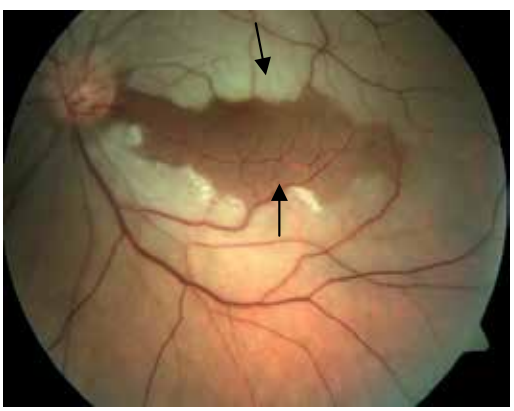

Fig. 2. Cilioretinal sparing central artery occlusion; sparing between the disc and fovea (arrows), representing irrigation area of the cilioretinal artery

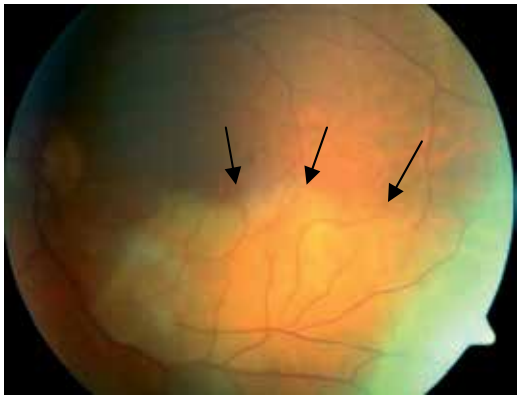

Fig. 3. Branch retinal artery occlusion; note pale, edematous retina in the area of affected vessel (arrows)

Late complication of CRAO is a neovascularization which indicates severe retinal ischemia and is more common at the far periphery and not at the optic disc or the posterior pole, and may complicate with vitreous or preretinal hemorrhage (Duker & Brown, 1989). This is why, in most cases, they are not observed clinically or angiographically with standard angle fundus camera. Only ischemia is usually seen by fluorescein angiography. The typical angiographic finding of neovascularization is the leakage of dye, whereas collateral shunting vessels do not present with such a feature. The fundoscopic findings typically resolve within days to weeks of the acute event, and residual optic atrophy may be the only physical finding. This feature also explains why it is crucial to treat the far periphery of the retina by cryo in addition to treatment by photocoagulation, in cases that the retinal periphery cannot be treated by photocoagulation.

Acute simultaneous obstruction of both the retinal and choroidal circulations is referred to as an ophthalmic artery obstruction. It can be differentiated clinically from central retinal artery obstruction by the following features: severe visual loss—bare or no light perception; intense ischemic retinal whitening that extends beyond the macular area; little to no cherry-red spot; pronounced choroidal perfusion defects on fluorescein angiography; nonrecordable electroretinogram; and late retinal pigment epithelium alterations (Brown et al., 1986). Cases of ophthalmic artery obstruction usually have associated local orbital or systemic diseases: orbital mucormycosis, orbital trauma, retrobulbar anesthesia, depot corticosteroid injection, atrial myxoma, or carotid artery disease (Sullivan et al., 1983). In conjunction with ipsilateral ischemic optic neuropathy, temporal arteritis may produce ophthalmic artery obstruction.

2.5 Evaluation and imaging

To summarize and to choose a rational approach in the workup, it is our opinion that the evaluation should be related to the age group. We recommend the following procedures to be undertaken in the persons over 50 years: the physical examination with complete cardiovascular assessment, ECG, the lab tests including full blood count, erythrocyte sedimentation rate, C reactive protein, fasting blood glucose, lipidogram, urine analysis, Doppler color imaging of the carotid arteries, and transthoracic echocardiography in patients with cardioembolic risk factors.

In the younger patients and those with unidentifiable systemic risk factors these are the proposed investigations: fluorescein angiography, vasculitis screen including anticardiolipin antibodies, antinuclear antibodies, anti-double stranded DNA antibodies, routine coagulation tests (prothrombin time, partial thromboplastin time), specialized clotting factor and platelet activity studies (levels of protein S, protein C, antithrombin III, plasminogen activator, plasminogen activator inhibitor, fibrinogen and resistance to activated protein C) and homocysteine.

Systemic cardiovascular disease
Hypertension, Diabetes mellitus, Atheromatous disease, Cardiac-valvular disease, bacterial endocarditis, myxoma, arrhythmias
Coagulopathies
Antiphospholipid antibodies, Protein C deficiency, Protein S deficiency, Antithrombin III deficiency, Elevation of platelet factor 4, Sickle cell anemia, Homocysteine
Systemic vasculitis
Polyarteritis nodosa, Temporal arteritis, Kawasaki's syndrome, Wegener's granulomatosis, Susac's disease, Systemic lupus erythematosus
Oncologic
Metastatic tumors, Leukemia, Lymphoma
Infective diseases
Syphilis, HIV
Trauma
Direct ocular compression, Penetrating injury, Retrobulbar injection, Orbital trauma, Purtscher's disease
Ocular conditions
Preretinal arterial loops, Optic nerve drusen, Necrotizing herpetic retinitis, Toxoplasmosis
Other causes
Oral contraceptives, Pregnancy, Drug abuse, Migraine

Table 1. Systemic and ocular conditions related to retinal arterial occlusion

It is important to exclude temporal arteritis in older patients, since it follows different clinical course and mandates the prompt administration of systemic corticosteroids. Giant cell arteritis is concerned as approved clinically if two of the three symptoms or signs exist: headache, tenderness over the temple and high sedimentation rate. Biopsy only approves it and treatment should not be deferred for biopsy result. It should be immediately initiated if two or more of the above are present. The purpose of the treatment is to prevent visual loss of the fellow eye, which usually occurs within 10 days of the event in one eye. Apart from the sudden, painless, nonprogressive vision loss in one eye, the patients may have headaches, jaw claudication, scalp tenderness, proximal muscle and joint aches, anorexia, weight loss, or fever.

All patients with acute retinal arterial occlusion must be evaluated for the source of embolism, which is the commonest cause for its development. The imaging techniques are used to confirm the diagnosis in uncertain cases and these are fluorescein angiography, visual field testing, optical coherence tomography and electroretinography.

2.5.1 Fluorescein angiography

Fluorescein angiography is not routinely indicated in the acute phase of arterial occlusive disease. The angiographic findings in both types, CRAO and BRAO (Fig. 4.), include delayed arm-to-retina time which is over 12 seconds (Richard G. et al., 1998), reduced arterial caliber and "cattle-trucking" of the blood column in the branch arteries. Sometimes, it may be minutes before the retinal arterial tree fills with fluorescein. Arteriovenous transit is also delayed, and late staining of the disc is common.

The CLRA dyes concurrently with the filling of the choroid and usually before the start of filling of the CRA (Justice & Lehmann, 1976).

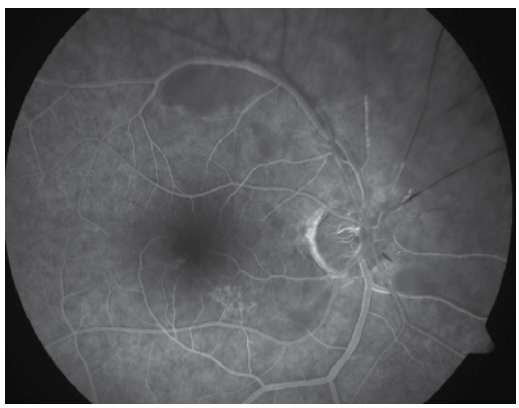

Fig. 4. Superior branch retinal artery occlusion of the right eye. Note the delayed filling of the dye in the superior quadrant of retina

2.5.2 Visual field testing

Visual fields show a remaining temporal island of peripheral vision. In cases of a patent cilioretinal artery, a small intact central island is found as well.

2.5.3 Electroretinography

Electroretinography characteristically shows a decreased to absent b-wave with intact a-wave.

2.5.4 Optical Coherence Tomography (OCT)

Optical coherence findings depend on the duration of the ischemia. Acute stages show increased reflectivity in the inner retinal layers and decreased reflectivity of the photoreceptor layer due to the shadowing effect (Fig. 4.). If involved, the macular region shows cystoid changes with loss of the foveolar contour. Old cases of arterial occlusion are presented with macular thinning with increased reflectivity of the retinal structure denoting ischemia.

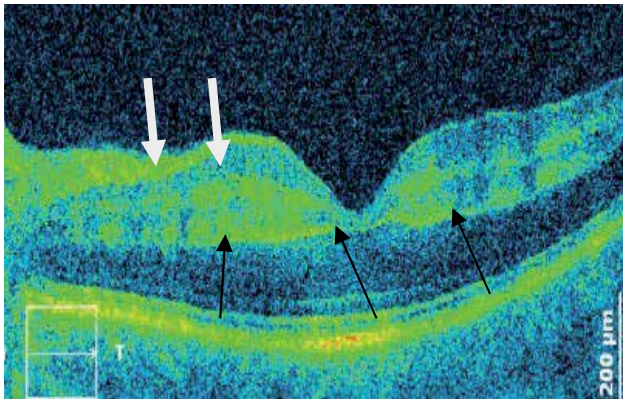

Fig. 5. CRAO – OCT changes, retinal edema in the inner layers (white arrows) denoting ischemia and the shadowing effect in the photoreceptor layer (black arrows)

2.5.5 Color Doppler imaging

Color Doppler imaging is an ultrasonographic evaluation of the blood flow characteristics of the retrobulbar circulation. Color Doppler studies of acute central retinal artery obstruction show diminished to absent blood flow velocity in the central retinal artery, generally with intact flow in the ophthalmic and choroidal branches (Sharma, 1998). Color Doppler imaging can be used to detect calcific emboli at the lamina cribrosa and also may be used to monitor blood flow changes induced by therapy. In addition, carotid artery studies may be carried out concurrently with ocular blood flow determinations to evaluate the possible causes of the central retinal artery obstruction. It is, however, important to determine the presence of plaques in the inspected vessels that are often the source of microemboli responsible for the occlusive event. In doubtful cases, the above-mentioned physical examination and laboratory testing should be carried out, especially in subjects younger than 40 years of age (Table 2).

2.6 Differential diagnosis

Ocular ischemic syndrome

Purtscher's retinopathy

Severe commotio retinae

Inflammatory or infectious retinitis

2.7 Management

Due to the poor prognosis of retinal artery occlusions, several treatment approaches have been attempted. These can be divided into two major categories: (1) conservative treatment, including mechanical (ocular massage and paracentesis), pharmacologic, and other means; and (2) invasive treatment, including catheterization of the proximal ophthalmic artery, usually through the femoral artery with infusion of thrombolytic agents. Any treatment that results in a statistically higher percentage of visual recovery compared with the spontaneous

recovery rate and has a low risk for morbidity and mortality could be considered the treatment of choice (Rumelt & Brown, 2003).

2.7.1 Management of central retinal artery occlusion

Conservative treatment

- First step is arterial vasodilatation using sublingval isosorbid dinitrat, or CO_2 rebreathing in the bag;
- Reduction of intraocular pressure (IOP) and improvement of perfusion by means of antiglaucomatous treatment topically (timolol, etc), systemically (manitol), or surgically by paracenthesis;
  - Ocular massage to move embolus further downstream through artery circulation in distant arterioles. Begin ocular massage with 3-mirror contact lens. Press the lens repeatedly for 10 seconds until the appearance of pulsation; or in the absence of pulsation, until collapse of the retinal blood flow. Observation for improvement of retinal blood flow is made through the lens during the ocular massage. If blood supply improves, ocular massage can be stopped and no further steps are required. If the blood flow does not improve, ocular massage should be continued meticulously for approximately 20 minutes. In addition, treatment prior to 24 hours is more highly to be successful and the success depends on the type of the embolus (calcified are the resistant ones). No light perception is also indication to start treatment. Our experience supports the statement of others that even patients with no light perception may recover (this was also seen in cases of orbital compartment syndrome) (Rumelt et al, 1999);
  - During the ocular massage, administer acetazolamide 500 mg IV;
  - During the ocular massage, administer mannitol 20% 1 mg/kg IV or glycerol 1ml/kg PO;
  - Scleral paracenthesis or anterior chamber paracenthesis – anesthetize the limbus with q-tip soaked with lidocaine 4%, and perform anterior chamber paracentesis with 25-G needle withdrawing 0.2 ml of aqueous humor;
- Antiplatelet therapy (streptokinase 750 000 I.U. IV, urokinase), heparin therapy, isovolemic haemodilution, which basically make no sense if there is no circulation in the occluded artery and agents cannot reach the embolus (Hayreh, 2011);
- Pentoxyfilline injection intravenously to reduce red blood cell rigidity;
- Systemic steroids, in case where CRAO is caused by giant cell arteritis;
- yperbaric oxygenation is one of the promising ways of treatment (Weinberger et al., 2002; Bradvica et al., 2009), which can override the time to artery recanalization. However, there is still need for further evaluation because of the lack of greater randomized studies.

Invasive treatment

- Nd:Yag laser arteriotomy and embolectomy (Opremcak et al., 2008), although this rather invasive treatment frequently caused vitreous hemorrhage and need for vitrectomy, so it requires further evaluation;
- Local intraarterial trombolysis, one of the very enthusiastically announced approaches in CRAO therapy, which is suspended due to a high adverse reactions incidence as

reported by the last European Assessment Group for Lysis in the Eye Study (EAGLE) (Schumacher et al., 2010). Probable reason for the high complication rate was the inexperience of some of the participating physicians. The results and complications were much lower when the procedure was performed by one group (Schmidt et al., 1992; Schumacher et al., 1993).

Since the outcome of invasive treatment depends on the experience of the physician and therefore is not applicable to most centers, the best treatment so far is the conservative multi-step treatment that requires the persistence of the physician (Rumelt et al, 1999).

2.7.2 Management of branch retinal artery occlusion

Management of BRAO depends on the type of occlusion; either it is permanent or transient. In permanent BRAO, like in CRAO there are a lot of advocated treatments but none of them has proven efficient. Transient BRAO does not require any treatment at all except a thorough diagnostics to establish the cause of the occlusion and possibly prevent permanent BRAO from occurring. Nonarteritic cilioretinal artery occlusion (CLRAO) can be treated with any of the procedures described in CRAO treatment. Only arteritic CLRAO associated with giant cell arteritis (GCA) has to be treated with a high dose of steroids, i.e. treat GCA to prevent affecting the other eye and total blindness.

It is important that CRAO and BRAO are both emergencies and any procedures leading to recanalization, or improving the outflow, have to be done urgently inside 97 min from the onset of occlusion (Hayreh et al., 2004), and certainly not after 240 min, because after that time the most part of the retinal tissue function is probably destroyed. It has to be emphasized though that these results are valid for experimental models in primates and for complete occlusion and not for humans that usually have partial obstruction. That is probably the reason why the treatment may be successful even more than 24 hours after the occlusion and the onset of symptoms. Therefore, prevention and education of patients to present immediately to an ophthalmologist or emergency care unit may be the one of the measures of improving the chances of treatment in such patients.

3. Retinal Vein Occlusion

Retinal vein occlusion (RVO) has been recognized as an entity since 1855 (Liebreich, 1855) and is one of the most common causes of acquired retinal vascular abnormality in adults as well as the frequent cause of visual loss. However, the pathogenesis and management of this disorder remains somewhat of an enigma. Current treatments for RVO and its sequelae are still evolving.

CRVO and HCRVO are commonly subdivided into nonischemic and ischemic (hemorrhagic) types according to the degree of obstruction. Ischemic type occurs in more severe (complete) obstruction. Such a distinction is relevant to the clinician, since these two types have very different clinical features, visual outcomes, complications, prognosis and management. Nonischemic RVO is a comparatively benign disease, with central scotoma, essentially due to macular edema, as its major complication, with no risk of ocular neovascularization. Ischemic RVO, by contrast, is a seriously blinding disease, since up to two thirds of patients develop the devastating complications of ischemia, and neovascularization that lead to neovascular glaucoma which causes blindness (Hayreh, 1994).

Retinal vein obstruction is divided into central (CRVO), an occlusion of the central retinal vein resulting in four quadrants of retinal involvement; hemi-central retinal vein occlusion (HCRVO) and branch (BRVO) which consists of major BRVO, an occlusion of either a major branch retinal vein draining one quadrant of the retina, macular BRVO (Hayreh, 1994), an occlusion of a macular branch vein draining a portion of the macula, and peripheral BRVO, an occlusion of a branch retinal vein draining a portion of the retinal periphery. According to the most study data, hemicentral (HCRVO) is an anatomic variant of central retinal vein occlusion (CRVO). Thus, HCRVO acts more like CRVO in terms of risk factors, visual outcome, risk of neovascularization, and response to laser treatment (Appiah & Trempe, 1989). CRVO and BRVO have both differences and similarities in pathophysiology, underlying systemic associations, average age of onset, clinical presentation, prognosis (natural history, complication rate) and treatment.

Furthermore, central and hemi-central occlusion are divided into ischemic and nonischemic subtypes each having different clinical implications and ischemic carrying the risk of developing macular edema and devastating consequences regarding the visual function.

3.1 Epidemiology

The worldwide RVO prevalence, according to the meta-analysis which used pooled data from 15 different international studies involving over than 50,000 participants, ranged from 30 to 101 years, has been calculated per 1000 as follows: 5.20 for any RVO, 4.42 for BRVO, and 0.80 for CRVO. On the basis of these rates, projected to the world population, 16.4 million adults are affected by RVO (Rogers et al., 2010). For comparison, more than 171 million adults with diabetes worldwide either have diabetic retinopathy or are at risk of developing this potentially blinding disease, according to a 2005 World Health Organization report (Wild et al., 2004). An estimated 13.9 million people globally are affected by BRVO and 2.5 million by CRVO. Prevalence varied by race/ethnicity and increased with age, but did not have a sex predilection. The age- and sex-standardized prevalence of any RVO was 3.7 per 1000 in whites, 3.9 per 1000 in blacks, 5.7 per 1000 in Asians, and 6.9 per 1000 in Hispanics. Prevalence of CRVO was lower than BRVO in all ethnic populations. Although BRVO prevalence appears to be highest in Asians and Hispanics and lowest in whites, the authors assume this may reflect differences in the prevalence of RVO risk factors, varying methodologies or definitions among reviewed studies (Rogers et al., 2010). Ischemic central retinal vein obstructions account for 20–25% of all central retinal vein obstructions (Klein et al., 2000).

3.2 Pathophysiology

All types of RVO are multifactorial in origin. A whole host of local and systemic factors acting in different combinations and to different extent may produce the vascular occlusion. The role of the various factors may vary, with some as predisposing factors and other as precipitating ones in one group and vice versa in another. Most investigators accept that BRVO and CRVO represent varying degrees of the same underlying disease process. Yet, other clinicians and researchers argue that ischemic and nonischemic types are distinct clinical entities. It is also essential to understand that CRVO and HCRVO are very different from BRVO pathogenetically. In conclusion, it is a mistake to try to explain all types of RVO by one common pathogenetic mechanism (Hayreh, 1994).

3.2.1 Central Retinal Vein Occlusion

The pathogenesis of CRVO is not fully understood and there are marked controversies on the pathogenesis of ischemic and especially nonischemic CRVO. A combination of vascular, anatomic, and inflammatory factors contributes to its pathophysiology.

The occlusive mechanisms in CRVO are mostly these: (i) external mechanical compression of the vein (i.e. by sclerotic adjacent central retinal artery and common adventitia, especially in elderly persons, structural changes in lamina cribrosa, e.g., glaucomatous cupping, inflammatory swelling in optic nerve and orbital disorders) followed by secondary endothelial proliferation; (ii) primary venous wall disease (degenerative or inflammatory); and (iii) hemodynamic disturbances produced by a variety of factors (e.g., hyperdynamic or sluggish circulation, blood dyscrasias, disturbances on the arterial side, etc.). Consequently, a stagnation of the vein flow occurs and a thrombus formation ensues (Hayreh, 1994; Williamson, 1997).

There are multiple anatomic variations of the branching pattern to the central retinal vein. In 20% of eyes there are, as a congenital abnormality, two trunks of the central retinal vein (CRV) in the optic nerve (instead of the usual one), and the merging of the trunks occurs posterior to the lamina cribrosa (Chopdar, 1984; S. S. Hayreh & M. S. Hayreh, 1980). If one of these trunks is occluded, the result is a nonperfusion to superior or inferior retina. Additionally, the venous outflow from the nasal retina may occur via a branch of one of the temporal branches, rather than an independent nasal vein. In an eye with such a branching pattern, an inferior or superior HCRVO may occur if one the venous branches that drain the nasal and temporal retina is occluded (Sanborn & Magargal, 1984). So, considering the various possible scenarios that can result in a HCRVO, a consensus as to whether HCRVO is a variant of BRVO or CRVO still has not been reached.

CRVO is significantly more common in patients with raised intraocular pressure (IOP) and glaucoma (up to 5- to 10-fold increased risk) (Risk factors for central retinal vein occlusion. The Eye Disease Case-Control Study Group, 1996). To maintain the blood flow, the pressure in the CRV at the optic disc has to be higher than the IOP, otherwise a retinal venous stasis and sluggish venous outflow occur (Hayreh, 2005).

There is much more congruence of the data on the pathogenesis of the ischemic CRVO. Most probably ischemic CRVO represents a more extensive (or complete) obstruction while non-ischemic RCVO represents a milder (partial) obstruction. A conception suggests that the vessels are in a tight compartment within limited space for displacement, because of a common adventitial sheath as CRA and CRV exit the optic nerve head and pass through a narrow opening in the lamina cribrosa. This anatomical position *per se* predisposes to thrombus formation in the central retinal vein. But, CRV has multiple tributaries during its course in the optic nerve, pial outside the optic nerve, none in the lamina cribrosa, and only a small one in the prelaminar region. These tributaries establish anastomoses with the surrounding veins. Since the severity of retinal venous stasis depends upon the site of occlusion in the CRV, and the number of available tributaries anterior to it, the site of the occlusion is likely to be much posteriorly to the lamina cribrosa in nonischemic CRVO than in ischemic CRVO (Hayreh, 2005). There is a possibility of changing nonischemic CRVO to ischemic in some patients, probably due to a further precipitous gradual or sudden fall of perfusion pressure (Hayreh, 1994).

Occlusion of the central retinal vein leads to the retention of the blood in the retinal venous system, and increased resistance to venous blood flow subsequently causes a stagnation of the blood and ischemic damage to the retina. It has been postulated that ischemic damage to the retina stimulates increased production of vascular endothelial growth factor (VEGF) in the vitreous cavity. Increased levels of VEGF stimulate neovascularization of the posterior and anterior segment (responsible for secondary complications due to CRVO). Also, it has been shown that VEGF causes capillary leakage leading to macular edema (which is the leading cause of visual loss in both ischemic CRVO and nonischemic CRVO) (Boyd et al., 2002; Noma et al., 2008; Pe'er et al., 1998).

The prognosis of CRVO depends upon the reestablishment of patency of the venous system by recanalization, dissolution of clot, or formation of optociliary shunt vessels.

3.2.2 Combined Retinal Vein and Artery Occlusion

A central retinal artery obstruction combined with central retinal vein obstruction can occur rarely (Richards, 1979), and the mechanism is probably increased pressure on both central retinal artery and vein. The most common cause for combined CRAO and CRVO is retrobulbar anesthetic injection, caused probably by inadvertent injection into the optic nerve sheath (Torres, 2005). If no CRV tributaries are available anterior to the site of occlusion in the CRVO, it converts the circulation into a closed loop and this results in complete hemodynamic block of the retinal circulation, and secondary CRAO. This condition is invariably diagnosed as simultaneous occlusion of CRA and CRV (Hayreh, 2005). Nonischemic CRVO associated with cilioretinal artery occlusion (CLRAO) is usually a result of transient rise i.e. a functional obstruction of the blood pressure in the entire retinal capillary bed due to a sudden blockage of blood flow by a thrombus in the CRV, which, in turn, results in a physiologic block in the CLRA circulation (Theoulakis et al., 2010). Within a day or two, with the development of venous collaterals by the CRV, the blood pressure in the retinal vascular bed falls, and normal cilioretinal filling occurs. However, the severity of retinal ischemia and associated visual loss depends upon the length of time elapsed before the circulation was re-established (Hayreh, 1994).

3.2.3 Branch Retinal Vein Occlusion

Branch retinal vein occlusion is defined as a focal occlusion of a retinal vein at an arterio-venous crossing site. In all but a few rare cases, the BRVO occurs at crossing sites where the artery is passing anteriorly (superficially) to the vein (Duker & Brown, 1989; Weinberg et al., 1990). The upper temporal vascular arcade is more often involved than the lower temporal vascular arcade. Most BRVOs involve the area inside the temporal vascular arcades (macular BRVO), whereas peripheral BRVOs are more rarely seen, partly because they tend to be asymptomatic (Christoffersen & Larsen, 1999).

The arterio-venous crossing plays an important role in the pathogenesis of BRVO, and the anterior position of the arteriole at the crossing somehow renders the underlying vein vulnerable to occlusion. It seems logical to assume that sclerotic retinal arteriole probably compresses the accompanying vein because of a common thickened, adventitial and glial sheath; however, histopathological studies failed to confirm this view. In addition, turbulent flow may injure the vessel wall exposing it for thrombus formation (Hayreh, 1994; Williamson, 1997).

3.3 Causes

Retinal vascular occlusions all have overlapping clinical presentation as well as the similar underlying causes. They are all multifactorial in origin and each patient may have a unique combination of systemic and local factors leading to the occlusive event (Hayreh, 1994). Since the systemic vascular disease is a possible underlying pathophysiological cause, it is important to ask about history of hypertension, diabetes mellitus, any condition predisposing embolic events (endocarditis, atrial fibrillation, atherosclerotic disease, drug and alcohol abuse, hypercoagulabile states) (Klein et al., 2003; Schmidt et al., 2007). Also, the questions regarding possible trauma as well as the undertaken surgical procedures should not be omitted from the medical history since the prolonged pressure to the globe may lead to the ischemic event.

The well-known risk factors contributing to retinal vein occlusions are systemic vascular diseases. The most recognized risk factors for retinal vein occlusion are hypertension, diabetes mellitus, arteriosclerosis and hyperlipidemia. Also, cigarette smoking has been related to increased risk of RVO. They predominately affect the older age group of patients but the younger patients may also develop this type of retinal occlusive disorder and they account for 10-15% of patients with RVO. Mild central retinal vein obstructions in patients younger than 50 years have been referred to as papillophlebitis or optic disc vasculitis. An inflammatory optic neuritis or vasculitis is hypothesized as the cause (Fong, 1992).

According to the recent studies by Hayreh et al. there may be some difference in the risk factors between CRVO and BRVO, with higher prevalence of hypertension, venous disease, peripheral vascular disease and peptic ulcer in the latter (Hayreh et al., 2001). This suggests that it may not be correct to generalize about these underlying causes for the entire group of retinal vein occlusions.

In addition to well-recognized risk factors, new thrombophilic factors have been investigated in these patients. The role of thrombophilic risk factors in RVO is controversial and the studies are showing conflicting results. Hyperhomocysteinemia as well as low levels of vitamin B_6 and folic acid have been identified as independent risk factors (Sofi et al., 2008; Taubert, 2008). Other potential risk factors include elevated factor V Leiden, protein C or S deficiency, anti-cardiolipin antibodies or lupus anticoagulant. Blood dyscrasias and dysproteinemias result in hyperviscosity syndromes, which may appear similar to central retinal vein obstruction but possibly represent curable disease. Hyperviscosity syndromes may produce a bilateral retinopathy similar to central retinal vein obstruction and may, in fact, induce a true central retinal vein obstruction with thrombus formation (Bandello et al., 1994). Simultaneous bilateral disease is an unusual finding in central retinal vein obstructions but occurs more commonly in hypercoagulabile and hyperviscous states. Diseases such as sickle cell disease, polycythemia vera, leukemia, and multiple myeloma are but a few of the possibilities. When there is a patient with bilateral central retinal vein obstructions, especially simultaneous, the medical and laboratory evaluation should include a search for evidence of hyperviscous and hypercoagulabile syndromes (Marcucci et al., 2001) Severe anemia with thrombocytopenia can masquerade as a central retinal vein obstruction, and it is differentiated from a central retinal vein obstruction by a complete blood count with platelets.

In combined central retinal vein occlusion with branch retinal artery occlusion systemic associations other than hypertension and diabetes have not been confirmed. In combination

with central retinal artery occlusion associated systemic or local disease is the rule—collagen vascular disorders, leukemia, orbital trauma, retrobulbar injections, and mucormycosis have been implicated (Jorizzo, 1987).

Oral contraceptive use in women may be associated with both thromboembolic disease and central retinal vein obstruction (Stowe et al., 1978). In addition, acute hypertensive retinopathy with disc edema may resemble bilateral central retinal vein obstruction. Obstructive sleep apnea affects more patients with retinal vein obstruction than other disorders and treatment of the sleep apnea may help prevent central vein obstruction (Glacet-Bernard et al., 2010). Other rare associations include closed-head trauma, optic disc drusen, and arteriovenous malformations of retina.

The Eye Disease Case-Control Study Group reported that the risk of CRVO is decreased in men with increased levels of physical activity and increased alcohol consumption (Risk factors for central retinal vein occlusion. The Eye Disease Case-Control Study Group, 1996). The same study group reported a decreased risk of CRVO with the use of postmenopausal estrogens and an increased risk with higher erythrocyte sedimentation rates in women.

An ocular risk factor for the development of central retinal vein occlusion is raised intraocular pressure; the risk of central retinal vein occlusion in glaucoma patients is 5-fold to 10-fold increase (Risk factors for central retinal vein occlusion. The Eye Disease Case-Control Study Group, 1996). Unlike CRVO and HCRVO, glaucoma plays no role in the pathogenesis of BRVO (Hayreh, 1994).

In ischemic CRVO, for example, neovascular glaucoma develops in about 45%. The chronic hypoxia of the retinal tissue induces ocular neovascularization by producing the vasoproliferative factor, which is the proposed mechanism in CRVO whereas in CRAO, there is acute retinal ischemia and infarction responsible for the occlusive event. Also a surprisingly small proportion of patients (2.5%) have the course of illness complicated with neovascular glaucoma (Hayreh, 2011).

3.4 Clinical presentation

3.4.1 Symptoms

Retinal vein occlusion is characterized by painless unilateral loss of vision. It may be subtle in character, with intermittent episodes of blurred vision. In other cases, it may be sudden and dramatic. The nonischemic type is often the more subtle of the two, while the ischemic type is prone to the more acute clinical presentations and may be accompanied by pain.

Ischemic CRVO Acute, markedly decreased visual acuity ranged from 20/200 (6/60) to hand-motion is the usual initial complaint. A prominent afferent pupillary defect is typical. Pain at the time of evaluation may occur if neovascular glaucoma already had developed.

Nonischemic CRVO The majority of patients with central retinal vein obstruction (75–80%) fall into nonischemic form. Patients usually have mild to moderate decreased visual acuity, although this can vary from normal to as poor as the finger counting. Transient visual obscuration may also be a complaint.

Branch retinal vein occlusion is characterized by painless decrease in vision on the affected eye and some patients may have a scotoma.

Combined Retinal Vein and Artery Occlusion Such patients present with acute, severe loss of vision, usually to bare or no light perception. The visual prognosis is generally poor.

3.4.2 Signs

The distinction between the ischemic and nonischemic type is important, because they carry a totally different prognosis regarding visual recovery and potential complication, which may result in permanent visual deterioration.

Both types of central retinal vein obstruction, ischemic and nonischemic, have similar fundoscopic findings—dilated, tortuous retinal veins and retinal hemorrhages in all four quadrants, optic disc swelling, cotton wool spots and macular edema (Fig. 5). Hemorrhages can be superficial, dot and blot, and/or deep. They may vary in severity, covering the whole fundus and sometimes even obscuring retinal and choroidal details, or can be limited to the peripheral fundus only. Vitreous hemorrhage may ensue when bleeding breaks through the internal limiting membrane. The optic disc is usually edematous during the early-stage disease, but the edema may persist in chronic cases (Ehlers & Fekrat, 2011). Many or all of the pathological retinal findings may resolve over the 6–12 months following diagnosis. The resolution of retinal hemorrhages may be complete whereas the optic nerve may appear normal, but optociliary collateral vessels are common finding. In spite the resolution of macular edema, a persistent cystoid macular edema can linger and result in permanent visual loss, often leading to pigmentary changes, epiretinal membrane formation, or subretinal fibrosis.

Ischemic CRVO The presence of cotton-wool spots located around the posterior pole is characteristic of and more common with ischemic CRVO (Fig. 6.). In ischemic CRVO, the ganglion cells in the macular retina are irreversibly damaged by ischemia during the initial stages of the disease; therefore, there is little chance of improvement of visual acuity in such an eye. The distinction between the two types of vein obstructions remains somewhat arbitrary and is based on the total area of nonperfusion on fluorescein angiography. However, dense intraretinal hemorrhage in acute stages may block retinal fluorescence and renders it impossible to determine the extent of retinal nonperfusion. Therefore, it is important to take into account other clinical features such as poor initial visual acuity, the presence of an afferent pupillary defect, neovascularization as well as the functional tests – visual field testing (Goldmann) and electroretinography (ERG) to establish the perfusion status of the retina (Hayreh et al., 2011). In central retinal vein obstruction, perfusion of the inner retina is affected, so that the amplitude of the b-wave is decreased relative to the a-wave; the b-to-a ratio has been shown to be reduced. Some studies indicate that a b-to-a ratio of less than 1 suggests an ischemic central retinal vein obstruction (Matsui et al., 1994). It is only the ischemic CRVO eye which is at risk of developing ocular neovascularization (Hayreh et al., 1983; Natural history and clinical management of central retinal vein occlusion. The Central Vein Occlusion Study Group, 1997). The incidence of anterior segment neovascularization in ischemic central retinal vein obstruction is 60% or higher and has been documented as early as 9 weeks after onset of an occlusive event. The greatest risk of developing anterior segment neovascularization is during the first 7 months, after which the risk of dreaded complication of neovascular glaucoma falls dramatically to minimal. Neovascularization of the optic disc and retinal neovascularization may be seen as well, but they are less common. As with nonischemic central retinal vein obstruction, the findings may decrease or resolve 6–12 months after diagnosis. The anterior segment structures may

show signs of ischemia: congestion of the conjunctival and ciliary vessels, corneal edema, iris and anterior chamber angle neovascularization with development of synechial changes predisposing the development of secondary glaucoma.

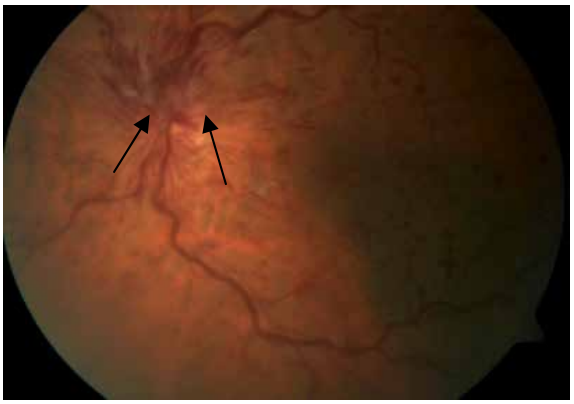

Fig. 6. Central retinal vein occlusion; dilated, tortuous retinal veins and retinal hemorrhages in all four quadrants, optic disc swelling (arrows), cotton wool spots and macular edema

Nonischemic CRVO Neovascularization of either the anterior or posterior segment is rare in a true nonischemic central retinal vein obstruction (less than 2% incidence), although conversion from an initially nonischemic vein obstruction to the ischemic variety is fairly common. The Central Vein Occlusion Study Group noted that 34% of nonischemic central retinal vein occlusions (CRVOs) progressed to become ischemic within 3 years and 15% of the study group converted within the first 4 months (Natural history and clinical management of central retinal vein occlusion. The Central Vein Occlusion Study Group, 1997).

Hemicentral RVO In hemicentral retinal vein obstruction venous outflow from the superior or inferior parts of retina is impaired. Although they involve half of the retina, in terms of visual outcome, the risk of neovascularization, and response to the laser treatment, they resemble the ischemic variant of the disease.

Branch retinal vein occlusion (Fig. 7.) Intraretinal hemorrhages (usually flame shaped), retinal edema, and cotton-wool spots are seen in the distribution of a retinal vessel.

Papillophlebitis The characteristic finding is optic disc edema out of proportion to the retinal findings, cotton-wool spots that ring the optic disc, and occasionally cilioretinal artery obstructions or even partial central retinal artery obstructions. Although spontaneous improvement occurs, the course is not always benign. Approximately 30% of these patients may develop the ischemic type of occlusion, a final visual acuity of 20/200 in nearly 40% of these subjects, and neovascular glaucoma has been reported (Fong, 1992).

Combined Retinal Vein and Artery Occlusion Examination shows a cherry-red spot combined with features of a central retinal vein obstruction, which include dilated, tortuous veins that have retinal hemorrhages in all four quadrants (Fig. 8.). The risk of neovascularization of the iris is about 75%. Exceptionally, a patient may manifest spontaneous improvement (Jorizzo, 1987). Branch retinal artery obstruction combined with simultaneous central retinal vein obstruction has also been reported. This rare entity behaves as a central retinal vein obstruction. Neovascularization of the iris is possible.

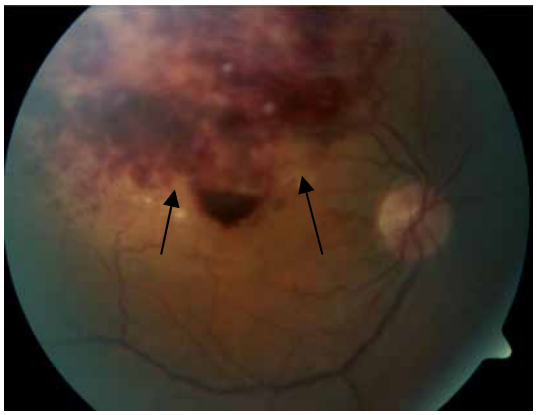

Fig. 7. Branch retinal vein occlusion; note hemorrhages and edema in superior temporal quadrant (arrows)

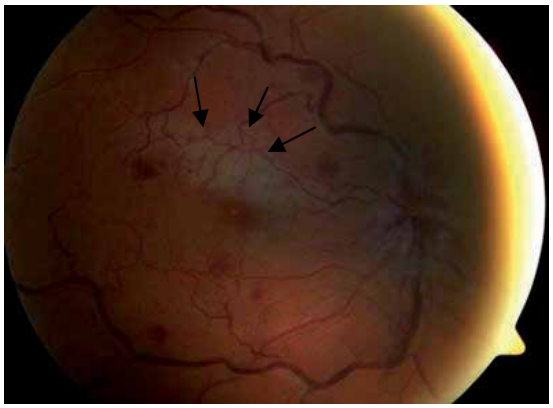

Fig. 8. Combined branch retinal artery occlusion (BRAO) and central retinal vein occlusion (CRVO) of the right eye, ischemia involving superior macular branches (arrows), optic disc swelling, tortuous veins and dot and blot hemorrhages

3.5 Evaluation and imaging

3.5.1 Systemic evaluation

Given the heterogenity of risk factors and their possible interaction in these subjects, the following algorithm of patients with RVO is proposed in the Table 2. As for the arterial occlusive retinal disease, these tests should be performed in younger patients and in doubtful cases.

We feel that, as with the arterial occlusive disease, the stepwise approach to each patient should be tailored, taking into account the age of the patient. Therefore the investigations in the patients older than 50 years of age should consist of: cardiovascular risk assessment, ECG, carotid and vertebral artery Doppler color imaging, echocardiogram; the lab tests including full blood count, erythrocyte sedimentation rate, C reactive protein, fasting blood glucose, lipidogram. The younger patients should be evaluated for thrombophilia, hyperviscosity syndromes, screening for autoimmune diseases and women should be asked about the use of oral contraceptives. Of course, other possible causes of retinal vein occlusions should be considered in cases of normal findings and the investigations should be expanded in stepwise approach, since each case may have a unique combination of risk factors and underlying causes.

Cardiovascular risk factors assessment (diabetes, hypertension, smoking habitus, dyslipidemia, BMI) **ECG** **Carotid and vertebral artery Doppler color imaging** **Echocardiogram** (transthoracic, transesophageal in selected cases) **Lab tests** (complete blood count, fasting glucose, lipidogram, autoimmune screen in selected cases: ANA, anti ENA, anti DNA; homocysteine level, folic acid, vitamin B12 and B6, antiphospholipid antibodies) **Thrombophilia assessment** in subjects younger than 50 years (factor V Leiden, antithrombin, protein C, protein S)

Table 2. Proposed systemic work-up in RVO patients

Although most cases are diagnosed straightforward from the fundus appearance, the following ancillary tests may be undertaken to distinguish between ischemic or milder, nonischemic form, which is very important in terms of the treatment options as well as the natural course and visual prognosis of the patients.

3.5.2 Fluorescein angiography

Arteriolar filling is usually normal, but venous filling in the affected vessel is usually delayed in the acute phase. Hypofluorescence caused by hemorrhage and capillary nonperfusion are common findings, and dilated, tortuous veins are seen (Fig. 9a.). The retinal vessels, particularly the vein walls, may stain with fluorescein, especially at the site of the occlusion (Fig.10.). The very important distinction should be made between neovascular fronds, which may show profuse leakage of dye, vs. collateral vessels, which do not leak fluorescein. Cystoid macular edema (Fig. 9b.) appears in the late stage of the angoigram shows typically petaloid pattern and may involve the entire fovea or just several clock hours, depending on the distribution of the obstruction. It is, however, important to emphasize that in early stages the retinal angiograms may be misleading because of the masking by abundant hemorrhages and the fact that retinal capillary obliteration is a progressive phenomenon which takes at least 3-4 weeks or even longer to develop after the occurrence of ischemic CRVO (Hayreh, 1994).

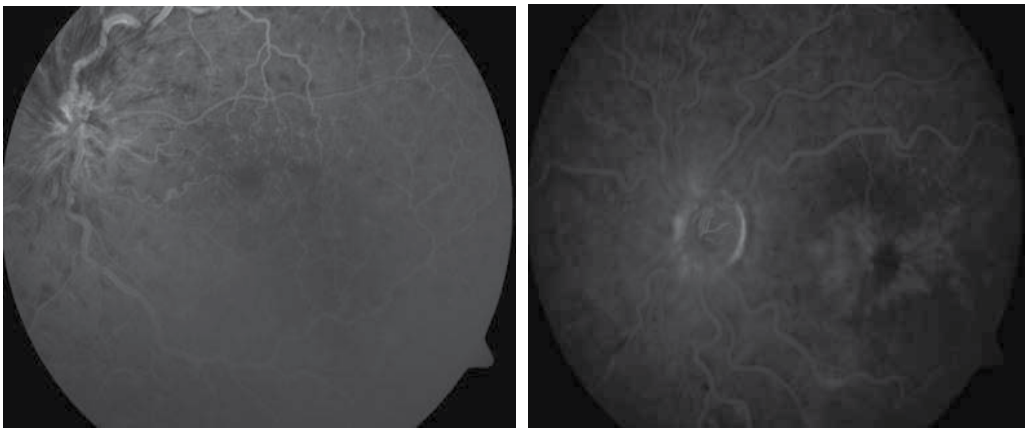

Fig. 9. Fluorescein angiogram of the left eye with central retinal vein occlusion a and b. a) staining of blood vessel walls, disc hyperfluorescence and blockage from intraretinal hemorrhage b) the late stages of angiogram shows leakage of dye in cystoid macular edema, with characteristic "petaloid" appearance.

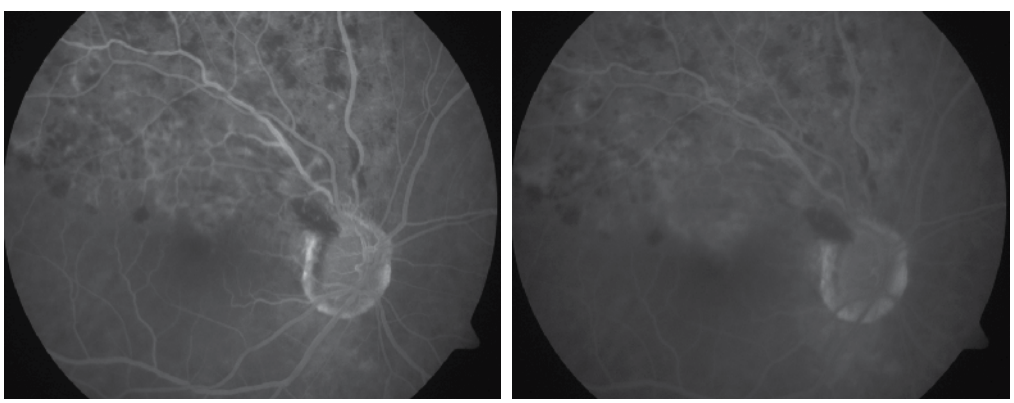

Fig. 10. Fluorescein angiogram of the right eye with superior branch retinal vein occlusion a and b. a) blockage of dye with hemorrhages, mottled areas of intraretinal leakage and microaneurysm formation with vascular teleangiectasia in the upper parts b) the late stages of angiogram shows further diffuse leakage of dye, through all layers of the retina, affecting the macular region as well.

3.5.3 Optical coherence tomography

The optical coherence tomograms show increase in the retinal thickness, which is seen as a loss of macular contour. In the area of edematous retina the presence of cystoids spaces denotes the existence of cystoid macular edema (Fig. 11.). The retinal hemorrhages, subretinal fluid accumulation, cotton wool spots and optic disc edema may also be visualized on OCT. OCT is useful in the management and treatment of the macular edema; it also offers certain advantages over angiograms because it quantifies the macular thickness useful in monitoring the response to treatment and gives valuable data on distribution of the fluid, is not invasive and has no potentially serious side effects. There have been some

disputes whether the macular thickness correlates significantly with visual acuity (Nussenblatt et al., 1987). What counts is the improvement in visual functions and not the anatomy. Several factors were predictive of better visual acuity outcomes and more favorable OCT outcomes, including younger age and shorter duration of macular edema, respectively. These factors may assist clinicians in predicting disease course for patients with CRVO and BRVO (Scott et al., 2011). Loss of foveal IS/OS junction line and absence of inner retinal layers in late stage significantly correlated with poorer visual outcome. Macular ischemia by fluorescein angiography shows significant correlation with thinner central subfield thickness, loss of inner retinal layers (Lima, 2011).

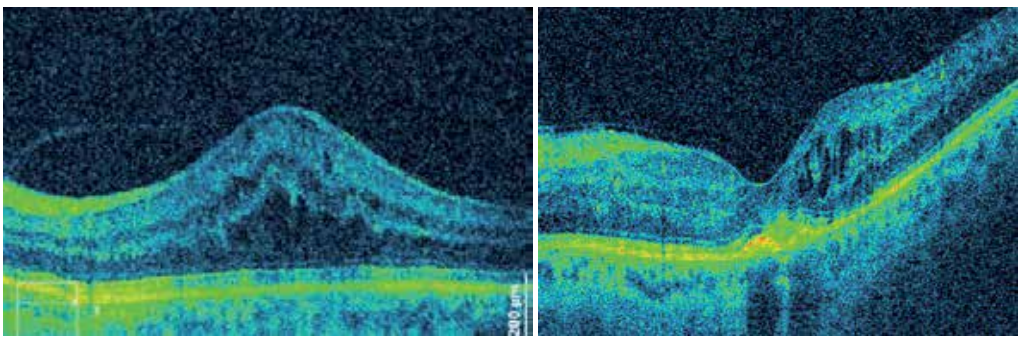

Fig. 11 a and b. Optical coherence tomography (OCT) changes of eye with central retinal vein occlusion a) Cystoid macular edema prior to anti-VEGF injection; b) Cystoid macular edema after anti-VEGF injection treatment Cross-section goes through inferior retina to superior retina, capturing the abnormally thickened retina associated with intracellular edema.

3.6 Differential diagnosis

Hypertensive retinopathy

Diabetic retinopathy

Ocular ischemic syndrome

Juxtafoveal retinal telangiectasia

Radiation retinopathy

Retinal artery occlusion

Retinal detachment

Vitreous hemorrhage

3.7 Management

Some treatments have addressed the venous outflow and the majority the sequelae of the venous occlusion (i.e. cystoid macular edema, neovascularization). In the following text the advocated treatment options are discussed.

3.7.1 Management of branch retinal vein occlusion

Etiology treatment

- Isovolemic hemodilution, used to lower plasma viscosity and to improve retinal perfusion. However, the true benefit of hemodilution has not been established because the published reports have used a combination therapy in the hemodilution groups ;
- Laser chorioretinal venous anastomosis, performed to bypass the occluded site by inducing a communication between the involved branch vein and the choroidal circulation by placing a laser burn directly on the vein and then on the adjacent Bruch's membrane. During the healing process, a chorioretinal anastomosis may form. The technique is studied on CRVO patient, but the small number of BRVO case series were reported (Bavbek et al., 2005; Fekrat et al., 1998);
- Pars plana vitrectomy and arteriovenous sheathotomy. Arteriovenous sheathotomy, in which the retinal vein and artery are surgically separated at the arteriovenous crossing by cutting the common adventitial sheath bare the same idea of improving perfusion. Several small, uncontrolled series have shown good results in improving macular edema and macular perfusion. However, others have reported a lack of efficacy of this procedure (Le Rouic et al., 2001; Cahill et al., 2003).

Sequelae treatment

- Grid laser photocoagulation. The Branch Vein Occlusion Study (BVOS) demonstrated the efficacy of grid laser photocoagulation in the treatment of BRVO-related macular edema. According to the study, grid photocoagulation performed in the first 12 months of onset of the occlusion can, compared to the natural course, improved the response almost twice (Argon laser photocoagulation for macular edema in branch vein occlusion. The Branch Vein Occlusion Study Group, 1984) Argon laser grid or sector treatment result in resolution of the edema but do not improve visual acuity;
- Sector Scatter Retinal Laser Photocoagulation. This treatment was also evaluated during the BVOS study in the ability of preventing the development of neovascularization and vitreous hemorrhage in the BRVO. It is recommended that scatter photocoagulation should be used in BRVO, if and when neovascularization occurs (Argon laser scatter photocoagulation for prevention of neovascularization and vitreous hemorrhage in branch vein occlusion. A randomized clinical trial. Branch Vein Occlusion Study Group, 1986);
- Intravitreal corticosteroids, using a long lasting corticosteroid such as triamcinolone (IVTA), or biodegradable carrier containing dexamethasone to manage macular edema. SCORE study was conducted to compare IVTA versus standard of care, i.e. grid-pattern macular photocoagulation (Scott et al., 2009). The results of this study suggest that both procedures have a similar effect on resolving macular edema and improving visual acuity, but IVTA has more side effects (increasing IOP, cataract progression). In a randomized pilot study of subjects with cystoid macular edema (CME) secondary to BRVO, the increase in visual acuity was significantly greater in those treated with combination of IVTA and grid-pattern laser photocoagulation than in the eyes treated with grid-pattern laser alone, suggesting that IVTA can be effective as an adjunctive treatment to laser (Parodi et al., 2008). Allergan conducted an international study at 167 centers in 24 countries on the effect of intravitreal dexamethasone sustained release delivery system (Ozurdex). The data for the first 6 months was released (Haller et al., 2010). It appears that visual acuity was significantly better in the group of patients who received 0.7 mg dexamethasone implant than in the control group after 60 and 90 days, but is similar 180 days after the treatment. Ozurdex received FDA approval for treatment of macular edema

secondary to BRVO in 2009. An implantable fluocinolone acetonide (Retisert, Bausch and Lomb, Rochester, NY), at present being registered for the intravitreal treatment of chronic non-infectious uveitis, is also being evaluated for the treatment of BRVO and CRVO. The beneficial effect of intravitreal corticosteroids is limited in time and repeated treatment is associated with the accumulation of the complications including steroid-induced glaucoma, cataract, endophthalmitis and retinal detachment. IOP sparing corticosteroids may only prevent glaucoma but not the other side-effects;

- Intravitreal Anti-Vascular Endothelial Growth Factor. It was noticed that VEGF plays a substantial role in the development of CME and neovascular complication in RVO patients. The first intravitreally used drug was bevacizumab, originally developed for the intravenous treatment of colorectal carcinoma metastases, but widely used for treating RVO complications and other retinal disorders (e.g. diabetic macular edema, age related macular degeneration). Several studies have reported a decrease in retinal thickness and improved visual acuity after receiving bevacizumab (Kreutzer et al., 2008; Kriechbaum et al., 2008; Pai et al., 2007). Visual acuity usually increased to maximum in 3-6 weeks after the injections (Stahl et al., 2007). A subsequent decrease in visual acuity appeared to be closely related to an increase in CME. Early recurrence of CME should prompt consideration for retreatment. The most appropriate timing interval between injections is still unclear. The other anti-VEGF agents on the market are pegaptanib, the first FDA approved intravitreal agent (for the treatment of neovascular age-related macular degeneration - ARMD) and ranibizumab, the first FDA approved agent for the treatment of not only ARMD but also macular edema caused by BRVO, based on the results of BRAVO study. Results of phase III BRAVO study show us that after six monthly intravitreal injections of ranibizumab 55% (0.3mg group), and 61% (0.5mg group) gain more than 15 letters, compared to 28.8% in the control group. Also a central foveal thickness decreased by 158 microns in the control group versus 337 microns in the 0.3 mg group and by 345 microns in the 0.5 mg group. Adverse events are rare - one retinal detachment in the 0.3 mg group, one endophthalmitis and one myocardial infarction in 0.5 mg group, and one stroke in the control group. According to our experience as well as numerous other authorities it is doubtfull that myocardial infarction and stroke are caused by the local treatment with anti-VEGF, since they are most prominent in the older population which is prone to these conditions (Rosenfeld, 2006). After six months the control group received intravitreal ranibizumab on as needed basis; i.e. if macular edema occurs. Therefore, the long-term results remain unknown. We can say that, according to this data, the use of anti-VEGF agents become an important option in macular edema treatment secondary to BRVO;
- Pars plana vitrectomy with removal of the posterior hyaloid is effective in resolving CME (only if the traction is the cause of retinal edema and usually if the duration of the edema is less than 6 months) and improving visual acuity (Figueroa et al., 2004). Due to complications associated with these procedures, such as vitreous hemorrhage, intraoperative retinal tears, rhegmatogenous retinal detachment and cataract development, they are not often in use.

3.7.2 Management of central retinal vein occlusion

Etiology treatment

- Isovolemic hemodilution. Several studies have suggested the presence of abnormal blood viscosity in CRVO patients. Based on that assumption, some authors have

advocated the use of hemodilution in CRVO, but other (Hayreh, 2003) claim that there is little scientifically valid evidence of beneficial effects of this therapy;

- Anticoagulant and antiplatelet therapy. Although no clear ocular benefit of antithrombotic drugs has been demonstrated, antiplatelet drugs (e.g. aspirin) are prescribed for many patients, including CRVO patients. Hayreh (Hayreh, 2002) claims that this therapy as well as the anticoagulant therapy, such as recombinant tissue plasminogen activator (rt-PA), is contraindicated and even harmful for CRVO patients. Some authors have tried local application of rt-PA into retinal branch vein but the results are controversial and complication rate (haemophtalmus, neovascular glaucoma, retinal detachment, eye phthysis) is unacceptably high; rt-PA should penetrate the retina to exert its activity
- Chorioretinal venous anastomosis. The techniques explained earlier may create an anastomosis, but also carry significant risks. Given the variable success rate, these techniques are rarely employed;
- Surgical decompression of the retinal vein. Proposed procedures can be divided into two mayor types; the first is the vitrectomy with radial optic neurotomy, in which a surgeon's approach is from inside the globe, and the second is optic nerve sheet decompression using orbital "outer" approach. Because of the danger and invasiveness of the procedures and the lack of scientific explanation (Hayreh et al., 2002), there is a need for a larger study to eventually find a place for these procedures in the management of CRVO.

Treatment directed at sequelae

- When speaking of sequelae treatment, we have to add an antiglaucomatous treatment as needed if increase of IOP occurs. Local medical therapy such as, β-blocker (timolol 0,5%), α-2 agonists (brimonidine 0'1-0,2%), carbonic anhydrase inhibitor (acetazolamide, dorzolamide) and panretinal photocoagulation. If failed, the other method of treatment has to be applied such as (i) trabeculectomy with antimetabolites as a first step when there is potential to improve state, (ii) aqueous shunt implants as a second step, and (iii) diode laser cyclophotocoagulation or retinal cryoablation , and in the worst case, with no vision and the patient suffering from great pain, (iv) evisceration or enucleation should be considered (Sivak-Callcott et al., 2001);
- Grid-pattern laser photocoagulation. According to CVOS study, these procedures have no beneficial effect on the visual outcome in macular edema due to CRVO, either ischemic or non-ischemic;
- Scatter panretinal laser photocoagulation. It has been almost universally accepted that prophylactic panretinal photocoagulation (PRP) is the treatment of choice to prevent neovascular glaucoma or treat neovascular glaucoma itself in ischemic CRVO. CVOS study revealed that there is no benefit of the prophylactic PRP in the eyes with ischemic CRVO. These results have led to the recommendation that PRP should be applied promptly after the identification of intraocular neovascularization in eyes with ischemic CRVO to minimize the risk of the development of neovascular glaucoma;
- Corticosteroids. Steroids reduce vascular permeability and stabilize the blood-retina barrier. The mechanism for these effects involves inhibition of the production of inflammatory mediators and vascular permeability factors (e.g. VEGF) as well as the stabilization of the vascular endothelial cell tight junctions. The inhibition of VEGF production may further help prevent neovascular sequelae. Some authors have proposed for some patients the systemic use of corticosteroids (Hayreh, 2010) in high

oral doses of about 80 mg of prednisone to control macular edema, which is the main cause of visual loss. Most of the patients with CRVO according to the SCORE study respond to intravitreal triamcinolone application of either 1 or 4 mg doses compared to the standard care in terms of improving visual acuity of more than 15 letters. As far as the safety is concerned, there are more complications such as cataract formation and IOP elevation in the triamcinolone group. Complications rate is higher in the group with higher dose (4 mg) (Ip et al., 2009). Although triamcinolone is a long lasting corticosteroid, it appears that it is not enough and it leads to the development of sustained corticosteroid delivery devices, which release the drug longer. One of them is Retisert which has good results in chronic refractory CME (Ramchandran et al., 2008), with the best results 12 month after injection. However, the complication rates are very high - all phakic eyes developed visually significant cataracts, and 92% have had an elevation of IOP that needed intervention. Allergan conducted an international study on dexamethasone sustained delivery devices (Ozurdex) and the six month results have been published. In CRVO subgroup of patients a significantly better result in gaining visual acuity (more than 15 letters) has been recorded in the group which received 0.7 mg implant compared with control group at 30 and 60 days control point, and not significantly better at 90 and 180 days point. There were no significant differences in cataract formation between groups and ocular hypertension occurred in only 4% of patients receiving an implant. In 2009 FDA gave approval for the Ozurdex in the treatment of macular edema secondary to CRVO;

- Intravitreal anti vascular endothelial growth factor (anti-VEGF). As VEGF plays a key role in the pathophysiology of CRVO, several anti-VEGF treatments have been developed to decrease VEGF and block vascular permeability and angiogenic activity (bevacizumab, ranibizumab, pegaptanib). According to the results of CRUISE study, FDA released approval of intravitreal ranibizumab for the treatment of CRVO (Brown et al., 2010);
- In cases of refractory CME secondary to CRVO with no resolution after bevacizumab or IVTA individually, a combination treatment with both agents may result in resolution of CME and significant recovery of visual acuity (Ehlers & Fekrat, 2011; Ekdawi & Bakri, 2007). These results suggest that for some patients, the complementary actions of bevacizumab and IVTA on VEGF and inflammation may be more effective than either therapy used alone in the treatment of RVO. Further studies examining multi-modal therapy are needed to answer these questions regarding optimal therapy. Probably a combined treatment or new drugs will have a better efficacy.

4. Ocular Ischemic Syndrome

Obstructions more proximal to the central retinal artery usually cause a more chronic form of visual problem – the ocular ischemic syndrome. Ocular ischemic syndrome (OIS) is a condition that has a variable spectrum of signs and symptoms that result from chronic ocular insufficiency, usually secondary to severe carotid artery disease (CAD). Moreover, they may be the first manifestations of CAD (Dugan & Green, 1991). OIS was firstly described in 1963 and named *venous stasis retinopathy* (Hedges, 1963; Kearns & Hollenhorst, 1963).

4.1 Epidemiology

The OIS occurs at a mean age of 65 years and generally does not develop before 50 years of age. Men outnumber women by a ratio of 2:1, because of the higher incidence of

atherosclerosis in men (Brown & Magargal, 1988). No racial predilection exists. Bilaterally OIS occurs up to 22% of cases (Mendrinos et al., 2010). The incidence of OIS is not known precisely, but is estimated at 7.5 cases per million people annually (Sturrock & Mueller, 1984).

Different studies found various incidence of OIS development in patients with hemodynamically significant CAD, which is 4%, 18%, and 1.5% respectively (Kearns & Hollenhorst, 1963; Kearns et al., 1978; Klijn et al., 2002). Ipsilateral transient monocular visual loss is the hallmark of carotid insufficiency and occurs in 30-40% of patients with CAD. CAD on the one common (CCA) or internal carotid artery (ICA) is often accompanied by occlusion or stenosis of the opposite carotid artery (Mendrinos et al., 2010).

4.2 Pathophysiology and causes

Both stenosis and occlusion of the common or internal carotid arteries are responsible for ipsilateral ocular signs and symptoms that may herald a devastating cerebral infarction (Biousse, 1997). The decreased vascular perfusion results in tissue hypoxia and increased ocular ischemia, leading to neovascularization (Leibovitch et al., 2009; Kahn et al., 1986; Takaki et al., 2008).

Patients who develop OIS show decreased blood flow in the retrobulbar vessels and reversal of blood flow in the ophthalmic artery (OA) (Mendrinos et al., 2010). OA shunts blood flow away from the eye to the low-resistance intracranial circuit. This blood steal leads to further reduction of retrobulbar blood flow, hypoperfusion, and subsequently ocular ischemia.

OIS develops especially in patients with poor collateral circulation between the internal and external arterial systems or between the two ICAs. The occurrence of cerebral infarctions and poor neurologic prognosis could also be explained by the insufficient collateral circulation.

4.3 Clinical presentation

Ocular ischemic syndrome encompasses a spectrum of ocular signs and symptoms that are the result of ocular hypoperfusion caused by severe carotid artery obstruction.

4.3.1 Symptoms

The presenting symptom is a variable degree of visual loss often accompanied by pain caused either by ischemia of the globe or elevated intraocular pressure in neovascular glaucoma. The natural course of the ischemic syndrome is generally poor, although there is certain proportion of cases with milder clinical picture retaining the visual function.

4.3.2 Signs

The anterior segment signs are often present: neovascularization of the iris in approximately two thirds of eyes at the time of initial examination; corneal edema and striae usually concurrent with increased pressure from neovascular glaucoma. Although the iris neovascularization is the presenting sign in large percentage of patients with ischemic syndrome, only one third of cases develop secondary neovascular glaucoma. This may be due to a lower arterial supply of the ciliary body causing hypotony or normal pressure in

spite neovascular changes in the iridocorneal angle. There may be signs of mild anterior chamber reaction in 20% of these eyes with flare being a more prominent feature than the cellular response (Kahn et al., 1986). Advanced lens opacification may also be present in the late stages of this syndrome. The fundoscopic findings may mimic other vascular retinal disorders and involutive changes seen in elderly population: constriction, straightening and narrowing of the arteries, dilated retinal veins, but without accentuated tortuosity commonly seen in vein occlusions. Venous beading may resemble features of proliferative diabetic retinopathy. In the majority of cases there are dot and blot retinal hemorrhages distributed diffusely around the periphery, but they can spread onto the posterior pole. The other features of retinal ischemia may also be present: cherry red spot appearance, cotton wool exudates, optic atrophy and edema.

4.4 Evaluation and imaging

A careful clinical examination and lab tests (ESR, CRP) must be undertaken to exclude possible temporal arteritis, which may resemble this clinical entity and mandates different diagnostic and therapeutic approach, which may prevent further visual loss and potentially blindness.

4.4.1 Fluorescein and indocyanine green angiography

Besides clinical examination, fluorescein angiography (FA) can help to establish the diagnosis of ocular ischemic syndrome. Prolonged choroidal filling time is the most specific angiographic sign of ocular ischemic syndrome (Mendrinos et al., 2010). Patchy filling of the choroid that lasts more than 5 seconds is seen in about 60% of eyes affected by ocular ischemic syndrome (Brown & Margargal, 1998). Staining of the retinal vessels, both the major vessels and its branches, is another sign seen in 85% of eyes with ocular ischemic syndrome. Demonstration of a well-demarcated leading edge of fluorescein dye within a retinal artery is a typical sign of OIS. Other findings on fluorescein angiography include an increased arteriovenous transit time (over 11 seconds), macular edema, retinal capillary nonperfusion, and evidence of microaneurysms (especially in the periphery) (Richard et al., 1998).

Indocyanine green angiography (ICG) shows signs of choroidal hypoperfusion – occlusion of choriocapillaries with filling defects in the posterior pole or the mid-periphery. There is also prolonged arm to choroid (over 10 seconds) and intrachoroidal circulation time (over 5-6 seconds). Another characteristic finding is slow filling of the watershed zones of the choroids) (Richard et al., 1998).

4.4.2 Electroretinography

Electroretinography demonstrates a decrease in both a and b waves in these eyes, which is in contrast to the sparing of the a wave found in central retinal artery occlusions (Brown et al., 1982).

It is of paramount role to assess the carotid artery function since the endarterectomy procedure reduces the risk of stroke as life threatening consequence and there is some evidence of improvement in retinal function viewed through the improvement of a and b waves in electroretinography, as well as the normalization of preoperative retrograde ophthalmic artery flow shown on Doppler color imaging (Kawaguchi et al., 2001; Story et al., 1995).

4.4.3 Duplex carotid ultrasonography

Duplex carotid ultrasonography combines B-mode ultrasound and Doppler ultrasound providing the morphologic imaging and flow velocity data. It is the most commonly used noninvasive method in evaluation of carotid artery obstruction.

Color Doppler imaging is a noninvasive tool for assessing the velocity of blood flow in the retrobulbar circulation. Diminished velocities of the blood flow in the central retinal artery, choroidal vessels, and ophthalmic artery are typical. There may be a reversal of flow in the ophthalmic artery, as well. Color Doppler imaging may assess the carotid arteries simultaneously.

4.4.4 Invasive diagnostics

If noninvasive carotid artery evaluation is unremarkable in an eye that shows signs suggestive of ocular ischemia, conventional carotid arteriography or digital subtraction angiography may be required to detect possible chronic obstruction of the ophthalmic artery (Wardlaw et al., 2006).

The new minimally invasive methods, magnetic resonance angiography and computed tomographic angiography are evolving and improving as adjunctive diagnostic tests in evaluating the patients with carotid occlusive disease.

4.5 Differential diagnostic

Diabetic retinopathy

Nonischemic central retinal venous occlusions

Giant cell arteritis

Takayasu arteritis

Ischemic optic neuropathy

Retinal artery occlusion

Neovascular glaucoma

4.6 Management

Management of OIS is basically multidisciplinary and the task of the ophthalmologist is to treat ocular condition, recognize the possible cause of OIS and refer the patient to a cardiologist, neurologist or other specialists, where they can get proper treatment of the cause of OIS.

Ophthalmology treatment consists of increased IOP control, management of neovascularization and control of anterior segment inflammation.

- Anterior segment inflammation is usually treated with topical steroids and long acting cycloplegic agents;
- Increased IOP, usually controlled with topical β-adrenergics blockers, ά-agonists and topical or oral carbonic anhydrase inhibitors to reduce aqueous production; prostaglandins (could increase ocular inflammation) and pilocarpin should be avoided;

- Ocular neovascularization following carotid occlusive disease is usually managed with panretinal photocoagulation and can prevent neovascular glaucoma (Carter, 1984; Chen et al., 2001). If PRP is not possible due to media opacities or refractory miosis, other modalities such as transconjunctival cryotherapy of peripheral retina or transscleral diode laser retinopexy should be considered to prevent neovascularization. In any case, PRP works effectively and reduces the iris neovascularization in only 36% of patients with OIS (Sivalingam et al., 1991). In other cases it can even get worse (Turut & Malthieu, 1986), which suggests that uveal ischemia can induce neovascularization, as it is shown on animal model (Hayreh & Baines, 1973). Therefore, in the cases where there is retinal ischemia, prophylactic PRP is advisable. Neovascularization and macular edema caused by OIS can be also treated with intravitreal bevacizumab (Amselem et al., 2007). In this case report neovascularization regressed, but there was no improvement in VA or IOP. Macular edema can also be treated with triamcinolone intravitreally, reducing macular edema and improving visual acuity (Klais & Spaide, 2004). Further investigation with a more reliable sample is needed to establish the role of this therapy in IOS patient. Additionally, we have to mention that when neovascular glaucoma occurs it is usually refractory to medical therapy and if panretinal photocoagulation failed the other method of treatment has to be applied, such as (i) trabeculectomy with antimetabolites as a first step when there is potential to improve state, (ii) aqueous shunt implants as a second step, and (iii) diode laser cyclophotocoagulation or retinal cryoablation, and in the worst case, with no vision and the patient suffering from great pain (iv) evisceration or enucleation should be considered (Sivak-Callcott et al., 2001).

Medical treatment includes conservative treatment by other specialists in order to manage associated systemic diseases or states such as coronary artery disease, hiperlipidemia, hypertension, diabetes mellitus etc.

Some of the surgical treatment is advocated to manage carotid stenosis and to improve ocular ischemia (Costa et al. 1999; Chaer & Makaroun, 2008; Sivalingam et al., 1991), such as carotid artery endarterectomy (CEA), carotid artery stenting (CAS) or extracranial-intracranial arterial bypass surgery (EC-IC), but without sufficient evidence to claim improvement of the ocular state with this treatment, except for CEA, where studies show some beneficial effect on the patient who has mild ocular ischemia and less effect on the patient with a greater degree of ocular ischemia, where retinal damage has probably become irreversible.

In conclusion, we can say that the ocular ischemic syndrome is a rare, vision-threatening condition and since the ophthalmologists may be the first to deal with such patients, they should be aware of the clinical presentation of OIS and recognize it early enough to start treating the condition when visual acuity is preserved enough and when prognosis is better. The continuing improvements in the diagnostic techniques, medical management and surgical treatment of carotid artery occlusive disease make the role of ophthalmologists increasingly important in the early detection and management of the OIS and its comorbidity.

5. Conclusion

Retinal vascular occlusions are an important cause of visual loss, particularly in elderly patients with multifactorial pathophysiological arms uniquely intertwined in each patient. They are often referred to as a „stroke"in the eye due to symptoms and clinical picture, often dramatic in its presentation. It also emphasizes the tremendous influence on patient's quality of life.

Apart from the similar clinical symptoms of visual loss there are some distinctive features that direct the clinician towards the diagnosis of arterial or venous occlusion. A thorough examination should assess the degree of vision loss by testing visual acuity, the presence of afferent pupillary defect, visual field testing, slit lamp examination of both anterior and posterior segments of the eye as well as ERG, which along with afferent pupillary defect and visual field testing provides the most sensitive diagnostic test in distinguishing between ischemic and non ischemic types of the occlusive disease (Hayreh, 2005). Visual acuity alone is not sufficient to validate peripheral retinal function but solely central vision. Therefore, it has been advocated by some authors to combine morphologic and functional tests in order to establish the type of the occlusion which has tremendous impact on the clinical course, prognosis and management of each case. The oxymetry (Gehlert et al., 2010) offers new possible tool in evaluating the perfusion status of the retina as this is extremely important prognostic factor when deciding which diagnostic and therapeutic algorithm should be undertaken in patient with occlusive disorder.

In conclusion we can say that retinal vascular occlusions are very common ocular diseases and the causes of visual loss with poor perspectives in the past, but recent studies on various medications and treatment modalities raise hope between a patient and ophthalmologist for establishing the proper treatment. Although we still cannot foresee, prevent, or causatively and successfully treat occlusive diseases of the retina, there are promising, recently introduced novel options focused on the management of visually deteriorating complications. Intravitreal agents, especially anti-VEGF medications and intravitreal corticosteroid implants have drastically changed the visual outcome for the affected patients. The perspective looks brighter as the development of the most effective treatment regimens and their combinations is evolving. Probably a combined therapy will better act than a single one. Developing new drugs is warranted.

Induction of Branch Retinal Vein Occlusion by Photodynamic Therapy with Rose Bengal in a Rabbit Model

Xiao-Xu Zhou[1], Yan-Ping Song[2], Yu-Xing Zhao[2] and Jian-Guo Wu[1,2]
[1]Tianjin Medical University Eye Center, Tianjin,
[2]Department of Ophthalmology of PLA Wuhan General Hospital, Wuhan,
People's Republic of China

1. Introduction

Branch retinal vein occlusion (BRVO) is a common vascular disorder that is frequently associated with severe vision loss due to its complications. There are two forms of BRVO, the ischaemic and the non-ischemic, both leading to loss of visual acuity. About 20-30% of the BRVOS are ischemic and the majority of them develop secondary glaucoma and rubeosis. [1] Although this disorder was first reported by J. von Michel in 1878, its pathogenesis has still not been fully understood, and no effective therapy has been developed for this disorder [1-3]. Comparative research on this disorder is based on clinical models of BRVO.

The pathological features of BRVO can be more accurately reproduced by a photodynamic method to induce thrombosis in retinal vessels[4–14] than by using other methods such as laser coagulation[15–17], electrocoagulation of the retinal vein via the vitreous body[18], intravenous thrombin instillation[19–21] and endothelin-I injection into the posterior vitreous body[22, 23]. In the photodynamic method, a photosensitizing agent, namely, rose Bengal, is injected intravenously. This dye absorbs light maximally at a specific wavelength of 550 nm. Dye activation in the presence of molecular oxygen leads to the generation of singlet oxygen, which in turn acts locally to injure or destroy the vascular endothelium. The altered endothelium provides a surface for platelet aggregation and subsequent thrombosis. By using this method, thrombi can be produced in vessels. Because relatively low light intensities are required to initiate this process, the thermal effects on the surrounding tissues are minimized.

In this investigation, we used a Xenon arc lamp as the light source, and visible light was transmitted through an intraocular fiber to induce BRVO in pigmented rabbits. The characteristics of BRVO were evaluated quantitatively, and histological studies were performed to support the clinical findings. The results provided a framework for future applications of this technique.

2. Materials and methods

2.1 Animals and husbandry

Thirty-two male Standard Chinchilla rabbits were purchased from the Experimental Animal Center of Tianjin Medical University (Tianjin, China) and allowed to acclimate upon arrival

for 10 d before the initiation of the experiment. At the beginning of the study, the animals were aged 3–4 months and weighed 2.5–3.5 kg. All experimental animals were housed in individual cages under stable environmental conditions: diet, commercial pellet diet (Lushifu, Beijing, China) and tap water ad libitum; relative humidity, 45–55%; temperature, 18°C; and light-dark cycle, 12/12 h (intensity, 300 lux).

The study was approved by the Ethics Committee of Tianjin medical university. All animal experiments were performed in accordance with the conventions of the Association for Research in Vision and Ophthalmology (ARVO) for ethics in animal experimentation.

2.2 Experimental design

The 32 rabbits (32 eyes, 32 vessels) were randomly divided into 15 treatment groups (n = 2) and 1 control group (n = 2). The treatment groups were administered 5 different rose Bengal doses (3, 6, 9, 12 and 15 mg/kg) and exposed to light of 3 different intensities (600, 1000 and 1400 lux) 1 min later. In the control group rabbits, the vessels were exposed to a light intensity of 1400 lux for 20 min without injection of the rose Bengal dye.

2.3 Experimental procedure

In preparation for the treatment and follow-up examinations, the rabbits were fully anesthetized with an intramuscular injection of 60 mg/kg ketamine (Beijing Shuanghe Pharmaceuticals, Beijing, China) and 8 mg/kg xylazine (Beijing Shuanghe Pharmaceuticals, Beijing, China). The pupils were dilated using 0.5% tropicamide eye drops (Beijing Shuanghe Pharmaceuticals, Beijing, China).

Rose Bengal (tetrachloro-tetraiodo-fluorescein sodium; certified purity, 90%; Sigma, St. Louis, MO) was dissolved in normal saline (30 mg/ml), sterilized by passage through a 0.22-μm filter and injected intravenously in doses of 3, 6, 9, 12 or 15 mg/kg before the light treatment. A Xenon arc lamp (Anshijia Instrument Co. Ltd., Beijing, China) was used as a light source, and light was transmitted by using a 0.2-mm intraocular illumination fiber (Alcon (China) Ophthalmic Product Co. Ltd., Shanghai, China). Light intensity was measured using a digital lux meter (LX-9621; Landtek Instrument Co. Ltd., Guangzhou, China). Average values of 600, 1000 and 1400 lux, for the low, medium and high settings, respectively, were obtained with less than 3% variation in repeated measurements throughout the study.

According to the treatment protocol, the rabbits were placed on a stage under a surgical microscope (OPTON Universal S3; Germany). 2% methylcellulose solution (Zhengda Co. Ltd., Shandong, China) is dropped on the cornea to couple the input light into the 30-degree prism lens (Anshijia Instrument Co. Ltd., Beijing, China). The operations were observed by using a contact lens and a surgical microscope. A 25-gauge trocar (Alcon (China) Ophthalmic Product Co. Ltd., Shanghai, China) was used to make an incisions in the conjunctiva and sclera at the projection holes located supratemporally 3 mm from the corneal limbus, then the needle was removed and the intraocular fiber was inserted through the incision and its direction was toward optic disc, the depth was 10 mm. Rose Bengal was injected intravenously through the marginal ear vein. After 1 min, the trunk vessels adjacent to the optic disc of 1~ 3 mm were exposed to a beam of white light. The duration of continuous exposure to light did not exceed 20 min, and the exposure time was recorded if complete vascular occlusion was observed. The fiber finally was then taken out and the sclera was finally sutured.

Fundus fluorescein angiography (FFA) was performed using a fundus camera (Zeiss FF450IR; Carl Zeiss Far East Co. Ltd., Beijing, China) before the treatment and everyday after the treatment until the occluded vein reopened. The 5 mg aqueous fluorescein sodium (100 mg/ml, Baiyunshan Pharmaceuticals Co. Ltd., Guangzhou, China) was injected into ear veins immediately prior to FFA under anesthesia and pupil dilation those were as same as the prior.

2.4 Experimental observation

The rate and duration of vessel occlusion are confirmed with an ophthalmoscope and by FFA. The blood flow was confirmed by a scleral depressor transiently applied pressure on the equator of the eyeball, thereby the higher intraocular pressure (IOP) reduced the flow rate until freely moving red blood cells were seen. Once the scleral depressor was removed, a rapid uninterrupted column of blood flow passed through without the presence of stagnant red blood cells. [9] These dynamic phenomenons were monitored by an ophthalmoscope and it was the character of reperfused vessels.

When reperfusion was noted on post-treatment day 1, the number of days of occlusion was defined as 0. When the vessel was observed to be occluded on day 1 but not on day 2, the number of days of occlusion was defined as 1 and so on.

Two rabbits in the control group and 1 rabbit in the treatment groups in whom BRVO was confirmed by FFA were euthanized using intravenous overdose of pentobarbital sodium (Beijing Shuanghe Pharmaceuticals, Beijing, China). Their eyes were enucleated and prepared for light microscopic examination by using standard techniques. Sections (5-µm-thick) were stained with haematoxylin/eosin. The remaining rabbits were euthanized by administering an overdose of pentobarbital sodium at the end of the experiment.

2.5 Statistical analysis

A partial correlation coefficient was used to analyze the relationship between the time of thrombosis, the drug dose, and light intensity. A P value of 0.05 or less was considered statistically significant. All data were analysed with the SPSS 11.5 software.

3. Results

3.1 Evaluation of BRVO animal model

BRVO models were developed in 22 of the 30 rabbits in the treatment group. The fundus could be observed in detail by using a surgical microscope (please see supplemental video 1). In the site exposed to light, photodynamic injury resulted in white debris (plaque-like thrombi) and the stagnation of blood flow. FFA showed the engorged distal ends of the venules proximal to the occlusion site and peripheral retinal oedema in the BRVO area (Figure 1).

Histological sections were studied to confirm the presence and extent of the photodynamic lesions. Retinal vein damage was confined to the area of direct light exposure in the treatment groups. Histological examination revealed thrombi consisting of platelet aggregates, stagnant red blood cells and a few white blood cells. Occluded retinal vein histological section indicated that compact thrombus filled the entire vein cavity and occlusion is evident. (Figure 2).

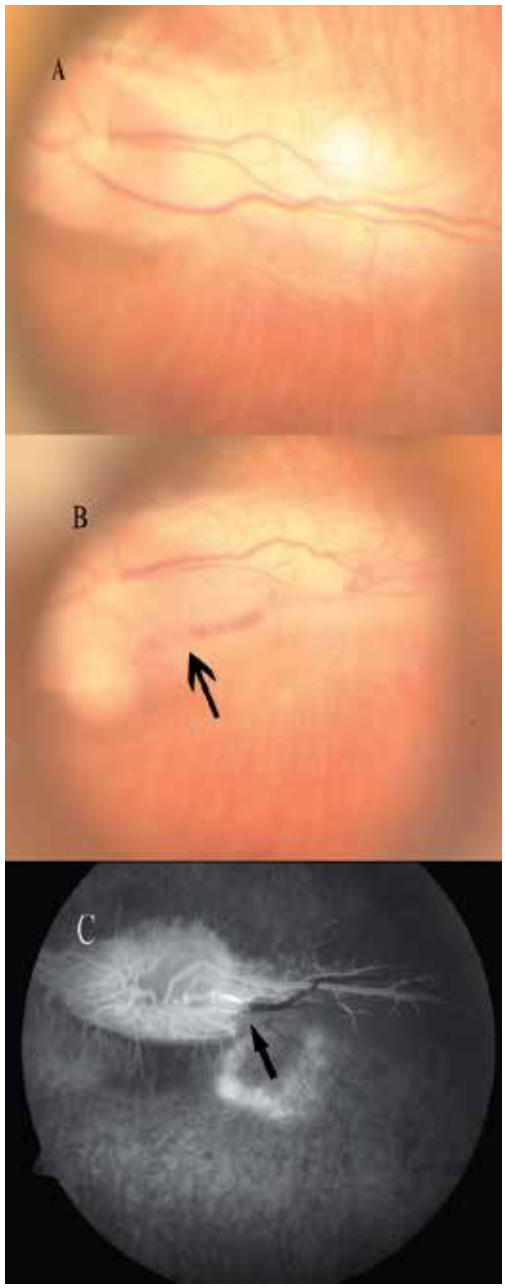

Fig. 1. **Photodynamic thrombosis of a branch retinal vein in a pigmented rabbit eye.** Initial formation of a thrombosis in the target vein (A) and complete obliteration of the vessel lumen (B). FFA showed a delay in the time required for angiosclerosis in the distal end of the vein and discontinuous intravenous blood flow in the vicinity of the optic disc (C). Arrows indicate the occlusion site and peripheral retinal oedema.

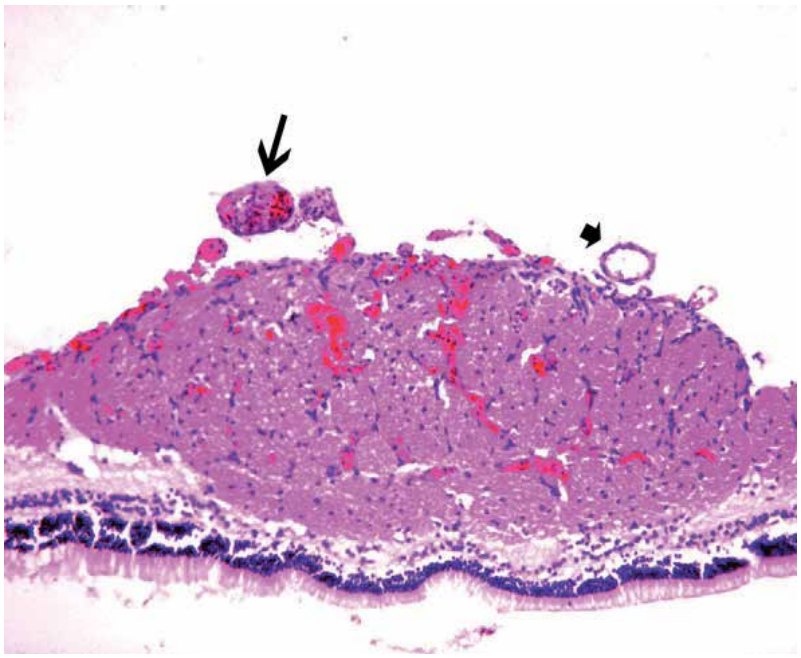

Fig. 2. **Histological findings.** Two hours after thrombosis, the thrombus filled the entire vein cavity (long arrow), and the artery was normal (short arrow). The thrombus consisted of platelet aggregates, stagnant red blood cells and a few white blood cells. Magnification, 200×.

The control vessels and the blood flow through them were as same as those in healthy animals. The histological sections from the rabbits that were not injected with rose Bengal showed no evidence of photochemical or thermal retinal damage in the site that was exposed to a light intensity of 1400 lux (maximum light intensity) for 20 min.

3.2 Dose- and light-response studies

Vein occlusion in the pigmented rabbits was considered as the end point for determining dose- and light-response relationships. In 22 successful BRVO models, the time required to produce an occlusion decreased with an increase in the dose of rose Bengal administered and the light intensity. Rose Bengal at doses of more than 9 mg/kg was effective in producing BRVO; a dose of 6 mg/kg was ineffective in producing BRVO at a light intensity of 600 lux. At a dose of 3 mg/kg, small plaques also developed in the target vessel; however, they did not progress to vascular occlusions in 20 min even if the light intensity was as high as 1400 lux. The total light energy required to produce an occlusion increased from an average of 600 lux with 9 mg/kg of rose Bengal to 1000 lux with 6 mg/kg of rose Bengal. The time of occurrence of thrombosis showed a negative correlation with the drug dose and light intensity. A decrease in the time required for the development of BRVO corresponded to a higher drug dose (partial $r = -0.7895$; $P < 0.001$) and a higher light intensity (partial $r = -0.9060$; $P < 0.001$) (Figure 3).

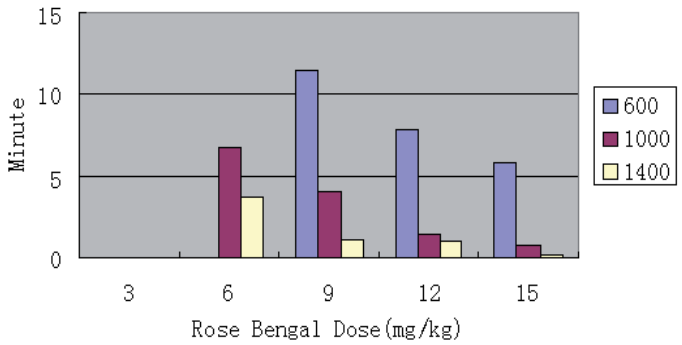

Fig. 3. **The relationship between the time required for thrombosis and the dose of rose Bengal and the light intensity.** The mean value of the time required for thrombosis was determined (n = 2). Complete BRVO formation did not occur when a dose of 3 mg/kg rose Bengal was used, and a dose of 6 mg/kg rose Bengal was ineffective in producing BRVO at a light intensity of 600 lux.

3.3 Duration of occlusion

In the early period of BRVO in the animal models, FFA and fundus photography documented the blood along the circuitous expanded vein, and retinal oedema that was similar to the lesion in humans. The area of the white thrombus gradually decreased with time, and the angiostenosis in the distal end of the retinal vein also gradually decreased. In 21 cases, the minimum duration record for the reopening of an occlusion was 3 d and the maximum, 10 d (Figure 4).

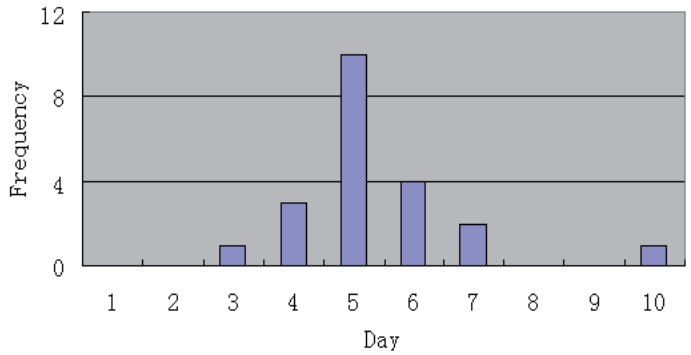

Fig. 4. **The frequency of the duration of vessel occlusion.** The duration of BRVO varied from 3 to 10 d. The data correspond to a Gaussian distribution ($P < 0.01$); the 95% confidence bound was 4.73–6.03 d, and the mean duration of vessel occlusion was 5.38 ± 1.43 d (n = 21).

4. Discussion

While developing an animal model, the following factors should be considered: the animal species used, the ease of development and reproducibility of the model and the degree of similarity of the model with the human disease. In this study, we focus on optimizing the method used to induce experimental thrombosis.

The animal species that are usually selected for the development of BRVO animal models are mouse, rat, rabbit, cat, pig, dog and monkey. Mice[14] and rats[5–7, 9] are suitable for the development of large numbers of RVO models for research because of their low price, easy availability and breeding management. Further, these models enable easy identification of the retinal artery and vein. However, the eye of mice or rats is too small to permit investigative surgical procedures. The structure of the retina in pigs[12, 15], cats[8] or dogs[4] is similar to that in humans except that it does not have a macular region. The retinal blood supply in rhesus monkeys[16, 17] is similar to that in human; however, the sources of these animals are limited, and they are difficult to breed and manage. Compared with the eyeballs of other animal species, the rabbit eyeball is sufficiently large to operate[19–23]. Further, rabbits are inexpensive, can be easily bred and the FFA of the rabbit eye is stable. Therefore, we selected pigmented rabbits for our study.

The combination of intraocular fibre illumination with the administration of rose Bengal should be classified as a photodynamic method of inducing BRVO because the wavelength of visible light include 550 nm. These findings correspond to Virchow's hypothesis of thrombosis in humans. Compared with the photodynamic method, laser coagulation[15–17] requires higher energy and a longer exposure time, which would inevitably result in heat injury and disruption of the vessel wall, and subsequently, frequent bleeding. Electrocoagulation of the retinal vein via the vitreous body[18] utilizes electrothermal energy to destroy the vascular endothelium and block the vessels, which is different from the process of thrombosis. In intravitreous thrombin instillation method[19–21], the location of the retinal thrombus could not be determined; thus, the thrombus may occlude other regions but not the target vessels. The injection of endothelin-I into the posterior vitreous body[22, 23] caused complete occlusion of the temporal retinal vessels, but this vasospastic mechanism is also unsuitable for application in the experimental induction of thrombosis because actual clinical BRVO was occluded at one or some spots in vein.

Presently, an argon (Ar) laser is often used as the excitation light source in the photodynamic method because its wavelength of 514 nm is similar to the light absorption peak of rose Bengal. However, heat injury from laser-coagulation to the retinal tissue and its vessels is observed. Moreover, due to the pulsed excitation of the laser, continuous exposure of the vessel to the laser beam is impossible. Consequently, it is difficult to adjust the level of energy used in this procedure: if the energy level is too low, no thrombus formation occurs and if it is too high, vessel hemorrhage occurs[8]. Some researchers utilize common light sources such as slit lamps and Xenon lamps to develop BRVO animal models. However, the use of these light sources resulted in an extensive arteriovenous obstruction caused due to the exposure of a large area to the light source, therefore, these light sources are not suitable for studying a typical BRVO[9, 10, 13]. In a previous study, we use a microsurgical illumination system, which comprised a 0.9-mm intraocular fibre that served as an endoilluminator to produce RVO in pigs[11]; the intraocular fibre illuminated the nearby retinal vascular target

and by localizing energy, it is able to produce a thrombus as effectively as laser irradiation. However, the diameter of the retinal trunk vein in rabbits was only 150–200 μm, and the microsurgical system was too wide to the rabbit. Therefore, in this study, we used a Xenon arc lamp as a light source and designed a 0.2 mm fiber for illumination to ensure that the light beam irradiate the trunk vein and not the accompanying artery. We find that this is a simple and reliable system for developing BRVO models in rabbits.

The process of formation of BRVO in our rabbit model can be visualized and photographed using a surgical microscope. At the site exposed to light, the following course of thrombogenesis is recognized: photodynamic injury resulted in a decrease in the rate of venous blood flow; this is followed by the appearance of stagnant red blood cells in the vessel, the gradual accumulation of white debris (plaque-like thrombi) and the development of a vascular occlusion. The distal ends of the venules are engorged proximal to the occlusion site. The morphological and histopathological changes are similar to Kohner's results[24]. No changes were observe in the light microscopic images of the control vessels; this confirmes that illumination do not produce heat injury in the retinal vessels and tissue.

The dose- and light-response studies show that the time of occurrence of thrombosis correlate negatively with the drug dose and light intensity; further, the basic set of parameters require to produce an occlusion is an average light intensity of 600 lux, a rose Bengal dose of 9 mg/kg and an exposure time of 11.5 min or an average light intensity of 1000 lux, a rose Bengal dose of 6 mg/kg and an exposure time of 6.75 min. Thus, we suggest that the optimum parameters should be 1000 lux, 9 mg/kg of rose Bengal and an exposure time of 3–5 min. This suggestion is based on the following considerations: the experimental dose of rose Bengal in this model is maintained as low as possible to prevent the leakage of rose Bengal into the vitreous humour and the anterior chamber[12]; the energy level of the light used to induce thrombosis is higher than that in the breeding conditions (300 lux); this ensures that thrombosis occur only in the area exposed to the light and not in other vessels. On the other hand, the exposure time of 3–5 min was suitable for operation. The optimization of this method may aid investigators in controlling thrombus formation more precisely.

Clinical BRVO is a disease of long duration and various types [1-3]; however, the experimental occlusion is maintained for 3 to 10 d (average, 5.38 d) in our model. This may be attributed to the use of young and healthy experimental animals, the sudden generation of an obstruction in the normal vascular bed and the activation of an autochthonous repair mechanism; all these factors result in rapid thrombolysis. Therefore, this BRVO model is very suitable for observation of immediate therapy experiment, for example, surgery; and not suitable for long-term drug treatment studies.

Regulation of Angiogenesis in Choroidal Neovascularization of Age Related Macular Degeneration by Endogenous Angioinhibitors

Venugopal Gunda[1] and Yakkanti A. Sudhakar[1,2]
[1]Cell Signaling, Retinal and Tumor Angiogenesis Laboratory, Department of Genetics, Boys Town National Research Hospital, Omaha, NE,
[2]Department of Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, USA

1. Introduction

The sense of vision has utmost significance and the loss of vision leads to the impairment of active human behavior as evident in pathological disorders that affect vision. Among different pathological visual disorders, Age Related Macular Degeneration (AMD/ARMD) is of serious concern as a leading cause of blindness, observed with aging globally. The clinical manifestation of AMD includes retinal damage with the degeneration of macula, leading to the partial or complete loss of acuity in vision. One form of pathologic AMD named, "wet form of AMD", involves the growth of new blood vessels from the choroid which lies underneath the retina, leading to the pathological blood vessel growth termed as Choroidal Neovascularization (CNV), with subsequent damage to the retina. Thus, choroidal neovascularization reflects a pathological angiogenic condition, where the loss of regulation over angiogenesis leads to the retinal damage. It also indicates that, the regulation of pathological angiogenesis can be an efficient strategy in preventing CNV of AMD. Though, some genetic disposition and aging factors are identified as peculiar etiological factors causing AMD; recent studies have shown that different cellular mechanisms regulating angiogenesis are common in different angiogenic scenarios including CNV. Further, the role of different endogenous angiogenesis inhibitors/angioinhibitors conferring the tissues with angiogenic regulation has been deciphered, which can be applied for regulation of CNV in AMD through inhibition of angiogenic signaling mechanisms. The present chapter provides an overview of the role of factors leading to choroidal neovascularization, the mechanisms underlying such angiogenesis and also the scope for endogenous angioinhibitors in regulation of CNV of AMD.

1.1 Retina and choroid

Retina is the inner most layer of the eye, which possesses anatomically ten distinct layers that are broadly categorized into two layers. The inner neural layer comprising of extensive

nervous tissue towards the vitreous chamber and the outer retinal pigmented epithelium (RPE) adhering to the choroid. Some of the functions of the RPE include the phagocytosis of outer retinal segmental discs, maintenance of chorio-capillaries, fluid and electrolyte balance in subretinal space. Choroid is the highly vascular and pigmented tissue of the eye lying between the retina and the sclera. It consists of lamina suprachoroidea adhering to sclera, followed by lamina vesculosa, chorio-capillaries, stroma and Bruch membrane adhering to the RPE. Choroid is rich in vasculature and the extracellular matrix (ECM) components, including collagen and elastin fibers. It provides nutrient, metabolite and gaseous exchange to the retina by diffusion through chorio-capillaries.

1.2 Choroidal neovascularization in age related macular degeneration

The histological proximity between retinal pigmented epithelium and choroid confers not only physiological but also pathological effect on RPE. The mechanical barrier that separates the RPE from choroid is the Bruch membrane, which in turn consists of basement membrane secreted by RPE, inner collagenous layer, elastic layer, outer collagenous zone and the basement membrane of chorio-capillaries acting as a mechanical barrier for the underlying chorio-capillaries, but facilitating diffusion of metabolites and gaseous exchange for RPE. In cases of CNV the Bruch membrane is distorted with initial deposition of lipid and protienaceous component called 'drusen' followed by the growth and penetration of blood capillaries from choroid into Bruch membrane, finally leading to the leakage of fluid into sub-retinal spaces and retinal or retinal pigmented epithelial damage (Green, 1999; Green and Enger, 1993; Jager et al., 2008).

1.3 Factors for choroidal neovascularization in age related macular degeneration

Pathological neovascularization in CNV of AMD is considered to be contributed by both the angiogenesis and vasculogenesis, which are the processes of *de-novo* blood vessel formation (Chan-Ling et al., 2011; Jager et al., 2008). Angiogenesis is the process of formation of new blood vessels from the pre-existing ones, which involves the role of different cell types and remodeling of ECM. The inception of different cell types involved in the angiogenesis, such as, the endothelial cells (ECs) of RPE and choroid involved in CNV, mural cells and inflammatory cells occurs through vasculogenesis, by the differentiation of endothelial progenitor cells (EPCs). The EPCs found in the normal circulation are recruited into angiogenic sites, where they differentiate into different cell types leading to angiogenesis (Chan-Ling et al., 2011; Jager et al., 2008). However, the salient feature of neovascularization involves the common sequential events of angiogenesis including the proliferation of ECs, degradation of ECM or vascular basement membrane (VBM) by ECs through secretion of proteases, migration and differentiation of ECs into tip and stalk cells, lumen development, ECM reorganization and finally vessel anastomosing into functional capillaries (Carmeliet and Jain, 2000). These sequential steps of angiogenesis are considered to be common for CNV, which are initiated by the release of angiogenic factors by the RPE and other cell types differentiated from EPCs or infiltrating through the leaky capillaries in response to aging evoked stress (Alon et al., 1995; Grossniklaus et al., 2002). The initiating cellular and physiological factors that lead to the secretion of angiogenic factors by ECs and other cell types have been identified in different studies, which can be systematically framed for synergistic interpretation of etiological factors leading to CNV.

The normal function of phagocytosis and degradation of phagocytosed membranes is impaired with aging in RPE, leading to the accumulation of lipofuscin in these cells, with senescence (Marshall, 1987; Young and Bok, 1969). Ischemia and hypoxia evident in the ocular tissues of CNV are identified as factors promoting free radical generation in RPE and also the release of cellular lipids and proteinaceous deposits into the Bruch membrane (Spaide et al., 2003). Thus, impairing Bruch membrane's barrier function and in turn leading to the secretion of different angiogenic factors like vascular endothelial growth factor (VEGF), transforming growth factor-β (TGF- β), basic fibroblast growth factor (bFGF), insulin-like growth factor-1 and platelet derived growth factor (PDGF) by the RPE and the macrophages and stromal cells that are recruited by the differentiation of EPCs (Alon et al., 1995; Grossniklaus et al., 2002; Lu and Adamis, 2006; Penn et al., 2008; Young and Bok, 1969). Damage to the Bruch membrane is considered to enhance the diffusion of the growth factors, which elicit angiogenic signaling in the ECs (Lu and Adamis, 2006; Marshall, 1987; Penn et al., 2008).

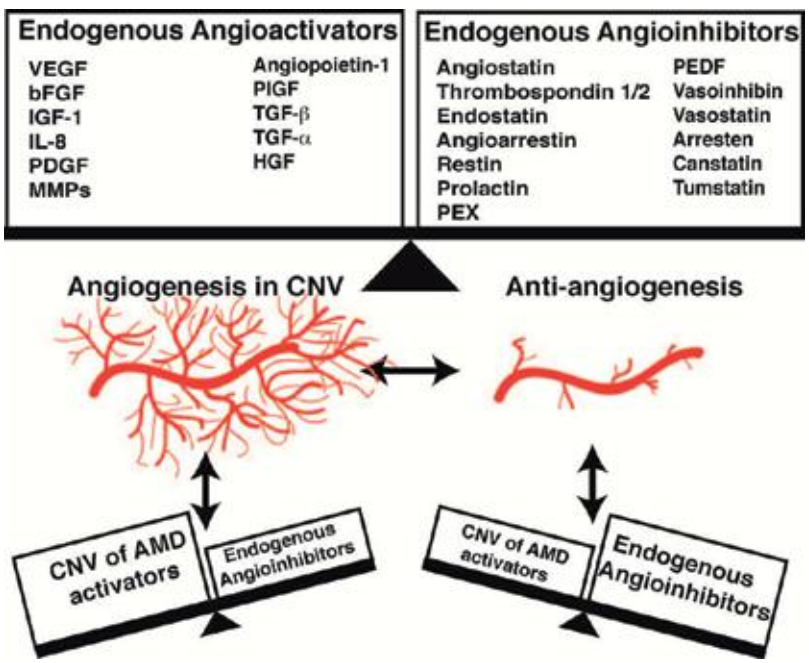

Fig. 1. **The angiogenic balance between endogenous angioactivators and angioinhibitors regulate vascular homeostasis.** Angiogenesis under physiological and pathological conditions is associated with up-regulation of endogenous angioactivators and/or down-regulation of endogenous angioinhibitors. Up-regulation of angioinhibitors and/or down-regulation of angioactivators may be associated with impaired neovascularization capacity in the choroidal neovascularization in age related macular degeneration (CNV of AMD). VEGF, vascular endothelial growth factor; bFGF, basic fibroblast growth factor; IGF-I, insulin-like growth factor-I; IL-8, interleukin-8; PDGF, platelet-derived growth factor; PlGF, placental growth factor; TGF-α and β, transforming growth factor-α and β; HGF, Hepatocyte growth factor

Endogenous Angioactivators	Potent Receptors	Angiogenic action
Vascular endothelial growth factor (VEGF) & Placental growth factor (PlGF)	VEGFRs (Flt-1, Flk-1, KDR, Flt-4), Neuropilins, HSPG, integrins	Increases EC permeability, proliferation, migration, NO, uPA/PAI-1 & MMP production Inhibiting EC apoptosis, Promotes ECM degradation Monocyte migration
Transforming growth factor-β (TGF-α, –β)	Transforming growth factor receptors	Increased vessel stability and organization, promote secretion of ECM components
basic Fibroblast growth factor (bFGF)	FGFRs, HSPG, integrins	Promotes EC proliferation, migration, tube formation, ECM degradation, vessel maturation
Insulin-like growth factor-1 (IGF-1)	Insulin-like growth factor receptors	Promotes EC migration, proliferation, tube formation
Platelet derived growth factor (PDGF)	PDGF-α, –β, GPCRs, integrins	Increases EC permeability, proliferation, migration
Angiopoietin-1	Tie-2, integrins	EC sprouting, Vessel stabilization
Hepatocyte growth factor (HGF)	Hepatocyte growth factor receptor	Promotes tubulogenesis along with other factors
Interleukin-8 (IL-8)	C-X-C chemokine receptor type (CXCR-1,2)	Activates neovascularization increasing invasiveness of different cell types
Matrix metalloproteinases (MMPs)		Degradation of ECM components promoting EC migration and vessel organization, release of ECM or cell surface bound/sequestred angiogenic fcators

Table 1. Endogenous activators, their receptors and angiogenic activities (EC: endothelial cell, ECM: extracellular matrix, FGFRs: Fibroblast growth factor receptors, Flk-1: Fetal liver kinase-1, Flt-1, 4: fms-related tyrosine kinase, GPCRs: G-protein coupled receptors, HSPG: Heparan sulfate proteoglycan, KDR: kinase insert domain receptor, MMP: matrix metallo proteinase, NO: nitric oxide, Pak: p21 protein activated kinase, PDGF: platelet derived growth factor, Tie: tyrosine kinase with immunoglobulin-like and EGF-like domains, VEGFRs: vascular endothelial growth factor receptors)

The integrins and other ECM binding receptors present on ECs are essential in maintaining the ECM promoted survival and migration in angiogenesis (Avraamides et al., 2008; Mettouchi and Meneguzzi, 2006). The synergistic activation of integrins and other ECM binding receptors on ECs by the growth factors and cytokines leads to the activation of different signaling cascades mediated by the kinases, secondary messengers, transcription factors such as, nuclear factor kappa β (NF-κβ), hypoxia inducible factor-1α (HIF-1α), and other enzymes such as, inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2) and metalloproteinases (MMPs) (Avraamides et al., 2008; Boosani et al., 2007; Egeblad and Werb, 2002; Mettouchi and Meneguzzi, 2006; Oklu et al., 2010). The transcription factors that are stabilized, up-regulated or expressed under hypoxia also lead to activation of different signaling cascades that promote effective survival and proliferation of ECs. The secretion of proteases such as matrix metallo-proteinases (MMPs) including collagenases and elastases, which degrade the collagen and elastin of vascular basement membrane (VBM) promote the migration of ECs. The urokinase is another proteinase, which binds to its receptors (urikanse binding receptor, uPAR) and activates signaling cascades leading to the secretion of MMPs, which promote migration of ECs and angiogenesis. The organization and differentiation of

migrating ECs into tip and stalk cells is further enumerated to be regulated by Wingless type (Wnt)/Frizzled-Notch signaling that provides an insight about formation of functional capillaries in neovascular vessels (Dejana, 2010; Zerlin et al., 2008).

The inflammatory cells that are recruited through the expression of cytokines such as monocyte chemo-attractant protein-1 (Ccl2/MCP-1), Chemokine (C-X-C motif) liagnd 1 (CXCL1), macrophage inflammatory protein-1/-2 (MIP-1, MIP-2) are also considered to play role in CNV progression (Hendricks, 2006). Further, the intriguing stimulative role of Bruch membrane in promoting AMD is also being deciphered by identifying the complement components 3a and 5a (C3a and C5a), which lead to the up-regulation of VEGF-A (Nozaki et al., 2006). Thus, the orchestration of various signaling events at different stages of angiogenesis leads to the neovascularization. The angiogenic ECs lining the neovascular vessels arising due to the above factors in CNV are found to possess fenestrations and also organize into defective capillaries leading to the leakage of macromolecules as well as vascular cells into the Bruch membrane and sub-retinal spaces leading to the degeneration of macula of retina (Dvorak et al., 1995; Roberts and Palade, 1995).

2. Endogenous angioinhibitors

In addition to the angiogenic factors, which activate angiogenesis, tissues and ECM also possess angioinhibitors, which have the potency to inhibit the angiogenesis and thus, regulating the pathological angiogenesis by inhibiting the signaling mechanisms activated by angiogenic factors (Boosani et al., 2010; Sudhakar and Kalluri, 2010, Zhang and Ma, 2007). Nearly, 40 endogenous angioinhibitors have been characterized and some of them are found in the ocular tissues or secreted into vasculature and released into ocular tissues, where they exhibit angio-inhibition and finally regulation of CNV (Boosani et al., 2011; Sudhakar and Kalluri, 2010). The significance of imbalance in the levels of endogenous angioinhibitors and angioactivators in regulation of vascular homeostasis can be summarized as in Figure 1. This significance was also ascertained by the evaluations showing the correlation between the decrease in specific angioinhibitors and the progression of CNV (Bhutto et al., 2008).

2.1 Mechanisms of regulation of CNV by endogenous angioinhibitors

2.1.1 Vasoinhibins

The vasoinhibins (14-18 kDa) are antiangiogenic peptides found in the pituitary, retina and extrapituitary tissues. They constitute the amino terminal regions of three different precursors; prolactin, growth hormone and placental lactogen. Though their precursors do not exhibit angioinhibitory activities; vasoinhibins found in the tissues or those expressed using recombinant methods exhibit antiangiogenic properties (Clapp et al., 2008). The therapeutic potential of vasoinhibins in regulating angiogenesis in CNV and tumor growth was evaluated and studies indicate that adenovirus mediated expression of vasoinhibins inhibits CNV, *in-vivo* and also angiogenesis (Zhou et al., 2010). Mechanisms of regulation of EC survival, proliferation and migration by the vasoinhibins have been deciphered in different studies; nevertheless, the receptors through which the mechanisms are mediated still remain enigmatic. Vasoinhibins regulate the EC migration and survival through inhibition of VEGF and bFGF stimulated MAPK activation (D'Angelo et al., 1995).

Endogenous Angioinhibitor	Parent molecule	Receptors	Mode of action/ Inhibition pathways
Vasoinhibins	Prolactin, growth hormone	Not known	Sos/Ras/MAPK or eNOS /Raf/MAPK, Ca2+/ eNOS/protein phosphatase 2, Ras/Tiam-1/Rac1/Pak1, Bcl-XL, NF-kβ, caspases
PEDF	PEDF	Not known	Possible apoptosis
Arresten	Collagen IV, α1 NC1	α1β1 integrin, HSPG	Raf/MEK/ERK1/2/p38-MAPK, HIF-1α, MMPs
Canstatin	Collagen IV, α2 NC1	αVβ3, αVβ5 integrins, Fas	procaspse-8 and -9, Akt/ FAK/mToR, eIF-4EBP-1, Ribosomal S6-kinase
Tumstatin	Collagen IV, α3NC1	CD47/IAP, αVβ3, α6β1 integrins	FAK/Akt/PI3K/mTOR/ eIF-4EBP1/NFκB, COX-2 signaling
Endostatin	Collagen XVIII-NC1	αVβ1/α5β1 integrins, HSP, glypican, caveolin-1	Ras/Raf/KDR/Flk-1 / ERK/p38-MAPK/p125 FAK/HIF1α/Ephrin/TNFα/NFκB, Wnt signaling
Angiostatin	Plasminogen	ATP synthases, αVβ3 integrin, angiomotin	αVβ3 integrin mediated apoptotis, ATP synthase
Thrombospondins	TSP	CD36, IAP, CD47, HSPG, α3β1 , other integrins	Src-family kinases/ Caspase-3/p38 MAPK, TGF-β signaling
Endorepellin	Perlecan	α2β1 integrins, lipid rafts, caveolin	cAMP-PKA/FAK/p38-MAPK/Hsp27, SHP-1, Ca2+ signaling

Table 2. Endogenous angioinhibitors, their precursors, cell surface receptors and mode of action AMD/ARMD: Age related macular degeneration, Akt: protein kinase B, Bcl-XL: B-cell lymphoma-extra large, bFGF: basic fibroblast growth factor, Ccl2/MCP-1: chemoattractant protein-1, CD(CD47, CD36): cluster of differentiation, CNV: choroidal neovascularization, COX-2: cyclooxygenase-2, eIF-4EBP-1: eukaryotic translation initiation factor-4E binding protein-1, eNOS: endothelial nitric oxide synthase, ECs: endothelial cells, ECM: extracellular matrix, EPCs: endothelail progenitor cells, ERK1/2: extracellular signal-regulated kinase1/2, FAK: focal adhesion kinase, Flk-1: fetal liver kinase-1, HIF-1α: hypoxia inducible factor-1α, Hsp: heat shock protein, HSPG: Heparan sulfate proteoglycan, IAP: integrin associated protein, KDR: kinase insert domain receptor, MAPK: Mitogen activated protein kinase, MEK: MAPK-ERK kinase, MMPs: matrix metallo proteinases, mToR: mammalian target of rapamycin, NF-kβ: nuclear factor kappa β, Pak: p21 protein activated kinase, PDGF: platelet derived growth factor, PEDF: Pigment epithelium derived factor, PEX: noncatalytic Carboxy-terminal hemopexin-like domain of MMP, PI3K: phosphatidyl inositol 3-kinase, Rac: Ras-related C3 botulinin toxin susbtrate 1, Raf: Ras activated factor, Ras: Rat sarcoma, RPE: retinal pigmented epithelium, SHP: Src homology region 2 domain-conatining phopshatase, Sos: Son of sevenless, Src: Schmidt-Ruppin A-2 sarcoma viral oncogene homolog, Tiam: T-lymphoma invasion and metastasis-inducing protein, TGF-β: transforming growth factor β, TNFα: tumor necrosis factorα, TSP: thrombospondin, VBM: vascular basement membrane, VEGF: vascular endothelial growth factor, Wnt: wingless-type

VEGF activated Sos/Ras/MAPK or eNOS/Raf/MAPK-mediated proliferative signaling and Ca2+/eNOS/protein phosphatase-2 mediated vascular permeability and vasodilatation were shown to be inhibited by the vasoinhibins (Gonzalez et al., 2004; Ziche and Morbidelli, 2000). In addition vasoinhibins also inhibit the migration of EC stimulated by IL-1β through Ras/Tiam-1/Rac-1/Pak1 and promote apoptosis through conversion of Bcl-XL to proapoptoctic Bcl-Xs and NF-kβ mediated activation of initiator and effector caspases (Martini et al., 2000; Tabruyn et al., 2003).

2.1.2 Pigment Epithelium Derived Factor (PEDF)

Pigment epithelium derived factor (PEDF) is a 50 kDa, secreted, serpin family glycoprotein, first identified from the cultured fetal RPE conditioned media (Tombran-Tink et al., 1991). PEDF accumulates in the vitreous humor and is also expressed in different adult tissues (Tombran-Tink et al., 1991). Addition of PEDF to the cultured HUVECs increased the number of TUNEL positive cells suggesting apoptotic mode of action of PEDF and thus, possibly preventing EC response to ischemia *in-vivo* (Ho et al., 2007). The levels of PEDF were found to be decreased in Bruch membrane with progression of AMD and concomitant increase in VEGF levels were also identified with decrease in PEDF levels (Bhutto et al., 2008). Different methods of PEDF upregulation have been applied to investigate the effect of PEDF on CNV. Intravitreous injections of adenovirus expressing the PEDF and ultrasound-microbubble technique of noninvasive gene transfer of PEDF gene in rats exhibited significant decrease in the CNV (Gehlbach et al., 2003; Zhou et al., 2009). However, studies also demonstrate that PEDF at lower doses (90μg/ml) has negative effect on CNV whereas; higher doses (2-4 fold) can augment CNV; thus, indicating a strategic approach to be developed during clinical trials for CNV treatment with PEDF (Apte et al., 2004).

2.1.3 Angiostatin

Angiostatins are 38-45 kDa kringle domains derived by the protease activity of parent molecule plasminogen, which itself has significant role in activation of fibrinogen and blood clotting (Hayashi et al., 2008). Some of the angiostatin peptide derivates exhibit anti-angiogenic properties including inhibition of EC proliferation, tube formation and migration. The application of angiostatins in regulating CNV of AMD was evaluated by the expression of the angiostatins *in-vivo*, using viral vectors (Lai et al., 2001). Angiostatins bind to ATP synthases on the surface of ECs leading to their apoptotic death (Burwick et al., 2005; Tarui et al., 2001). Further αVβ3 integrin and angiomotin are also shown to bind angiostatin and induce apoptosis (Burwick et al., 2005; Tarui et al., 2001).

2.1.4 Thrombospondins

Thrombospondins (TSPs) are secreted ECM glycoproteins playing key role in the cellular and ECM interactions (Bornstein, 2001; Lawler, 2000). The NH2-terminal peptides derived from the TSPs, by the action of different proteases are identified to possess angioinhibitory properties. TSP-1 and TSP-2 are trimeric globular domain subunits (145 kDa) categorized into subgroup-A and subgroup-B consists of TSP's 3-5, which are pentameric subunits (110 kDa) (Bornstein, 2009). TSP-1 was the first identified ECM derived endogenous

angioinhibitor from many normal tissues and produced by a variety of cells including platelets, megakaryocytes, epithelial, endothelial and stromal cells (Bornstein, 2009). TSP-1 is secreted by the retinal-pigmented epithelium (RPE) and regulates angiogenesis in normal eye (Miyajima-Uchida et al., 2000). Immunolocalization studies showed decrease in the levels of TSP in the chorio-capillaries and the Bruch membrane of AMD samples (Bhutto et al., 2008). Wispostatin-1 (WISP-1) repeat derived peptide from TSP-1 was shown to inhibit the CNV in LASER induced CNV mice models (Cano Mdel et al., 2009). TSP-1 induces apoptosis in ECs through CD36 and integrin associated protein (IAP)/Src-family protein kinases/Caspase-3/p38 MAPK signaling (Dawson et al., 1997). In addition TSP-1 can also bind to different integrins, including CD47 and heparin sulfated proteoglycans (Kaur et al., 2011). Thus the significance of TSPs in regulation of CNV have been evaluated through detection of endogenous levels in pathological tissues and also by evaluating the effects of TSPs both *in vitro* and *in vivo.*

2.1.5 Arresten

Arresten [α1(IV)NC1], is the 26 kDa collagen type IV, α1 chain derived non-collagenous domain, which functions via binding to α1β1 integrin and heparan sulfate proteolgycans, regulating bFGF and VEGF stimulated activation of ECs (Boosani and Sudhakar, 2006; Colorado et al., 2000; Sudhakar et al., 2005). It inhibits the survival of mouse lung endothelial cells through inhibition of FAK phopshorylation in AKT independent manner (Sudhakar et al., 2005). FAK inhibition by arresten via α1β1 integrin leads to inhibition of downstream Raf/MEK/ERK1/2/p38 MAPK signaling and HIF-1α expression **(Figure 2)**. Inhibition of HIF-1α by arresten is critical in preventing hypoxic survival of ECs through VEGF regulation (Sudhakar et al., 2005). Arresten inhibited VEGF-mediated angiogenesis by promoting apoptosis, caspase-3/PARP activation and negatively impacting FAK/p38-MAPK phosphorylation, Bcl-2 and Bcl-x_L expressions leading to mouse retinal endothelial cell (MREC) death (Boosani et al., 2009). In addition angioinhibitory activity of arresten was found to inhibit bFGF induced proliferation of MREC *in-vitro* in a dose dependent manner. It also inhibited the bFGF-induced migration of MREC mediated by MMP-2 activity but not the expression levels of MMP-2 (Boosani et al., 2010). Thus, arresten was shown to effect the proliferation and migration of choroidal endothelial cells and regulate CNV of AMD. The endothelial specific inhibitory actions of arresten may be of benefit in the treatment of a variety of eye diseases with a neovascular component.

2.1.6 Canstatin

It is the 24 kDa collagen type IV, α2 derived non-collagenous domain [α2(IV)NC1], which binds to the αVβ3 and αVβ5 integrins and inhibits EC proliferation, migration and tube formation by enhancing apoptosis in these cells (Magnon et al., 2005; Magnon et al., 2007; Petitclerc et al., 2000; Roth et al., 2005). The antiangiogenic efficacy of canstatin in regulating the neovascularization of cornea was also evaluated using the recombinant canstatin in alkali burn induced neovascularization study (Lima et al., 2006; Wang et al., 2011). Cantstain was shown to induce apoptosis through the induction of Fas-ligand, activation of procaspse-8 and -9 cleavage, reduction in membrane potential, inhibition of Akt, FAK, mToR, eIF-4E/4E-BP1 and ribosomal S6-kinase phosphorylations, in cultured HUVECs **(Figure 2)** (Panka and Mier, 2003).

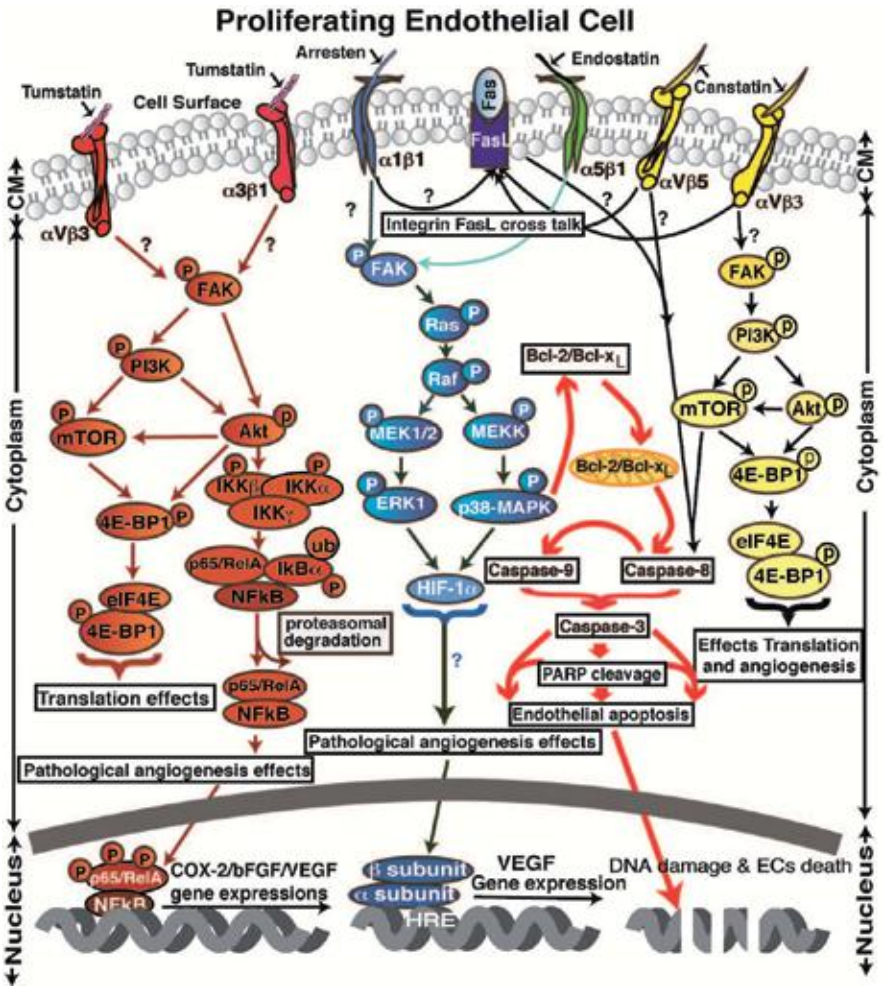

Fig. 2. **Schematic illustration of distinct angioinhibitory signaling mediated by different extracellular matrix (ECM) reloaded molecules.** Tumstatin, arresten, canstatin and endostatin interact with αVβ3/α3β1, α1β1, αVβ3/αVβ5 and α5β1 integrins respectively, to inhibit the phosphorylation of focal adhesion kinase (FAK). Tumstatin: It binds to αVβ3 and α3β1 integrins and inhibits the pathway that includes phosphorylation of FAK, PI3-K, Akt, mTOR, 4E-BP1 and eIF4E to decrease endothelial cell protein synthesis and proliferation. In addition tumstatin also inhibits NFκB mediated signaling in hypoxic conditions leading to the inhibition of COX-2, VEGF and bFGF expressions, resulting in inhibition of hypoxic tumor angiogenesis. Arresten: It binds to α1β1 integrin and inhibit phosphorylation FAK, causes inhibition of Ras, Raf, extra cellular signal related kinase 1 (ERK1) and p38 MAPK pathways that leads to inhibition of HIF-1α and VEGF expression resulting in inhibition of endothelial cell migration, proliferation and tube formation. In addition arresten initiates two apoptotic pathways, involving activation of caspase-9 and -8, leading to activation of caspase-3 and PARP cleavage. (a) Arresten activates caspase-3 directly through inhibition of FAK/p38-MAPK/Bcl-2/Bcl-x_L and activation of caspase-9; (b) Integrin α1β1 cross talk with Fas-L through mitochondrial pathway and leads to activation of caspase-8 and-3 in

proliferating endothelial cells. Canstatin: It binds to αVβ3/αVβ5 integrins and inhibits two apoptotic pathways, involving activation of caspase-8 and casoase-9, leading to activation of caspase-3. Canstatin activates procaspase-9 not only through inhibition of the FAK/PI3K/AKT pathways but also by integrins cross talking mitochondrial pathway through Fas-L dependent caspase-8 activation leads to endothelial cell apoptosis. CM represents cell membrane. Endostatin: It binds to α5β1 integrin and inhibit phosphorylation FAK, causes inhibition of Ras, Raf, extra cellular signal related kinase-1 (ERK1) and p38 MAPK pathways that leads to inhibition of endothelial cell migration and tube formation.

2.1.7 Tumstatin

Tumstatin [α3(IV)NC1], is a 28 kDa collagen type IV, α3 chain derived non-collagenous domain with anti-angiogenic and proapoptotic activities. It binds to the CD47/IAP, αVβ3, α3β1 and α6β1 integrins and inhibits the signaling cascade mediated by FAK, Akt, PI3K/mTOR/eIF-4E/4E-BP1 and NFκB/COX-2 (Boosani et al., 2007; Hamano et al., 2003; Maeshima et al., 2002; Monboisse et al., 1994; Sudhakar et al., 2003). Inhibition of eIF-4E/4E-BP1 by tumstatin leads to the regulation of cap dependent translational level of genes, whereas inhibition of transcriptional factor signaling such as NFκB leads to regulation of genes such as COX-2 at transcriptional level (Figure 2) (Boosani et al., 2007). Thus, tumstatin exhibits gene regulation in endothelail cell-specific and integrin-dependent manner. Angioinhibitory effect of tumstatin has been evaluated in regulation of CNV in mice (Boosani et al., 2011). Recombinant tumstatin regulated tube formation by mouse corneal endothelial cells (MCECs) *in-vitro* and adenoviral mediated expression of tumstatin *in-vivo* in mice has shown reduction in CNV (Boosani et al., 2011; Gunda et al., 2011).

2.1.8 Endostatin

Endostatin is the partial 20-kDa fragment of collagen type XVIII, carboxy terminal non-collagenous domain, derived from the parent collagen by proteolytic cleavage activities of elastase and cathepsin-L (Felbor et al., 2000). Endostatin is found in normal circulation enabling it to be utilized as an effective angioinhibitor without toxic effects (Fukai et al., 2002). Lower levels of endostatin have been recorded in CNV samples compared to the healthy donor eyes and within the tissues of progressive AMD (Bhutto et al., 2008; Fukai et al., 2002). Deletion of endostatin or collagen type XVIII massively up-regulates LASER induced CNV; where as administration of physiological concentrations of endostatin was able to inhibit such CNV in these mice (Marneros et al., 2007). Endostatin also down regulates the expression of VEGF in experimental CNV rat models (Takahashi et al., 2003). These observations along with the evidence of inhibition of CNV with intravenous injection of adenoviral vectors that express secretable endostatin, confirm the significance of endostatin in regulation of CNV (Mori et al., 2001; Wickstrom et al., 2003).

Endostatin elicits the anti-proliferative and anti-migratory effects by binding to different EC surface molecules and regulating the signaling cascades (Faye et al., 2009). Recombinant endostatin binds to αV integrin as shown in human endothelial cells (Rehn et al., 2001). Further studies have also shown localization of endostatin in the lipid rafts and association with caveolae (Wickstrom et al., 2002; Wickstrom et al., 2003). Surface plasmon resonance assays characterized the binding of endostatin to both αVβ1 integrins and the heparin

sulfates and also localization to the lipid rafts (Ricard-Blum et al., 2004). *In-vitro* assays using ECs also showed the co-localization of endostatin with α5β1 integrin, actin stress fibers, membrane anchor protein and caveolin-1, which enumerates the interaction of endostatin with caveolae, inhibiting EC migration through the disassembly of actin stress fibers/focal adhesions, activation of Src and impaired fibronectin deposition by ECs in response to bFGF (Wickstrom et al., 2002; Wickstrom et al., 2003; Sudhakar et al., 2003). Binding of endostatin with integrins also down-regulates the activity of RhoA-GTPase and inhibits signaling pathways mediated by small kinases of the Ras and Raf families (Ricard-Blum et al., 2004). In addition, binding to the KDR/Flk-1, endostatin inhibits the VEGF-induced tyrosine phosphorylation of KDR/Flk-1 and activation of ERK, p38 MAPK, and p125FAK in HUVECs (Kim et al., 2002; Sudhakar et al., 2003). Further signaling cascades regulated by the endostatin are being identified, which are mediated by activator protein 1 (Id), HIF1α, ephrin, tumor necrosis factor-α (TNFα), nuclear factor-κB (NFκB), coagulation cascades, adhesion molecules and Wnt, which indicate the potential role of endostatin as an endogenous angioinhibitor (Nyberg et al., 2005) **(Figure 2).**

2.2 Scope for endogenous angioinhibitors in CNV treatment

Current modalities of treatment for the CNV in AMD include the regulation of angiogenesis as angiogenesis being one of the pathological factors of neovascularization. The therapies such as LASER photocoagulation, photodynamic therapy and anti-VEGF therapies using Macugen or Lucentis, that are currently being applied to regulate the CNV have their own constraints such as development of lesions, loss of acuity in vision and frequent administration, respectively (Gallemore and Boyer, 2006). Alternative strategies for the treatment of CNV in AMD are therefore being developed in which the specific targeting on angiogenesis can be possible. Endogenous angioinhibitors are considered as one of the area to be explored in this arena to include them in regimens of complementary treatments for the regulation of CNV (Chappelow and Kaiser, 2008; Do, 2009). The signaling cascades regulated by some of endogenous angioinhibitors have been identified **(Table 2 and Figure 2),** which enabled the application of those inhibitors in CNV.

3. Conclusions

The cellular, extracellular milieu and genetic factors responsible for the neovascularization arising in AMD are being deciphered with emphasis on identifying those factors that play a key role in the inception and progression of CNV. In this scenario, different etiological factors have been identified which regulate angiogenesis, effecting both extracellular milieu and intracellular angiogenic signaling pathways. Identification of the signaling cascades leading to the pathological angiogenesis in CNV has further lead to the possibility of regulating CNV, by focusing on signaling pathways as one of the targets. Application of endogenous angioinhibitors has proven as a promising strategy in this scenario of inhibiting angiogeneic pathways that are identified in CNV. The inhibitors such as vasoinhibins, PEDF, angiostatin, endostatin, tumstatin, canstatin and arresten that have been so far evaluated for regulation of CNV have not only shown promising evidence of CNV regulation, but also provided new strategies for inhibiting CNV through differential mode of actions. Such variation exhibited by different endogenous angioinhibitors can be beneficial in targeting CNV using different combinations of these inhibitors. It can be

realized that these naturally occurring inhibitors can pose low immune reactions and thus, an efficient way of regulating diseases. Further, clinical studies using individual and combinations of endogenous angioinhibitors, included in different regimens along with current therapies of CNV would elaborate the application of endogenous angioinhibitors for regulating CNV of AMD.

NRF2 and Age-Dependent RPE Degeneration

Yan Chen, Zhenyang Zhao,
Paul Sternberg and Jiyang Cai
Vanderbilt Eye Institute,
Vanderbilt University Medical Center, Nashville, TN,
USA

1. Introduction

Retinal pigment epithelium (RPE) is a single layer of epithelial cells lined between the neurosensory retina and choriocapillaris. It is part of the blood-retinal barrier and is a central component of the visual phototransduction pathway. RPE cells regenerate 11-cis-retinal by RPE65 isomerase and its related enzymes and chaperones (Moiseyev et al., 2006; Xue et al., 2004). They are professional phagocytes and are responsible for the clearance of daily shed photoreceptor outer segments (POS) (Young, 1967; Young & Bok, 1969). The multi-step process of phagocytosis includes receptor-mediated binding of POS to the RPE (Finnemann et al., 1997), internalization (Feng et al., 2002; Finnemann & Silverstein, 2001), transport to lysosome and degradation. The importance of RPE phagocytosis has been clearly illustrated by the Royal College of Surgeons (RCS) rats, which carry a mutation in *Mertk* gene (D'Cruz et al., 2000). MERTK is a membrane-associated receptor tyrosine kinase and is activated upon binding of POS to the RPE (Feng et al. 2002). In RCS rats, loss-of-function mutation of *Mertk* causes defects in phagocytosis and consequently these animals develop inherited retinal dystrophy and photoreceptor apoptosis (Tso et al., 1994). In addition to their roles in the visual cycle, RPE cells provide vital support for the structure and function of the outer retina. They transport ions, water and nutrients between choroidal blood supply and the retina, and synthesize melanin which absorbs light and shields the retina. RPE-produced growth factors, such as vascular endothelial growth factor (VEGF), are indispensable for the choroidal vasculature (Saint-Geniez et al., 2009).

Degeneration of the RPE with aging is an initiating event in age-related macular degeneration (AMD), a major cause of blindness in elderly people. Approximately 11% of persons between ages 65 and 74 have AMD, with prevalence rates rising to 30% in individuals at age 75 or older (Lee et al., 2003). Vision loss in AMD occurs through photoreceptor loss in the macula, the central area of the retina, and results either from a gradual "geographic atrophy" of the RPE (dry or atrophic disease) or from leakage and/or bleeding from choroidal neovascularization (CNV) (wet or neovascular disease). During CNV, blood vessels break through Bruch's membrane, leading to rapid loss of central vision in many cases. In recent years anti-VEGF agents have achieved unprecedented success in preserving visual acuity in patients with CNV (Brown et al., 2006; Rosenfeld et al., 2006; Galbinur et al., 2009). Detailed clinical aspects of wet AMD and anti-VEGF therapy are covered by other chapters of this book.

The genetic and biochemical mechanisms of RPE degeneration in dry AMD, however, remain largely unknown. Several hypothetical models have been proposed, including accumulation of lipofuscin and its bisretinoid fluorophore (Sparrow et al., 2003; Zhou et al., 2006), iron overload (Dunaief, 2006; Hahn et al., 2004), autoimmune response (Hollyfield et al., 2008) and exposure to double strand RNA (Ambati, 2011; Kaneko et al., 2011). All of them have suggested clinical associations with AMD and their causal relationships to the disease have been demonstrated by respective animal models (Ramkumar et al., 2010). Oxidative stress is a common mechanism underlying these diversified pathological processes. Photooxidation of the bisretinoids can produce singlet oxygen and release methylglyoxal to form advanced glycation end product (Wu et al., 2010). Iron overload increased isoprostane, a marker of lipid peroxidation, in the RPE/choroid (Hadziahmetovic et al., 2008). Mice immunized with serum albumin conjugated with carboxyethylpyrrole, an oxidation product of docosahexaenoic acid, developed signs of RPE degeneration and deposition of complement proteins in the Bruch's membrane (Hollyfield et al., 2008). Oxidative stress can downregulate DICER1, a RNA processing enzyme whose deficiency was shown to cause Alu RNA-induced cytotoxicity and RPE apoptosis (Kaneko et al., 2011).

Results from earlier clinical and laboratory studies also support the contributing roles of oxidative stress to AMD. Smoking is the strongest environmental risk factor of AMD (Cano et al., 2010; Smith et al., 2001) and has been clearly associated with oxidative stress (DeBlack, 2003; Mitchell et al., 2002; Pryor et al., 1983; Smith et al., 2001). A number of interventional studies showed that antioxidant supplementation had protective effects against development of AMD or limiting its progression. Experimental animals fed with diets supplemented with antioxidants demonstrated an increased resistance to retinal degeneration (Ham et al., 1984; Organisciak et al., 1985; Tso et al., 1984). Results from the Age-Related Eye Disease Study (AREDS) showed that supplemental antioxidants (vitamin C, vitamin E and beta carotene) and zinc can decrease the risk of progression from intermediate AMD to advanced AMD by 25% (AREDS 2000 & 2001). Taken together, the findings from the research of the past two decades suggest that AMD is a multifactorial disease, with oxidative stress viewed as a common mechanism involved in the gene-environmental interaction of its etiololgy.

Oxidative stress is due to an imbalance between the generation of reactive oxygen species and their clearance by antioxidant systems. The RPE has powerful endogenous antioxidant capacity to overcome the high level of oxidative stress, which is caused by both focal light exposure and high metabolic rate of the retina. In addition to utilizing direct radical scavengers such as β-carotene, ascorbic acid and α-tocopherol, RPE cells have an elaborate enzymatic antioxidant system that can prevent and repair oxidative injury. Nuclear factor erythroid 2-related factor 2 (NRF2) is a master regulator of cellular antioxidant and detoxification responses (Kensler et al., 2007). We and others have shown previously that elevating the transcriptional activity of NRF2 can protect against oxidative injury to the RPE; while mice that are deficient of NRF2 developed pathological features similar to human AMD (Zhao et al., 2011; Cano et al., 2010). Oral zinc supplementation, which was used in the AREDS to slow AMD progression, can activate NRF2-dependent antioxidant system in the RPE (Ha et al., 2006). More recently, a newer class of NRF2 inducers, which are based on synthetic triterpenoid 2-cyano-3,12-dioxooleana-1,9-dien-28-oic acid (CDDO) and its

derivatives, have achieved potent protection in various models of retinal damage (Pitha-Rowe et al. 2009). In this chapter we will review past and recent literature reports, based on cell culture, animal models and human clinical studies, to address how NRF2 regulates RPE function both *in vitro* and *in vivo*.

2. NRF2-dependent antioxidant defense

NRF2 is a transcription factor that controls the expression of phase 2 detoxification genes. It heterodimerizes with members of the Maf family of transcription factors and binds to the *cis*-acting antioxidant response element in the promoter regions of various phase 2 genes (Katsuoka et al., 2005; Motohashi et al., 2004). The latter encode a group of enzymes, such as glutamate-cysteine ligase, glutathione S-transferase, glutathione peroxidase, heme oxygenase, NAD(P)H:quinone reductase and glutamate-cysteine exchanger, which are essential for detoxification of xenobiotics and endogenous reactive intermediates (Kensler et al., 2007; Wakabayashi et al. 2010). NRF2-deficient mice showed increased sensitivity to a variety of pharmacological and environmental toxicants (Kensler et al., 2007; Rangasamy et al., 2004). The protective effects of NRF2 inducers have been tested in a number of models of human diseases, including cancer, neurodegeneration, cardiovascular disease, and liver and lung injury (Kensler et al., 2007; Wakabayashi et al., 2010).

Activation of NRF2 is subjected to multiple levels of regulation. Under basal conditions, NRF2 is sequestered by its inhibitor protein, Keap1, and is targeted for Cullin 3/Rbx1-mediated ubiquitination and degradation (Cullinan et al., 2004; Furukawa & Xiong, 2005; Kobayashi et al., 2004). Upon conditions of oxidative stress or exposure to electrophilic compounds, NRF2 protein can be liberated from Keap1 and will translocate into nucleus to mediate gene trasncription. As illustrated in Fig. 1, there are six Neh (NRF2 ECH homology) domains that are responsible for most of the functions of NRF2. The Neh domains show amino acid sequence homology conserved between different species including human, rodents and chicken (McMahon et al., 2004; Zhang et al., 2007).

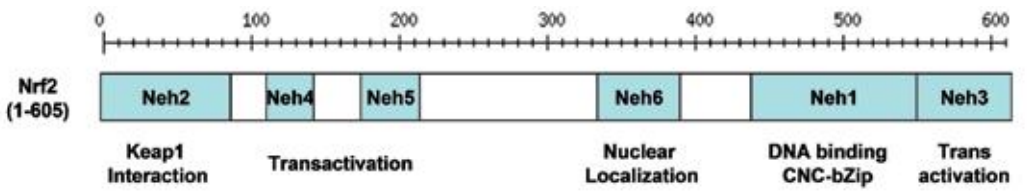

Fig. 1. Illustration of the Neh domains of the NRF2 protein. Human NRF2 is a polypeptide of 605 amino acids and contains 6 Neh domains. The relative positions of each domain and their putative functions are listed. Neh1 contains the signature cap-n-collar motif which is a highly conserved basic leucine zipper domain for DNA binding. The nuclear localization and export signals are present in both Neh6 and Neh1.

3. NRF2-mediated protection in cultured RPE cells

Compounds that promote the nuclear translocation of Nrf2 and elevate its transcriptional activity can protect against oxidative injury in cultured RPE cells. In 2001, Talalay and

colleagues first reported that sulforaphane could prevent RPE cell death caused by treatments with menadione, t-butyl hydroperoxide, 4-hydroxynonenal and peroxynitrite (Gao et al., 2001). Since then numerous other studies reported the protective effects of a wide range of structurally-different NRF2 inducers including isothiocyanates (sulforaphane) (Gao & Talalay, 2004), polyphenols (curcumin, resveratrol and flavonoids) (Alex et al., 2010; Johnson et al., 2009; Mandal et al., 2009), 1,2,dithiole-3-thiones (oltipraz) (Nelson et al., 2002), zinc (Ha et al., 2006) or triterpenoids (Pitha-Rowe et al., 2009). Many of them are naturally occurring compounds present in fruits and vegetables, making them ideal for dietary supplementation. Some of the compounds have either gone through human clinical trials or are currently used for other applications. For instances, zinc was used in the AREDS supplementation either alone or with antioxidant vitamins. Oltipraz, a dithiole derivate, is used in treating schistosomiasis and cancer chemoprevention (Jacobson et al., 1997). A common mechanism underlying the antioxidant and detoxification functions of NRF2 is to increase cellular glutathione (GSH) synthesis.

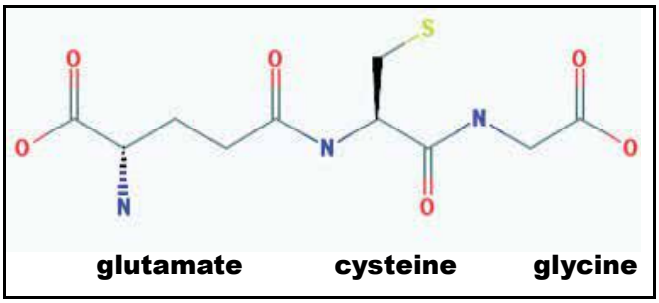

Fig. 2. Structure of glutathione. The γ-glutamylcysteine is formed by a peptide bond between the carboxylate group of glutamate and animo group of cysteine. The sulfhydryl group of cysteine is responsible for the antioxidant function of the tripeptide.

GSH is a tripeptide consisted of glutamate, cysteine and glycine. It contains a unique peptide bond between the amine group of cysteine and the carboxyl group of the glutamate side chain so that it is much more resistant to degradation by peptidase (Fig. 2). The sulfhydryl group of cysteine of GSH can be used by glutathione S-transferase to conjugate electrophilic centers on a wide variety of substrates (Pool-Zobel et al., 2005). GSH is also used by glutathione peroxidase to reduce lipid hydroperoxides and hydrogen peroxide to alcohols and water, respectively. The glutamate cysteine ligase (GCL) is the rate-limiting enzyme of GSH synthesis. It generates γ-glutamylcysteine from glutamate and cysteine. NRF2 inducers can elevate the mRNA levels of the catalytic and modulatory subunits of GCL. Cystine uptake by the RPE is mediated by a sodium independent, cystine/glutamate exchanger (Bridges et al., 2001; Ishii et al., 1992). The transporter is consisted of two subunits, xCT as the light chain and 4F2hc as the heavy chain (Wagner et al., 2001). NRF2 controls the expression of *xCT* gene (Sato et al., 1999). In *xCT* knock out mice, the plasma cystine concentration almost doubled, resulted from decreased tissue uptake (Sasaki et al., 2002). The *xCT*$^{-/-}$ mice showed more several renal injury caused by ischemia-reperfusion (Shibasaki et al., 2009). Thus, NRF2 inducers can increase both the rate of GSH synthesis and cellular concentration of its amino acid precursor.

Monitoring the RPE glutathione content is a reliable assay for initial screening of model compounds designed to activate NRF2. For instance, RPE cells pretreated with oltipraz showed increased total and mitochondrial GSH. At 50 μM, oltipraz increased total cellular GSH by 18% and mitochondrial GSH by 50%, and achieved significant protection against tert-butylhydroperoxide-induced RPE cell death (Nelson et al., 2002). Similar results were obtained from cells pretreated with dimethylfumarate (DMF) for 24 hours (Nelson et al., 1999). However, when the time course of the DMF was evaluated, a transient decrease in GSH levels was found that preceded the increase noted at later time points. Compared to vehicle-treated control cells, cells pretreated with DMF for 3 hours showed a significant reduction in viability when further challenged by peroxide (Nelson et al, 1999). Thus, the initial decrease of GSH after DMF treatment rendered the RPE cells more sensitive to oxidative injury, although it can subsequently lead to a feedback increase of GSH synthesis and a more robust antioxidant response (Nelson et al., 1999). Many of the NRF2 inducers are thiol-reacting compounds and may cause a similar initial depletion of cellular GSH. Therefore, although the *in vitro* culture system does not present the complexity of the retinal microenvironment and cell-cell interaction *in vivo*, it is a valuable tool for assessing both the pharmacological properties of new NRF2 inducers and their potential toxicities. For treatment of a chronic disease like AMD, the RPE cells are already stressed by oxidative burden and may not tolerate transient GSH depletion after repeated administration of agents that react with cellular thiols with low selectivity.

4. Ocular pathology of *Nrf2* knockout mice

Nrf2 knockout mice have normal embryonic development (Chan et al., 1996) and their basal level of antioxidant status in many tissues is not different from age-matched wild type mice. However, the *Nrf2* null mice show increased sensitivity to a variety of pharmacological and environmental toxicants (Cano et al., 2010; Kensler et al., 2007; Osburn & Kensler, 2008). Depending upon the stimuli, injuries occur in different organs and tissues. The phenotypes vary, but commonly involve oxidative and inflammatory stress. For ocular pathology, neonatal *Nrf2* knockout mice develop more severe retinal vaso-obliteration at early phase after hyperoxia exposure (Uno et al., 2010). NRF2 also modulates the innate immune response in the retina and iris-ciliary body in a mouse model of uveitis induced by intraperitoneal injection of lipopolysaccaride (Nagai et al., 2009).

Aging and smoking are the major demographic and environmental risk factor of AMD, respectively. Cano and colleagues (2010) reported that NRF2-deficient mice were more susceptible to smoking-induced retinal injury. At 8 months, *Nrf2* null mice showed a mild degree of ultrastructural change in the RPE. Comparing to age-matched wild type mice, RPE of the knockout mice exposed to cigarette smoking for 6 months (starting at 2 months) displayed markedly increased staining of 8-hydroxydeoxyguanosine, an indicator of accumulated oxidative DNA damage (Cano et al., 2010). On electron microscopy, *Nrf2*$^{-/-}$ smoking mice displayed abnormal RPE basal infoldings and vacuoles, without apparent changes of the choroidal endothelium or sub-RPE deposit formation (Cano et al., 2010). Thickening and deposits in the outer collagenous layer of Bruch's membrane were often observed in smoking mice. The data suggest that NRF2-mediated protection to the RPE is important against chronic environmental toxicities associated with AMD.

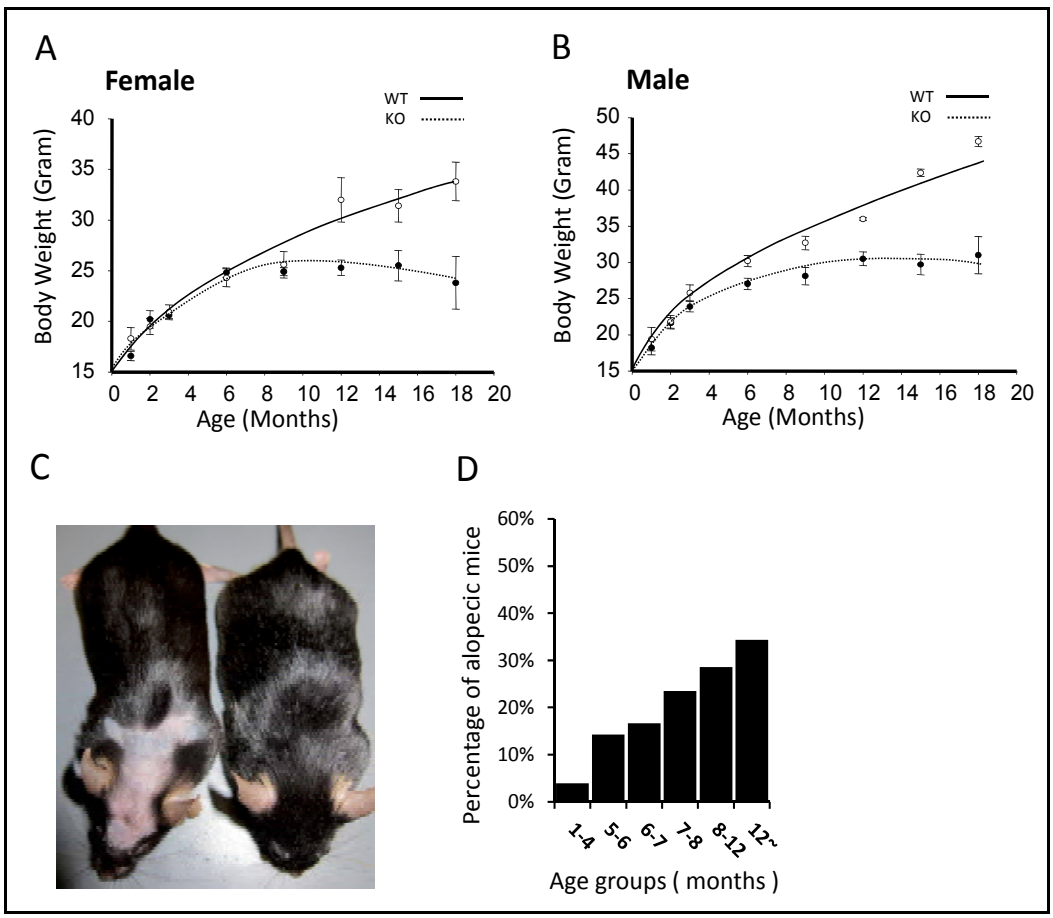

Fig. 3. Accelerated aging in *Nrf2*$^{-/-}$ mice. (A) and (B) Growth curves of male and female *Nrf2*$^{-/-}$ mice and their age-matched littermates. Knockout animals showed a lower body weight after the first year. (C) and (D) Hair loss in *Nrf2*$^{-/-}$ mice. A representative picture of a 12-month-old alopecic *Nrf2*$^{-/-}$ mice is shown in (C). Hair loss was often first observed between 5 to 6 months of age (D).

We recently reported that *Nrf2*$^{-/-}$ mice developed age-related RPE and choroidal degeneration resembling cardinal features of human AMD (Zhao et al., 2011). The *Nrf2*$^{-/-}$ mice have accelerated aging. Some of the animals exhibited extensive hair loss (alopecia), which began as early as 4 months and peaked at 8 months (Fig. 3). Interestingly, more female *Nrf2*$^{-/-}$ mice suffered from hair loss than male ones; this could possibly be attributed to the higher susceptibility of female mice to autoimmune diseases as reported by Takahashi and colleagues (Yoh et al., 2001). After 12 months, the *Nrf2*$^{-/-}$ mice started to show lower body weight than the age-matched wild type littermates (Fig. 3). The life expectancy of *Nrf2*$^{-/-}$ mice is about 20 months which is only 60% of wild type mice with the same genetic background (Pearson et al., 2008).

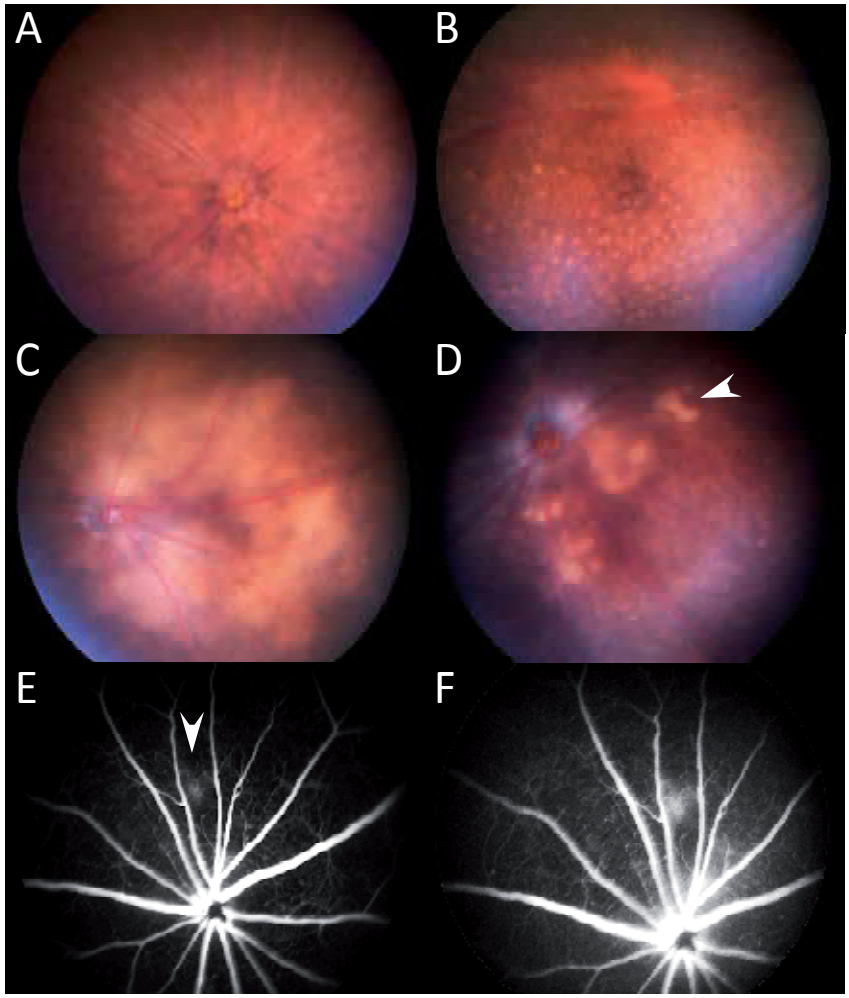

Fig. 4. Fundus examinations of *Nrf2*$^{-/-}$ mice. (A) Normal fundus image taken from a 12-month-old wild type mouse. (B) Drusen like deposits developed in the peripheral retina of an 8-month-old *Nrf2*$^{-/-}$ mouse. (C) Yellowish patchy lesions found in a 14-month-old *Nrf2*$^{-/-}$ mouse. (D-F) A 16-month-old knockout mouse developed extensive RPE lesions (D), one of which showed hyperfluorescence in both early (E) and late (F) phase of fluorescein angiography. Arrowheads in D and E indicate the same lesion.

Drusen-like deposits were noted in around 70% of eyes from *Nrf2*$^{-/-}$ mice, as examined by funduscopy between 8 to 11 months (Fig. 4B). With aging, these small, dome-shaped whitish spots in the fundus tended to become confluent yellowish lesions, gradually increasing in area (Fig. 4C). Atrophic RPE lesions were frequently seen in *Nrf2*$^{-/-}$ mice after the first year (Fig 4C and 4D). Some of these lesions would eventually develop into sites of CNV, which were identified by both fundus fluorescein angiography (Fig 4E and 4F) and histopathology (Zhao et al., 2011). Moderate but statistically significant decreases in both a- and b-wave amplitudes on ERG were observed between the *Nrf2*$^{-/-}$ and wild-type mice at 12 months of age (Zhao et al., 2011), indicating compromised visual function in knockout mice.

The fundus phenotype in aged *Nrf2*$^{-/-}$ mice was further confirmed by histology (Fig. 5 and Zhao et al., 2011), which showed drusen formation, extensive RPE atrophy with numerous vacuoles, increased autofluorescence inside the RPE layer and CNV. Thickening of the Bruch's membrane with age and basal laminar and basal linear deposit were found exclusively in *Nrf2*$^{-/-}$ mice by electron microscopy (Zhao et al., 2011). Immunostaining of eye sections revealed increased deposition of proteins that are related to innate immunity (i.e., C3d, vitronectin and serum amyloid P) and marker of oxidative injury (nitrotyrosine) between the RPE and Bruch's membrane in *Nrf2*$^{-/-}$ mice (Zhao et al., 2011). The same proteins have been found in drusen and Bruch's membrane of human AMD eyes (Crabb et al., 2002; Mullins et al., 2000).

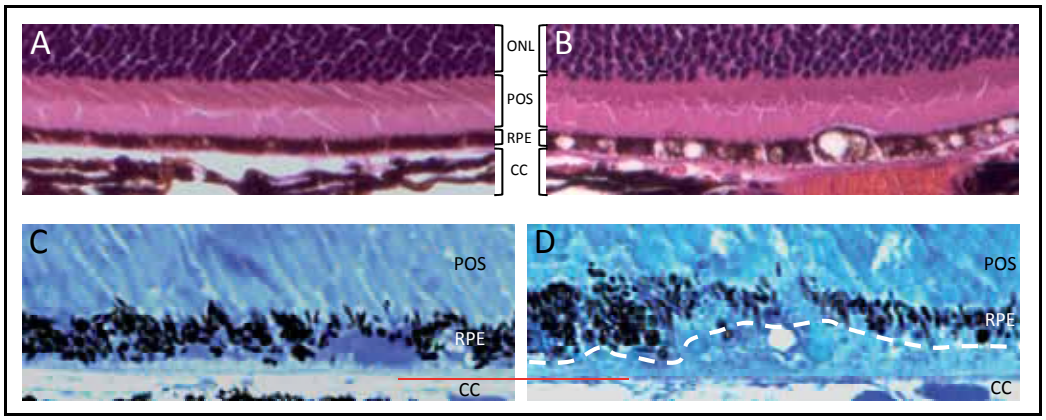

Fig. 5. Histology examination of retina of *Nrf2*$^{-/-}$ mice. (A) A 14-month-old wild type mouse showed normal structure of the outer retina. (B) Representative image of RPE degeneration with big vacuoles, taken from a 14-month-old *Nrf2*$^{-/-}$ mouse. (C-D) Semi-thin sections from a 12-month-old wild-type mouse (C) and an age-matched *Nrf2*$^{-/-}$ mouse (D). Bruch's membranes of the two were aligned at the same level (red line). Note that the RPE layer was elevated due to heterogeneous deposits (under the dotted line) in the sub-RPE space. (A and B: Paraffin section with hematoxylin and eosin staining. C and D: Plastic section with toluidine blue staining. ONL: outer nuclear layer; POS: photoreceptor outer segment; CC: choriocapillaris)

The accelerated degeneration after middle age and the typical pathology of the RPE/choroid indicate that the *Nrf2*$^{-/-}$ model shares many features of human AMD. At advanced age, the retinal pathology progressed from atrophic form to neovascularization and about 15% of the *Nrf2*$^{-/-}$mice developed spontaneous CNV (Zhao et al., 2011). Photoreceptor degeneration was moderate and was probably secondary to RPE dysfunction. Rodents do not have macula and, therefore, cannot be used to generate ideal models of AMD. On the other hand, mechanistic studies exploring the molecular and biochemical mechanisms of age-related RPE degeneration and CNV can greatly benefit from animal models that at least partially reproduce representative lesions commonly seen in human AMD eyes. Animal models, such as the *Nrf2*$^{-/-}$ mice, will display the dynamic process of the disease and offer windows of intervention that can either slow down or accelerate the progression. Similar experiments will be difficult if not impossible to perform with human eyes mainly at late stages of AMD.

5. Pharmacological interventions that activate NRF2 *in vivo*

A number of *in vivo* studies have investigated the protective roles of NRF2 inducers in models of retinal injury and inflammation. A study by Yodoi and colleagues (Tanito et al., 2005) showed that sulforaphane, a prototypic NRF2 inducer, could upregulate thioredoxin in both the RPE and neural retina, and was effective in protecting photoreceptors from photo-oxidative damage. Compared to vehicle-treated controls, mice received sulforaphane showed fewer apoptotic cells in the outer nuclear layer and RPE, and had moderate but statistically significant improvement of both a- and b-wave amplitudes. At four days after light exposure, the ONL was significantly thicker in sulforaphane-treated mice (Tanito et al., 2005). Sulforaphane also delayed photoreceptor cell death in *tubby* mouse, a model of Usher syndrome (Kong et al., 2007). Homozygous *tubby* mice develop progressive photoreceptor degeneration shortly after birth. Sulforaphane-treated *tub/tub* mice showed significantly increased ONL thickness and b-wave amplitude at P28 and P34, as compared to vehicle-treated animals (Kong et al., 2007).

For human clinical studies, AREDS reported (2001) that supplementation with zinc alone, or antioxidants plus zinc, decreased the risk of progression towards advanced AMD by 20%. We showed that zinc could activate NRF2 both in cultured RPE cells and in RPE of NRF2 reporter mice (Chen et al., data not shown). In an ancillary study of AREDS, we analyzed the effects of long-term zinc supplementation on plasma thiol metabolites and their redox status (Moriarty-Craige et al., 2007). There was a significant decrease in plasma cystine concentration in the zinc-supplemented group. The systemic effects may be due to increased tissue uptake of cystine, as NRF2 regulates the transporter protein xCT (Sasaki et al., 2002). These results prove the concept that long term dietary supplementation of an NRF2 inducer is a feasible approach for treating early stage AMD patients.

A new class of synthetic triterpenoids derivatives of oleanolic acid have been tested both in cultured RPE cells and *in vivo*. These agents exerted highly potent activity at concentration as low as 10 nM. They reacted with a broad range of accessible protein thiols and activate NRF2 about 10 times more potently (by the ARE reporter assay) than previously used compounds (Pitha-Rowe et al., 2009). The *in vivo* protection against light-induced retinal toxicity has been demonstrated. Mice receiving 200 mg/kg CDDO-trifluoroethylamide (-TFEA) showed significantly increased ONL thickness after light-induced retinal degeneration (Pitha-Rowe et al., 2009). CDDO-imidazolide decreased mouse leukocyte adherence to retinal vasculature after lipopolysaccaride treatment, and reduced expression of inflammatory mediators including ICAM-1, IL-6, COX-2, TNF-α and MCP-1 (Nagai et al., 2009; Cano et al., 2010). CDDO-methyl ester inhibited neutrophil infiltration in vitreous and internal limiting membrane after retinal ischemia-reperfusion induced by high intraocular pressure, and inhibited degeneration of retinal capillary (Wei et al., 2011). The CDDO compounds are currently under clinical trials for chronic kidney disease and type 2 diabetes. Their potential applications in treating dry AMD can be explored in human studies in the near future.

6. Signaling pathways that regulate NRF2 activation

The interaction between Keap1 and NRF2 is considered as a major determinant of the stability and function of NRF2 (Dinkova-Kostova et al., 2002; Hong et al., 2005). Electrophilic compounds, such as sulforaphane, can directly react with various cysteine residues of Keap1 and consequently cause dissociation and activation of NRF2 (Eggler et al., 2005). Keap1-

deficient hepatocytes had increased NRF2 activity and were more resistant to acetaminophen (Okawa et al., 2006). In addition to thiol modification and redox regulation, it is well established that there are cross-talk between the protein kinase pathways and NRF2-dependent antioxidant system (Sherratt et al., 2004).

Several phosphorylation sites of NRF2 protein have been mapped out and associated to its activity (Fig. 6). Phosphorylation of NRF2 at Serine 40 by protein kinase C promotes its dissociation from Keap1 and translocation into the nucleus (Bloom and Jaiswal, 2003; Huang et al., 2002). Phosphorylation at Tyrosine 568 by a Src subfamily kinase Fyn controls the export and inactivation of NRF2 at the late phase of induction (Jain and Jaiswal, 2006; Salazar et al., 2006). Other Src subfamily kinases, Src, Yes and Fgr, can also function as negative regulators of NRF2 by phosphorylating the protein at Tyr568 (Niture et al., 2011). A recent study by Rada et al (2011) demonstrated that a serine cluster in the Neh6 domain (Ser335, 338, 342, 347, 351, and 355) (Fig. 1) of NRF2 can be phosphorylated by glycogen synthase kinase-3β (GSK-3β). The phosphorylation enhanced the association between Nrf2 and SCF/β-TrCP, which is an adaptor protein for ubiquitin ligase and targets NRF2 for cullin-1/Rbx1-mediated degradation (Rada et al., 2011). Thus, phosphorylation of NRF2 by GSK-3β will facilitate it proteosomal degradation and inhibit its transactivation function. GSK-3β may also act upstream of Src family kinases (Jain and Jaiswal, 2006; Kaspar and Jaiswal, 2011). It remains elusive whether those two mechanisms work independently or additively. Mitogen-activated protein kinases (MAPKs) have been shown to phosphorylate NRF2 at Ser215, 408, 558, 577 and Tyr559; however, impacts on NRF2 location and activity were marginal after phosphorylation at those residues (Sun et al., 2009).

Results from the functional studies consistently showed that inhibition of the PI3K/Akt pathway decreased NRF2 activation induced by a variety of stimuli in different cell lines, while expression of a constitutive active mutant of Akt increased NRF2 activity, indicating that PI3K/Akt signalling is a positive regulator of NRF2 (Chen et al., 2009; Jain and Jaiswal, 2006; Kang et al., 2000; Lee et al., 2001; Wang et al., 2008). PI3K/Akt controls NRF2 via multiple indirect mechanisms. They can facilitate translocation of NRF2 into the nucleus via rearrangement of cytoskeletal actin (Kang et al., 2002). They are upstream kinases of GSK-3β. Akt phosphorylates GSK-3β at Ser9 and inhibits its kinase activity, which in turn will potentiate NRF2 activation because GSK-3β is its negative regulator (Jain and Jaiswal, 2006; Niture et al., 2011; Rada et al., 2011; Salazar et al., 2006).

There are other kinases that can be positive regulators of NRF2. PKR-like endoplasmic reticulum kinase phosphorylates and activates NRF2 under conditions of ER stress (Cullinan and Diehl, 2004; Cullinan et al., 2003). Casein kinase 2 phosphorylates endogenous NRF2 and regulates its activity and degradation (Pi et al., 2007). MAPK family proteins, extracellular signal-regulated protein kinases (ERKs) and the c-Jun N-terminal kinases (JNK), also play positive roles in NRF2-signaling pathway (Shen et al., 2004; Yu et al., 2000a; Zipper and Mulcahy, 2003). However, the positive regulation by ERKs and JNK may not through direct phosphorylation of NRF2 (Shen et al., 2004; Zipper and Mulcahy, 2003). Instead, they may upregulate NRF2 activity by phosphorylating and activating Nrf2 binding partner, such as the nuclear transcriptional coactivator CBP (Shen et al., 2004; Yu et al., 2000a). The p38 kinase may either stimulate or inhibit NRF2 activity, depending on the different type of cells and the pharmacological agents used for the studies (Yu et al., 2000b; Zipper and Mulcahy, 2000).

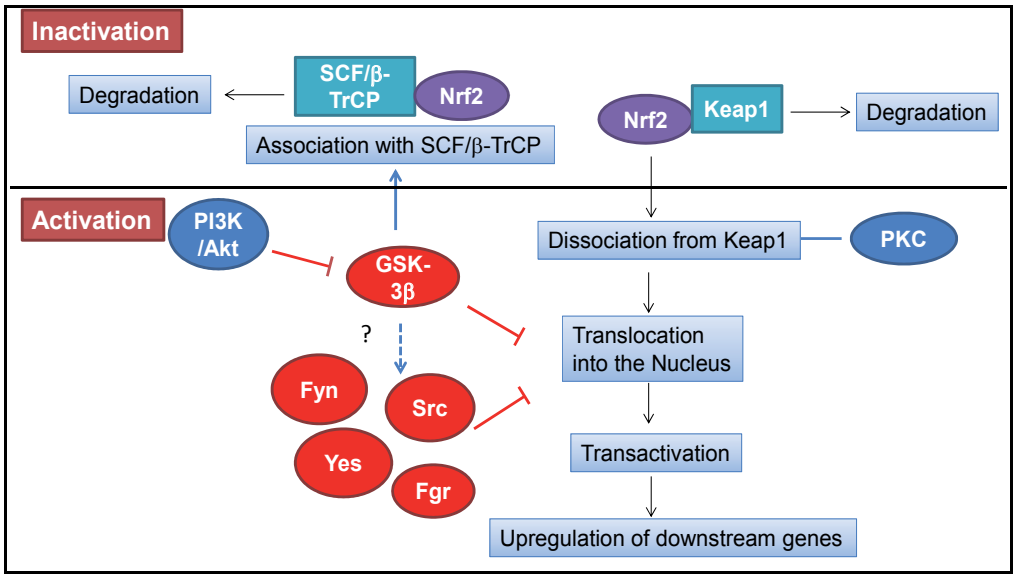

Fig. 6. Regulation of NRF2 activity by protein phosphorylation. There are positive and negative regulators of upstream kinases that function at various steps of the signalling pathway. Phosphorylation can leads to either its activation or degradation/inactivation.

Because of the multiple putative phosphorylation sites of NRF2, and its dual regulation by cellular redox status and protein phosphorylation, it is difficult to clearly define its upstream signalling network both at basal level and in response to oxidative stress. Identification of authentic phosphorylation sites and development of antibodies specific for phosphorylated NRF2 can greatly advance our knowledge in this area. More importantly, most of the works on signal transduction of NRF2 have been performed in transformed cancer cells, which harbour genetic and biochemical variations and function quite differently from the RPE. Future mechanistic studies of NRF2 will be needed to address cell type-specific signalling mechanisms involved in RPE aging and degeneration.

7. Potential mechanisms linking NRF2 to AMD

A unique pathology of AMD is that RPE degeneration occurs before severe loss of photoreceptors, a retinal phenotype also seen in NRF2-deficient mice. In contrast, in model systems of retinal toxicities, animals exposed to excessive levels of oxidative stress often showed much more severe retinal degeneration than the RPE damage. Compared to epithelial cells, neurons are less efficiently protected by the endogenous antioxidant system. The outer segments of rods and cones have very low GSH (Winkler 2008). As shown in both the SOD1- and SOD2-deficient mice, severe loss of neurons occurred before or at the same time of RPE degeneration (Imamura et al. 2006; Justilien et al., 2007). In *Vldlr*$^{-/-}$ mice, antioxidant supplementation protected retinal degeneration and improved the retinal electrophysiology (Dorrell et al., 2009). The fact that *Nrf2*$^{-/-}$ mice showed preferential loss of RPE suggests that NRF2 can have functions other than antioxidant protection.

It is noteworthy that the retinal ultrastructure of aged *Nrf2*$^{-/-}$ mice showed signs of dysregulated autophagy (Zhao et al., 2011). Autophagy is a major self-renewal process which is essential for organelle turnover and removal of aggregated proteins that cannot be processed by proteasome (Klionsky 2007). During autophagy, unwanted proteins and organelles are sorted to double-membrane autophagosomes, which are further delivered to and fused with lysosomes to degrade the sequestered cargos. The accumulation of various intermediate forms of autophagic vacuoles and multivesicular bodies in the RPE and Bruch's membrane was evident on EM images of aged *Nrf2*$^{-/-}$ mice (Zhao et al. 2011). This can be caused by either increased autophagic flux or decreased final degradation by lysosome. Similar findings of dysregulated autophagy were reported in another study using human AMD eyes (Wang et al., 2009).

Autophagy is of particular importance in non-dividing cells like neurons and RPE which, unlike proliferating cells, are incapable of diluting the waste products by mitosis. Dysregulated autophagy is considered as pathogenic in various neurodegenerative diseases; and the underlying mechanisms are disease-specific. In Alzheimer's disease, mutations in presenilin-1 impairs lysosomal targeting of v-ATPase V0a1, which is essential for lysosome acidification and protease activation (Lee et al., 2010). In Parkinson's disease, mutated α-synuclein cannot be efficiently degraded by autophagy (Cuervo et al., 2004). In Huntington's disease, mutant huntingtin may impair the initial cargo assembly of autophagic vesicles (Martinez-Vicente et al., 2010). It has been hypothesized that dysregulated autophagy is also involved in AMD (Wang et al., 2009; Kaarniranta 2010).

NRF2 can be an important regulator of RPE autophagy via multiple mechanisms. In normal RPE cells, autophagy is responsible for the removal of ubiquitinated and/or aggregated proteins. Cargos inside autophagosomes will be delivered to lysosome for degradation and recycled for catabolism. NRF2 is likely involved in autophagosome formation. Several previous studies reported that p62, which is a receptor protein of ubiquitinated proteins and essential for the initial assembly of autophagosome, is transcriptionally regulated by NRF2 (Komatsu et al., 2010). Whether NRF2 controls other specific molecular components of the autophagy pathway remains to be characterized by future studies. Accelerated accumulation of lipofuscin was observed in *Nrf2*$^{-/-}$ RPE (Zhao et al., 2011). Reactive metabolites from bisretinoids inhibit lysosome-mediated autophagic degradation. NRF2-dependent detoxification can be protective in both formation and elimination of lipofuscin-related metabolic waste products. Thus, compromised NRF2 signalling can impact both the early and late stages of RPE autophagy.

NRF2 may also be involved in the innate immune response that amplifies the initial RPE lesions in AMD. As shown in the uveitis model, NRF2-deficient retina had higher number of infiltrated leukocytes and increased production of pro-inflammatory cytokines (Cano et al., 2010). Thioredoxin 1, a downstream protein of NRF2, can interact with complement factor H and regulate its activation (Inomata et al., 2008). Autophagy can be a possible mechanistic link between oxidative stress and inflammation (Levine et al., 2011). Elevated cellular stress will cause increased damage to proteins and organelles and overwhelm the degradation capacity of RPE autophagy. Consequently, the undigested wastes could be exported into Bruch's membrane via exocytosis and deposited in the sub-RPE space (Wang et al., 2009). The exported proteins, possibly in oxidatively modified forms, may further promote drusen formation and cause local inflammation mediated by complement proteins and

macrophages. Loss of endothelial fenestration was observed in choriocapillaris of aged *Nrf2*$^{-/-}$ mice (Zhao et al., 2011). In human AMD eyes, choroidal vascular degeneration occurs in areas of geographic atrophy (McLeod et al., 2009; Mullins et al. 2011). Decreased transport function of choroidal vessels can facilitate the accumulation of damaged proteins in the sub-RPE space and Bruch's membrane.

Single nucleotide polymorphisms (SNPs) in the coding region of *NRF2* gene have been detected in human cancerous tissues (Shibata et al. 2008). Functional polymorphisms in the promoter region of *NRF2* have been reported (Marzec et al., 2007). However, according to the GWAS data (Chen et al., 2010), NRF2 is not a major risk allele of AMD and SNPs of *NRF2* are unlikely to be a major genetic factor. A recent study showed that age-dependent decline of NRF2 function could be caused by upstream regulatory mechanisms, such as GSK-3β, that control its localization and activity (Tomobe et al., 2011). Defining these mechanisms will open up new revenues of intervention to prevent oxidative injury and RPE loss during dry AMD. Unlike the inherited genetic variations, the biochemical changes associated with RPE aging are likely treatable.

8. Conclusion

NRF2 is a protein that has been extensively studied in cancer and other chronic human diseases. Accumulating evidence suggests that NRF2-mediated signalling pathways have central roles in protecting the RPE cells from aging and age-related degeneration. The *Nrf2*$^{-/-}$ mice represent a new model for translational and mechanistic studies of AMD. Agents that activate Nrf2 are potential candidates for treating AMD and other retinal diseases involving oxidative and inflammatory stress.

Retinitis Pigmentosa in Northern Sweden – From Gene to Treatment

Irina Golovleva and Marie Burstedt
University Hospital of Umeå, Umeå, Sweden

1. Introduction

Blindness is a loss of vision resulting in the inability to continue with a normal lifestyle. The prevalence of blindness varies from country to country and from region to region within the same country. An average estimate of the number of blind people in industrialized countries is 1–2 per 2000, compared to 5–10 per 1000 in developing countries. According to World Health Organisation estimates, there are between 27 and 35 million blind people in the world today.

Retinal dystrophies and degenerations represent a heterogeneous group of disorders affecting the function of the retina. They are characterized by degeneration of photoreceptors or adjacent cells such as retinal pigment epithelium or Müller cells. Retinitis pigmentosa (RP), hereditary maculopathies, and age-related macular degeneration (AMD) are representative of these diseases. RP as well as macular degeneration can be part of syndromes with symptoms from other organs or organ systems, for example, Usher syndrome with RP and deafness. More than 190 loci for different retinal diseases have been localized, and 140 genes have been identified (http://www.sph.uth.tmc.edu/Retnet/).

In northern Sweden the presence of all hereditary disorders is higher than in the southern part of the country. Explanations offered include a low migration rate in the sixteenth to nineteenth centuries and a certain number of marriages among relatives, which influenced the presence of autosomal recessive disorders. Furthermore, a disposition to a genetic abnormality in a geographically restricted area gave rise to a 'founder' effect, which influenced the presence of autosomal dominant disorders. These factors are taken into consideration in studies of all hereditary disorders, including those affecting vision.

2. Retinitis pigmentosa

Retinitis pigmentosa is a genetically and clinically heterogeneous group of hereditary retinopathies characterized by a degeneration of photoreceptors (rods primary) with a progressive loss of peripheral vision. This leads to night blindness, 'tunnel vision', and eventually, complete blindness. Typical signs of the disease, except for night blindness and progressive loss of the peripheral visual field, are typical pigment deposition in the retina, attenuation of the retinal blood vessels, and optic disc pallor. The diagnosis is confirmed by an abnormal or extinguished electroretinogram (ERG). RP can be nonsyndromic, syndromic,

or systemic, when multiple tissues are affected. Nonsyndromic RP can be inherited in autosomal dominant (15–25%), autosomal recessive (5–20%), and X-linked (5–15%) manners (Daiger & Pagon, 2000). However, an inheritance pattern is still unknown in many cases. So-called simplex usually represents an isolated case without any family history. Due to different degrees of penetrance and expressivity of RP genes, the phenotype can vary between families and even within the same family (Shintani et al., 2009).

The prevalence in the United States and Europe is approximately 1/3500 to 1/4000, and the disorder is the most common cause of blindness among young adults. In Denmark the lifetime risk of developing RP is 1/2500 (Haim et al., 2002), and in Sweden it is 1/2000 (Burstedt et al., 1999). Similar frequencies can be expected in other populations, but they have not been well documented. Frequency of RP in certain isolated or consanguineous populations might be higher due to mutations in particular genes (Daiger & Pagon, 2000). Among known loci and genes there are 57 identified for autosomal dominant RP and autosomal recessive RP. Many genes associated with RP encode proteins functioning as photoreceptor transcription factors; others are involved in phototransduction and the visual cycle or photoreceptor structure (Phelan & Bok, 2000; Fig. 1). Despite many retinal diseases having been mapped to specific chromosomal regions, the genes and their functions still have not been identified in all cases.

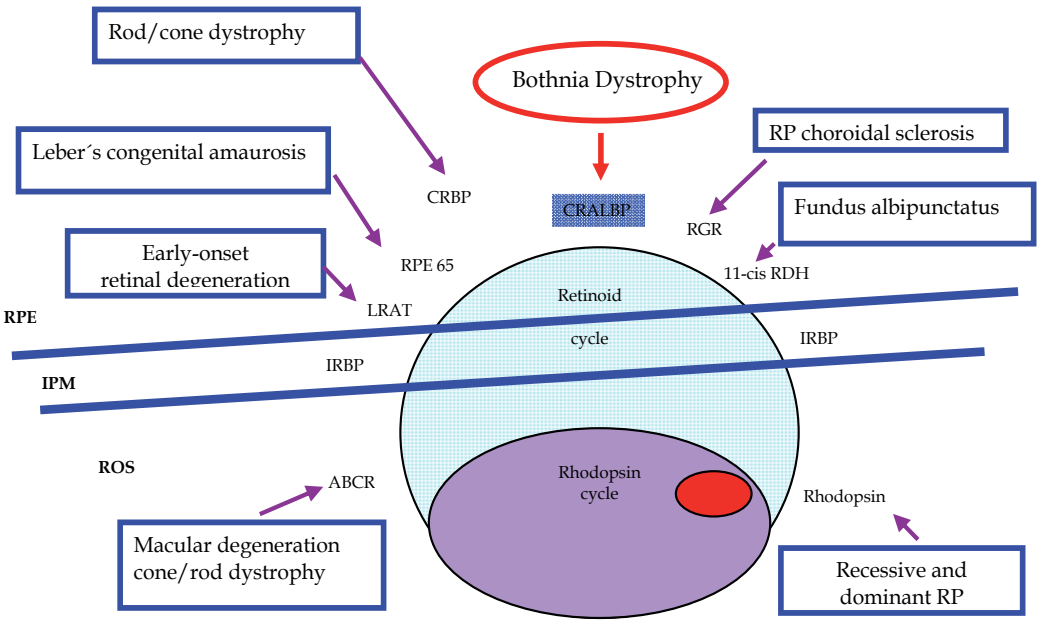

Fig. 1. Visual cycle proteins cause retinal degenerations. CRBP = cellular retinol binding protein, RPE65 = retinal pigment epithelium-specific protein 65kDa, LRAT = lecithin retinol acyltransferase, IRBP = interphotoreceptor retinoid-binding protein, RPE = retinal pigment epithelium, IPM = interphotoreceptor matrix, ROS = rod outer segment, ABCR = retina-specific ATP-binding cassette transporter, CRALBP = retinaldehyde-binding protein 1, RGR = retinal G protein coupled receptor, 11-cis RDH = retinol dehydrogenase 5 (11-cis/9-cis).

In Västerbotten County of northern Sweden 160 RP cases were identified and genetic defects were found in 66%, representing 79 patients with autosomal recessive RP of Bothnia type and 27 patients with autosomal dominant RP. However, genetic mechanisms of RP are still unknown in patients from other counties of northern Sweden. In this chapter we will focus on a disease with characteristic phenotype common in northern Sweden form of autosomal recessive RP, Bothnia dystrophy.

2.1 Autosomal recessive RP, Bothnia Dystrophy (BD)

Examination of medical records for patients with RP in Västerbotten County in northern Sweden has shown an accumulation of cases with a unique phenotype of RP called Bothnia dystrophy. Bothnia is the region in northern Sweden west of the Gulf of Bothnia, historically known as Bothnia Occidentalis (Fig. 2). Affected individuals showed night blindness with onset in early childhood, retinitis punctata albescens (RPA) at some stage of the disease, macular degeneration, and markedly elevated dark adaptation (DA) thresholds.

Fig. 2. The map shows the location of Västerbotten County in Scandinavia.

2.1.1 Genetic cause of BD

Initially, twenty patients from seven families originating from the same geographic area were included in the linkage analysis study aimed at identifying a disease-causing gene (Burstedt et al., 1999). All affected individuals had a nonsyndromic type of retinal degeneration inherited in an autosomal recessive way (Fig. 3). By statistical two-point lod (logarithm [base 10] of odds) score analysis, which is used to determine the linkage between trait and a chromosome marker, BD was mapped between the markers D15S526 and FES on chromosome 15q26.1. The D15S116, located near the *RLBP1* gene showed a maximum lod score of 7.79. Since lod score greater than 3 is considered evidence for linkage, the *RLBP1* gene was a strong candidate to cause the BD. Mutation analysis showed that all patients were homozygous for a cytosine (C) to thymine (T) change in exon 7 of the *RLBP1* gene, resulting in a substitution of a conservative arginine to tryptophan at position 234

(c.700C>T, p.R234W) in encoded cellular retinaldehyde-binding protein (Burstedt et al., 1999). No homozygotes for the c.700C>T mutation were found among 33 unaffected control subjects who underwent ophthalmologic examinations or 92 anonymous blood donors.

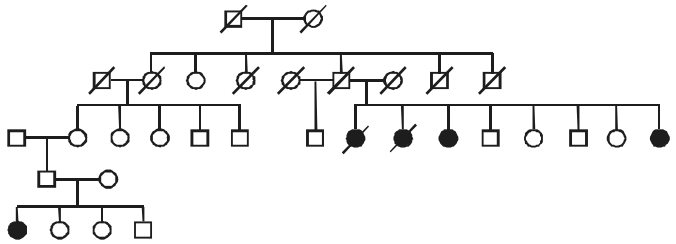

Fig. 3. A pedigree demonstrating autosomal recessive inheritance of BD in one of the families used for linkage analysis study.

2.1.2 Compound heterozygosity in BD

Sixty-nine BD cases homozygous for the c.700C>T were identified amongst patients with retinal dystrophies. In addition, 10 patients with similar to BD phenotype were heterozygous. Further screening for known mutations causing autosomal recessive RP revealed a second *RLBP1* mutation, a thymine (T) to adenine (A) change, resulting in a substitution of a methionine to lysine, c.677 T>A, p.M226K (Köhn et al., 2008). R234W and M226K were shown to be allelic and the patients were compound heterozygotes, c.[677T>A]+[700C>T] (Fig. 4).

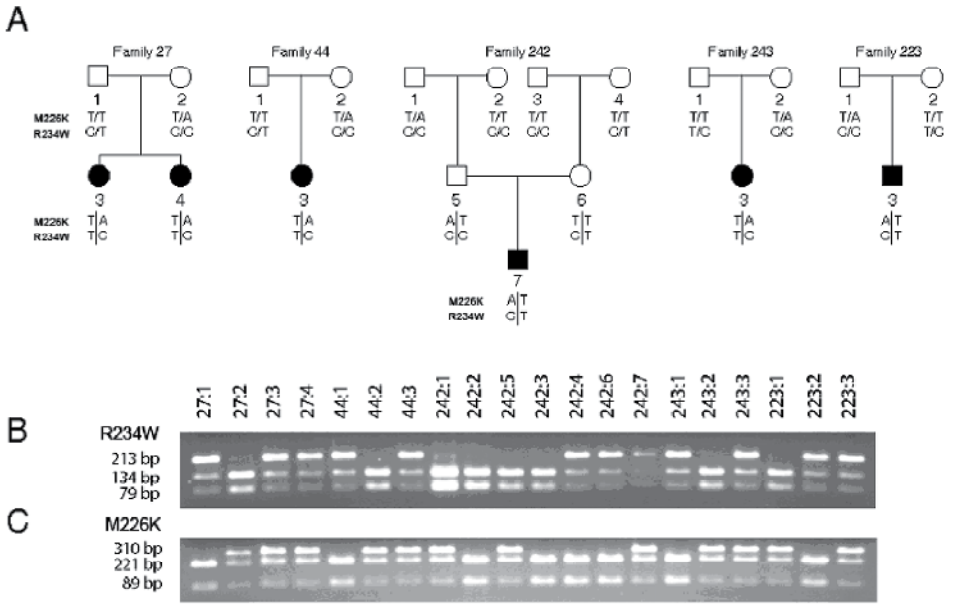

Fig. 4. Pedigrees of compound heterozygotes (A) and segregation analysis of *RLBP1* c.700C>T (B) and c.677T>A (C) performed by polymerase chain reaction and restriction fragment length polymorphism. (Figure published in Invest Ophthal Vis Sci, 2008;49(7):3172–3177).

Frequency of c.677 T>A allele in a matched control population was 0.0021. Among RP patients from northern Sweden two were homozygotes for p.M226K mutation. Based on allele frequency of R234W (3/250) and M226K (1/466), we believe that R234W was the first mutation to appear in northern Sweden, resulting in expected disease incidence of 1.5 per 10,000 in a population of 257,000 inhabitants.

Notably, one *RLBP1* compound heterozygote BD patient tested for 848 mutations in 29 genes causing autosomal dominant RP was shown to be a carrier of a mutation in carbonic anhydrase IV (CAIV), known to be associated with autosomal dominant retinitis pigmentosa RP17 (Rebello et al., 2004; Yang et al., 2005). Presence of this sequence variant in 6 out of 143 blood donors from a control Swedish population (4%) and phenotype undistinguishable from the other BD patients casts doubt on the pathogenic role of the CAIV (Köhn et al., 2008), though modifier genes switching off the mutant CAIV protein or other factors resisting its function in carriers of Swedish origin remain to be investigated.

2.1.3 *RLBP1* mutations in RP

To date, at least 12 mutations representing single nucleotide changes, in addition to small and one gross deletion have been reported (http://www.hgmd.cf.ac.uk). First homozygous *RLBP1* mutation was found in a consanguineous family of Indian origin and in one of consanguineous kindred from Saudi Arabia, both diagnosed with retinitis punctata albescens (Maw et al., 1997; Katsanis et al., 2001). Three additional mutations in the *RLBP1* gene were identified in the patients of European ancestry with recessively inherited RPA (Morimura et al., 1999), and in patients of Newfoundland origin with a severe rod cone dystrophy two splice junction mutations were detected (Eichers et al., 2002). The reported cases of retinal degeneration associated with *RLBP1* mutations were either homozygous or compound heterozygous (Demirci et al., 2004; Eichers et al., 2002; Fishman et al., 2004; Morimura et al., 1999; Nakamura et al., 2005). One of the compound heterozygotes, a Japanese patient with RPA, carried the c.700C>T mutation on one allele (Nakamura et al., 2005). Finally, changes involving single nucleotides are not the only type of mutation that affects the *RLBP1* gene. A large homozygous deletion was described in a RPA patient (Humbert et al., 2006).

2.1.4 Cellular retinaldehyde-binding protein (CRALBP)

RLBP1 gene mapped to chromosome 15q26 (Rosenfeld & Dryja, 1995) encodes the human cellular retinaldehyde-binding protein (CRALBP) expressing in outer epithelium of the iris, ciliary body pigment epithelium, cornea, optic nerve, pineal gland, Müller cells of the retina, and retinal pigment epithelium (RPE) (Bridges et al., 1987; Bunt-Milan & Saari, 1983; Eisenfeldt et al., 1985; Futterman & Saari, 1977; Saari et al., 1997; Sarthy, 1996). In the RPE, CRALBP functions as a carrier protein for endogenous retinoids, such as 11-cis-retinol, participating in the visual cycle. 11-cis-retinol can either be stored as an ester in the RPE or become oxidized to 11-cis-retinal by 11-cis-retinol dehydrogenase for visual pigment regeneration, and consecutively recycled back to the outer segment of photoreceptor cells of the retina (Saari, 1990). In vitro studies indicate that the presence of CRALBP diminishes the esterification and enhances oxidation of 11-cis-retinol (Saari et al., 1994).

A missense mutation of a conserved residue arginine at position 150 of CRALBP abolished binding to 11-cis-retinaldehyde. The mutation was shown to be associated with an atypical form of autosomal recessive RP in a small consanguineous Indian family (Maw et al., 1997).

We evaluated binding activities for two recombinant mutant proteins causing BD (Golovleva et al., 2003). M226K mutation completely abolished binding of the recombinant protein with 11-cis retinaldehyde, while the R234W, in contrast, increased binding activity of the recombinant CRALBP (Fig. 5). Double mutant M226K + R234W showed less solubility than the wild type rCRALBP (Köhn et al., 2008).

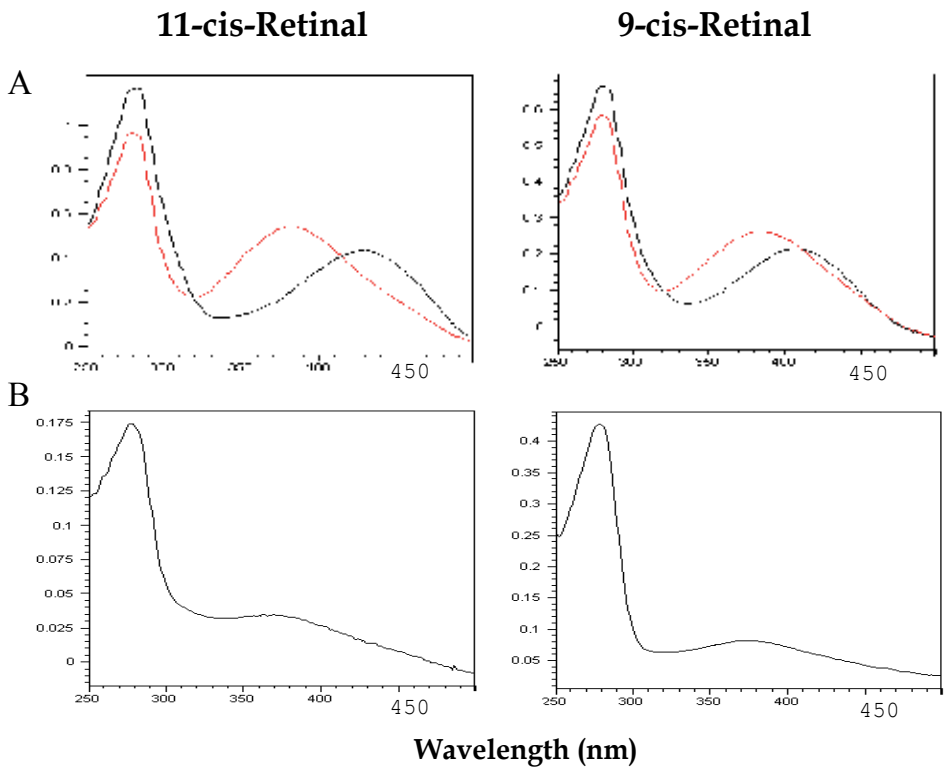

Fig. 5. Retinoid binding analysis of CRALBP mutants R234W (A) and M226K (B). UV-visible absorption spectra are shown before and after exposure to bleaching illumination following retinoid labelling with either 11-cis- or 9-cis-retinal. Spectra from wild-type rCRALBP (black line) and mutant R234W (red line) are indistinguishable and reflect stoichiometric binding of 11-cis- and 9-cis-retinal. The absorption spectra from mutant M226K show no chromophore absorbance at 425 nm or 400 nm, indicating no bound retinoid (Figure published in J Biol Chem, 2001;278:14,12397–12402).

We also analysed *RLBP1* promoter by sequencing 4kb in the upstream region in two BD compound heterozygotes. Seven single nucleotide polymorphisms (SNP) were identified; six had been reported previously and one was unique (cytosine to thymine change at position 2614, C2614T). Haplotype was constructed for BD patients. R234W and C2614T

were both associated with BD phenotype. In experiments with reporter gene expression, decrease of expression level was shown when using either the entire 'affected' promoter haplotype or only C2614T (Golovleva, personal communication).

Thus, M226K mutation resulted in loss of functional CRALBP, which is true even for R234W mutant, since gene expression was decreased due to sequence variant in promoter.

2.2 Phenotype of retinitis pigmentosa of Bothnia type

All 79 patients originating from Västerbotten County, with a population of 257,000 inhabitants, present the phenotype caused by loss of CRALBP function.

2.2.1 Clinical findings and effects of age

The BD phenotype is characterized by central and peripheral degeneration of the retina with a unique expression of retinitis pigmentosa. All BD patients from the north of Sweden being homozygous for either the c.700C>T (p.R234W) (n = 67) or for the c.677T>A (p.M226K) (n = 2), and compound heterozygous [c.677T>A]+[c.700C>T] (p.M226K+p.R234W) (n = 10), have a clinical expression of the disease with a progression of retinal degeneration. The progressive maculopathy in BD presents an overall decrease of the visual acuity (VA) with age, leading to legal blindness in early adulthood (Fig. 6; Burstedt et al., 2001).

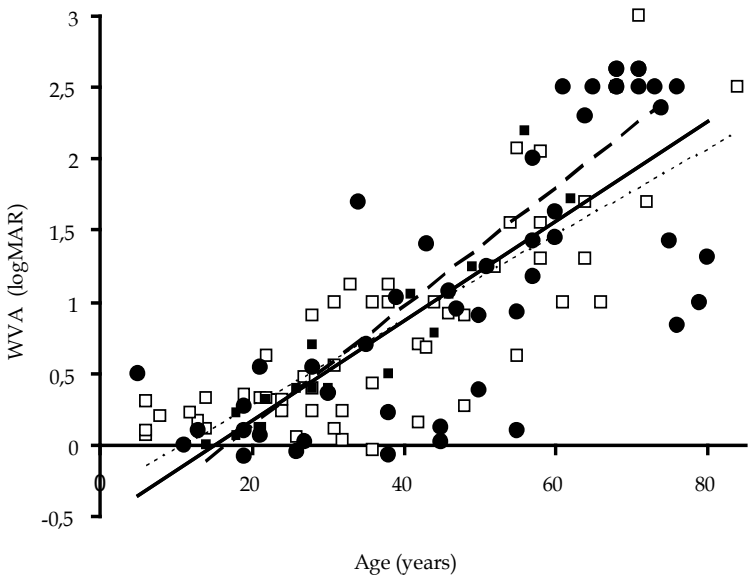

Fig. 6. Scatterplot of BD patients showing the relation of weighted distance logMAR visual acuity (WVA) with age. (●) Single observations of WVA vs. age in homozygotes c.700C>T (p.R234W); n = 49, (y = 0.035 × -0.53). (□) Retrospective recordings of WVA vs. age in compound heterozygotes [c.677T>A] + [c.700C>T] (p.M226K + p.R234W); n = 10 (y = 0.04 × −0.7), and homozygotes c.677T>A (p.M226K) (■); n = 2 (y = 0.03 × -0.32). Trendlines are drawn.

Notably, testing of monocular low-contrast VA using Sloan letter logarithmic translucent contrast charts (10% and 2.5%, Precision Vision®) allowed recording of measurable results, predominantly in the younger patients (Burstedt et al., 2005).

The retinal findings in BD patients show distinct maculopathy with central pigment deposits in the teens, and areolar maculopathy is observed in the younger adults (Burstedt et al., 1999, 2001, 2010). In the peripheral retina the pigmentations are similar to a 'salt and pepper' pattern and round retinal atrophies develop paracentrally and/or peripherally with age. The areolar atrophies are the most common peripheral findings in BD fundus as the degeneration progresses, though discrete pigmentations with an appearance similar to bone spicules may occasionally be found. No premature cataract of significance is observed in BD, and in advanced cases narrowing of the retinal vessels and pale optic disc are not typical findings (Fig. 7).

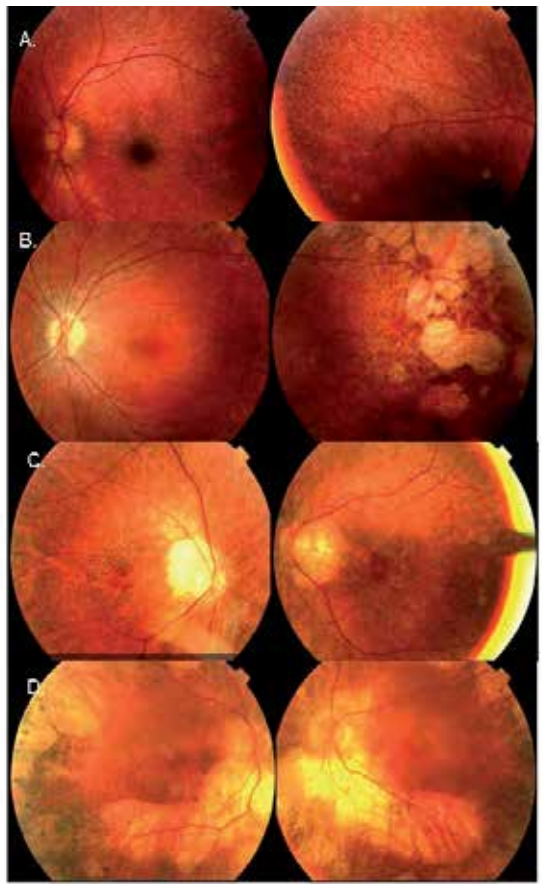

Fig. 7. Fundus photography. (A) 16-year-old girl, discrete central maculopathy and peripheral mottling, (WVA, weighted visual acuity, 0.00 logMAR). (B) 25-year-old woman with maculopathy and peripheral areolar atrophies (WVA 0.5 logMAR). (C) 41-year-old woman with central maculopathy and central RPA changes (WVA 0.3 logMAR). (D) 52-year-old woman with maculopathy, pigmentary changes (WVA 1.2 logMAR), and advanced retinal degeneration with retinal atrophies.

2.2.2 Morphological changes in BD found with ocular computed tomography

A generalized early decrease of the central foveal thickness (Ø 1 mm) and the inner ring of the retina (Ø 3 mm) are shown with optical coherence tomography (Burstedt et al., 2010). In the outer ring (Ø 6 mm), the generalized thinning is seen predominately in the inferior regions of the OCT measurement and a trend of more preserved areas of the retinal thickness of the superior and nasal regions are observed. The total macular volumes in all ages of BD patients are low compared with those of controls. Comparisons of macular thickness in each region of the BD patients and age-matched controls are presented in Fig. 8.

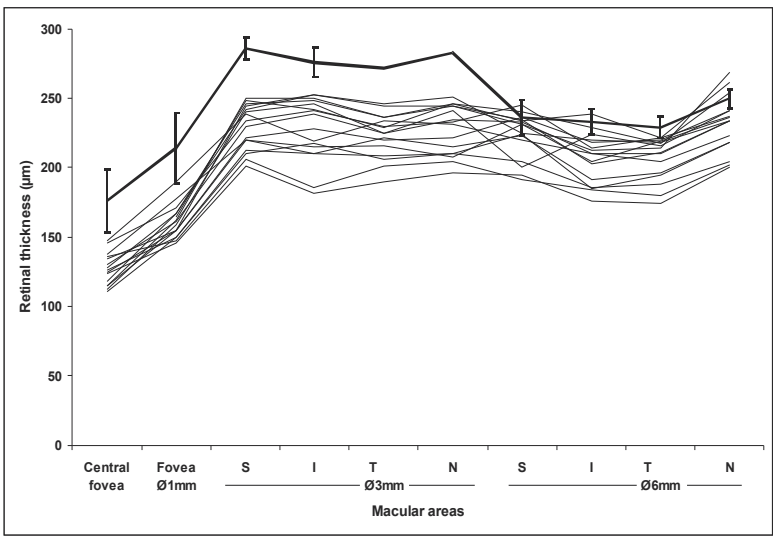

Fig. 8. Optical coherence tomography (OCT) macular thickness measurements of 9 areas in young BD patients (age 9–34 years, n = 8) and controls (in bold), using a Stratus OCT, model 3000 (Carl Zeiss Meditec AG, Jena, Germany): the central foveal, the foveal (Ø 1mm), the inner ring (Ø 3mm), and the outer ring (Ø 6 mm) with Superior area (S), Inferior area (I), Temporal area (T), and Nasal areas (N). The controls are presented with standard deviation shown on the graph. (Figure was published in Arch Ophthalmol. 2010;128(8); 989–995).

The cross-sectional morphology visualized by OCT presents a general thinning of cell layers and a reduced outer nuclear layer (ONL) in the youngest BD patients (9–34 years). Also, a third high-reflectance band, (3rd HRB), found in the younger cases, diminished in younger adults with BD, possibly representing the loss of the outer segment length of photoreceptors, predominately the cones in the fovea measured with OCT (Burstedt et al., 2010; Costa et al., 2004; Sandberg et al., 2005). This finding probably indicates an affection of the cone photoreceptors, and a possible degeneration of the outer segments of cones early in the course of the BD disease. The decreased retinal thickness and degenerative signs in the outer retinal layer were detected early in the course of the disease reported in a compound heterozygous patient with mutations in the *RLBP1* gene (R103W/R234W) (Nakamura et al., 2005). Similar to BD, prominent photoreceptor loss in the foveal and extrafoveal retina even in the youngest patients studied (6–17 years), with relative preservation localized in the

superior–temporal and temporal pericentral retina and the ONL, were demonstrated in the patients with Leber congenital amaurosis, another retinal degenerative disease caused by mutations in *RPE65* gene encoding for a protein active in the visual cycle (Jacobson et al., 2008). How can an early foveal thinning, suggesting early degeneration of cone photoreceptors in BD patients possibly be explained? Studies show that not only the rods but the cones also incorporate 11-*cis* retinoids, derived from the rod and cone visual cycles, in their visual pigments, and when examining the visual cycle in the *RPE-65* and *LRAT* knock-out mice, diseases affecting the visual cycle, a key role for cell survival, was found to be 11-*cis*-retinal bound to cone opsins, important for retinal protein sorting, transport, and targeting (Collery et al., 2008; Zhang et al., 2008).

2.2.3 Morphological findings of retinitis punctata albescens (RPA)

The subretinal white lesions, retinitis punctata albescens, were initially observed in the teens with BD phenotype (Burstedt et al., 1999, 2001, 2010). The RPA spots often dominate in the macula area and adjacent to the arcades, varying from single to multiple generalized white lesions scattered over the posterior pole of the retina. Notably, these changes fade as the progressive retinal degeneration advances (Fig. 9).

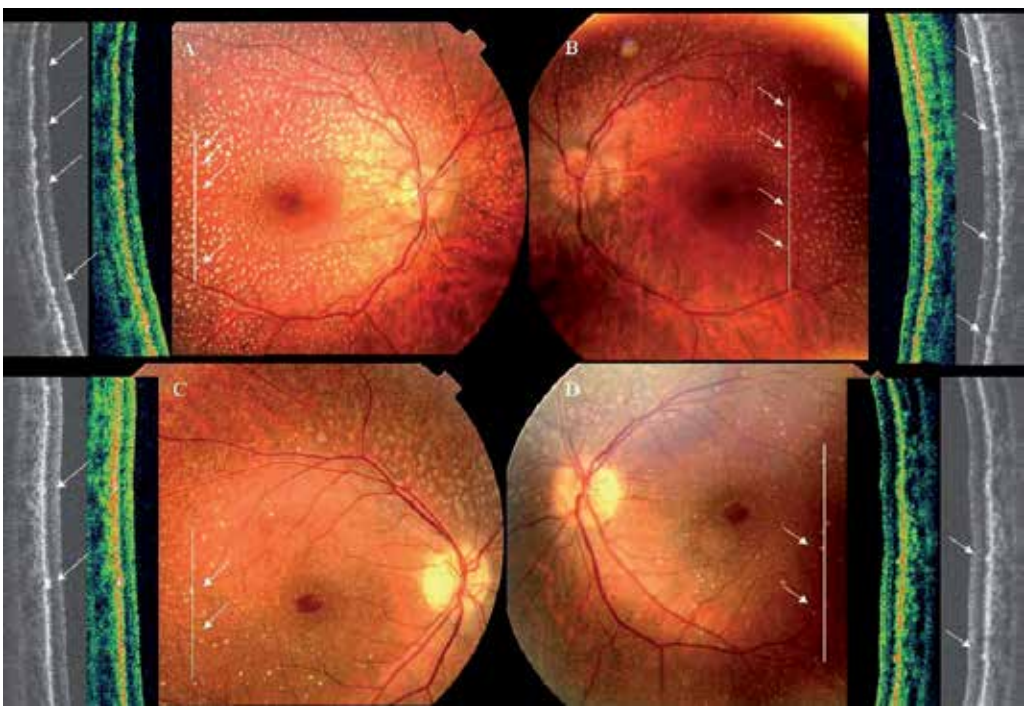

Fig. 9. Colour fundus photo and OCT. Top**:** 23-year-old man; below: 30-year-old woman. The vertical line of the binocular fundus photo with multiple generalized RPA traversing the retina at the temporal area of the macula between the arcades represents the scan lines of the corresponding OCT image presenting cross-sectional, visualized RPA (marked with arrows). (Figure published in Arch Ophthalmol. 2010;128(8);989–995).

RPA or subtle white lesions of the fundus have previously been described in several autosomal recessive RP cases with *RLBP1* mutations, and also in other progressive degenerative diseases, for example, the rhodopsin-related RP (Demirci et al., 2004; Eichers et al., 2002; Fishman et al., 2004; Katsanis et al., 2001; Nakamura et al., 2005; Souied et al., 1996). The localization of RPA lesions and their appearance may resemble more commonly known retinal lesions like drusen in age-related macular degeneration. However, the RPA lesions in BD do not present elevation, disruption, or detachment of RPE. Another finding in AMD is an accumulation of drusen between the retina and choriocapillaris that is shown to interfere with the exchange of nutrients and products close to the drusen, inducing RPE or neural retinal damage with overlaying photoreceptor cell layer thinning, predominately the photoreceptor outer segment affection (Holz et al., 2004; Pauleikhoff et al., 1990; Schumann et al., 2009). Since similar thinning or compression of the ONL overlaying the RPA lesions is observed in BD, a possible cause could be an accumulation of products in the RPE, possibly due to the higher affinity and impaired 11-*cis*-retinal release in the visual cycle in the BD phenotype shown in previous studies (Golovleva et al., 2003; He et al., 2009; Saari, 1990).

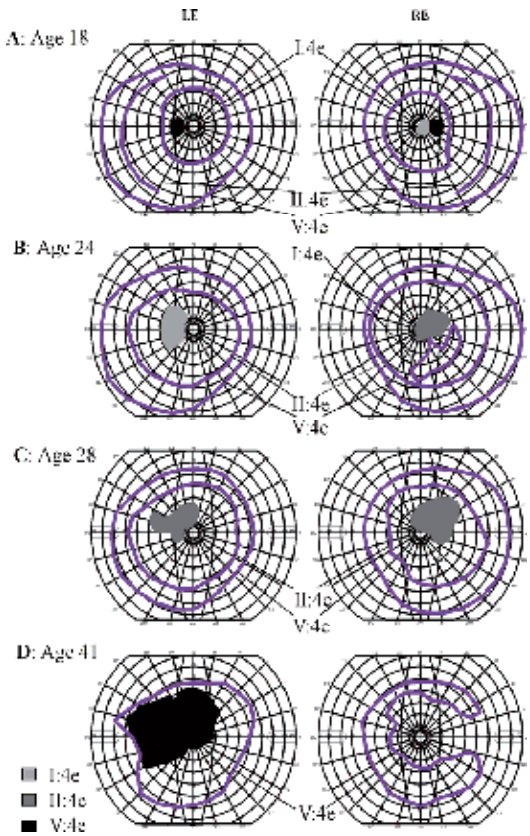

Fig. 10. Progression of visual field defects in a BD case. (A) Small central scotoma is noted in one eye at the age of 18. (B, C) Deeper and larger central-paracentral scotomas develop in young adulthood. (D) In middle age absolute central-paracentral scotomas are present and expanded, finally affecting the peripheral border. (Figure published in Arch Ophthalmol. 2001;119(2):260–267).

2.2.4 Psychophysical findings

Significant foveal depression was found early in BD by testing foveal threshold with Humphrey SITA standard 24-2. The mean deviations in all younger cases show significant loss, indicating an overall depression and/or loss of the central parts of the visual field in BD. Goldmann perimetries are unaffected in the BD cases under the age of 10, and relative parafoveal scotoma and/or ring scotoma is found in the teens, with additional large, deep to absolute central scotomas in both eyes, accompanied by a decrease in visual acuity in adulthood. The visual fields and the development of defects, registered over a time period of 23 years, are presented in Fig. 10.

In the fifth decade, extensive scotomas are present and only peripheral islets of the visual fields remain in middle age.

2.2.5 Angiographic findings

The fundus fluorescein angiograms in the early arteriovenous phase show a diffuse hyperfluorescence in the anatomic macular area, and locally, in the centre of the fovea, also presenting an early retinal thinning. As well as outside the arcades, corresponding to the atrophic areas in the colour fundus photograph, a general hyperfluorescence of granular type appears, indicating a gross atrophy of the pigment epithelium of the entire retina as a common clinical finding in this retinal degeneration (Burstedt et al., 2001).

2.3 Dark adaptometry and electrophysiological findings

2.3.1 Dark adaptometry and electrophysiological findings during standard dark-adapted conditions

Recovery of dark adaptation shows abnormalities of both rod and cone function (Fig. 11).

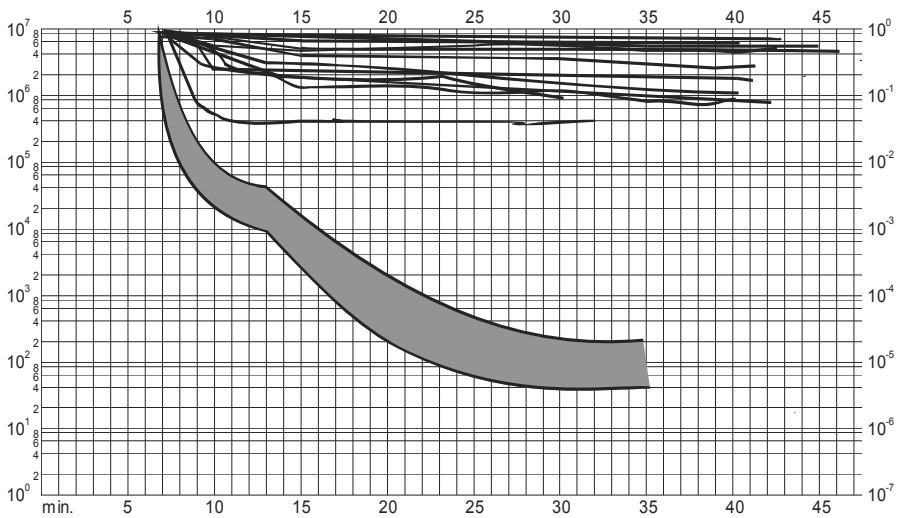

Fig. 11. Results of dark adaptometry in 14 cases aged 8–59 years. The grey area indicates the normal range of recovery of cone and rod sensitivity during dark adaptation for corresponding ages. (Figure published in Arch Ophthalmol. 2001;119(2):260–267).

In the younger patients the rod function is severely affected or absent and the cone adaptation often shows an extremely high, elevated final threshold, with the final dark-adapted sensitivity about four log units higher than a normal range. In elderly affected cases an even more pronounced cone dysfunction is found (Burstedt et al., 2001, 2003).

Full-field, single flash, and flicker electroretinograms (ERGs), including the oscillatory potentials (OPs) are recorded (UTAS-E 2000 LKC Technologies Inc., Gaithersburg, MD) using Burian-Allen bipolar electrodes during standard dark-adapted conditions, according to the recommendations of ISCEV (International Society for Clinical Electrophysiology of Vision). The outcome of the ERGs in all BD cases is subnormal or with non-recordable amplitudes of the rod-isolated b-waves with peak times either within the normal range or prolonged compared to controls (Burstedt et al., 2001, 2003, 2008). Representative full-field ERGs from five individuals from one family are presented in Fig. 12. The mixed rod-cone b-waves amplitudes are subnormal/non-recordable with comparatively short peak times in the younger cases. The amplitudes of the mixed rod-cone a-waves are found to be within the normal range in younger patients and subnormal to non-recordable with a prolonged peak time in adulthood. The amplitudes of the cone b-waves are better preserved and are within the normal range at the very young age, with peak times within the normal range, but prolonged in young adulthood and thereafter. Most of the younger patients had normal amplitudes and implicit times of the 30-Hz flicker ERGs that are within the normal limits, but already in early adulthood subnormal and delayed. The summed amplitudes of the individual oscillatory peaks, representing the Ops, show subnormal values at young age, decreasing with age and becoming non-recordable in BD cases older than 40 years of age.

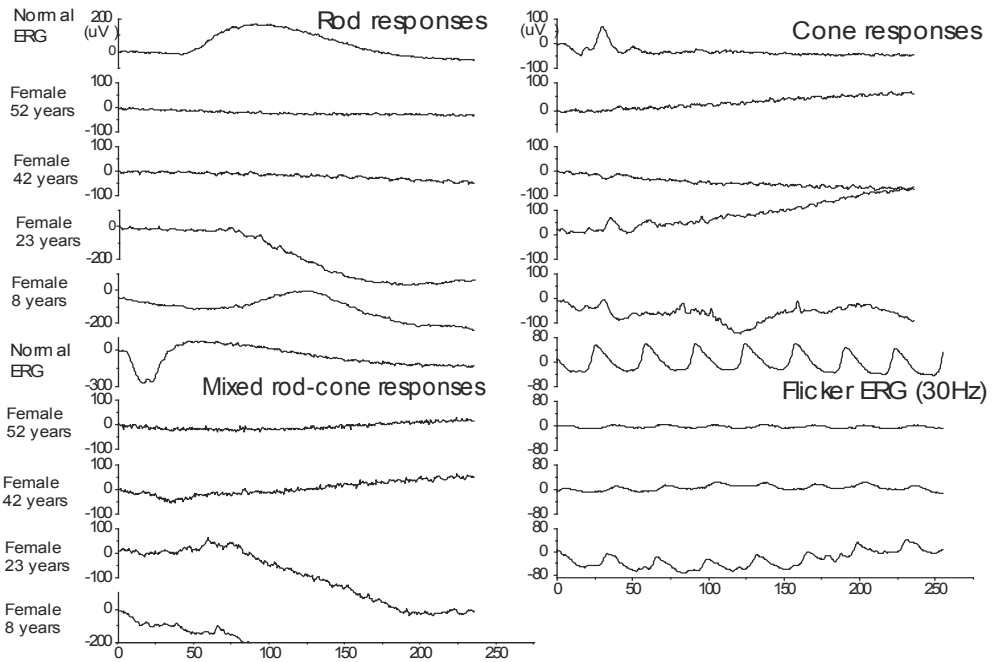

Fig. 12. Full-field ERG responses of the nonaffected individual (above) and BD patients, two elderly, and two younger women (52, 42, 23, and 8 years of age, respectively) from the same family. (Figure published in Arch Ophthalmol. 2001;119(2):260–267).

The ERGs recorded under standard conditions show that the rod and mixed rod-cone b-wave responses are relatively more affected than the mixed a-wave. The cone b-wave and the 30 Hz flicker amplitudes are significantly better preserved than the b-wave amplitudes of the rod and mixed rod-cone responses as well as the a-wave amplitude of the mixed rod-cone response, indicating later disturbance of the cones compared with the rods. At the same time the glial and inner retinal cell types seem to be affected at a relatively early stage in retinal degenerative disease (Burstedt et al., 2003).

2.3.2 Dark adaptometry and electrophysiology findings during 24 h prolonged dark-adaptation conditions

It has been shown that after illumination, the rhodopsin regeneration, 11-*cis*-retinal production, and dark adaptation are delayed by >10-fold in the visual cycle in *RLBP1* knockout mice (Saari et al., 2001). This could also be observed in humans, in six younger adults with BD, examined with a standardized Goldmann-Weekers adaptometer during an extremely prolonged dark adaptation of 24 hours (Burstedt et al., 2003). The extremely slow DA reaches steady state within 5 to 12 hours (Fig. 13); however, the final visual sensory thresholds do not return to normal levels after 24 hours of DA in most of the cases studied, probably affected by the disturbance in the normal function of CRALBP and lack of regeneration of 11-*cis* retinal in the RPE. An apparent plateau of recovery in the dark is observed, and duration for about 1 to 4 hours possibly represents a removal of bleached pigments, which has been suggested to occur in other retinal diseases affecting visual cycle function (Cideciyan et al., 1997). The 11-*cis*-retinal has been estimated to range from about 3.5% to 8% of that in normal subjects (Lamb & Pugh, 2004), with an average level of about 6% in the RPE in the BD phenotype.

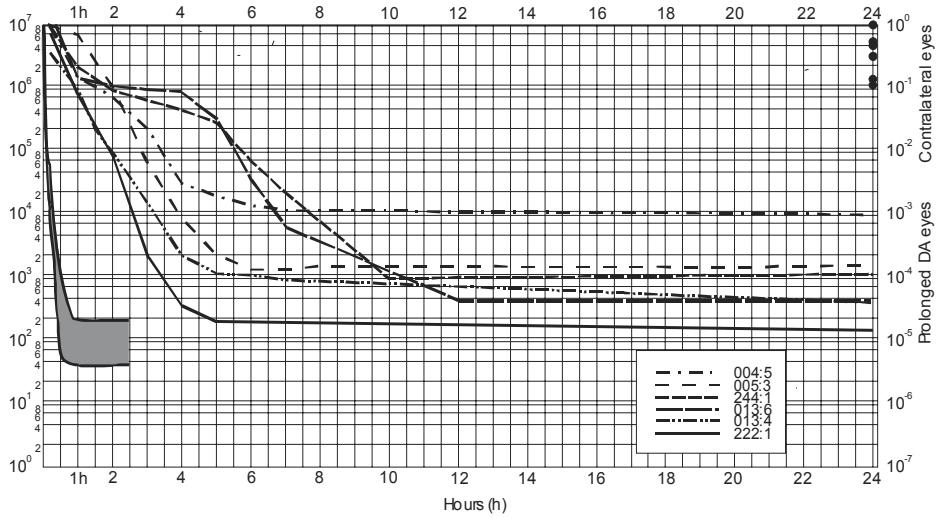

Fig. 13. Results of extremely prolonged (24 h) dark-adaptometry examinations in single eyes in BD patients, n = 6 (age 12–47 years). The final thresholds after 24 h were measured in both the patched single eye and in the unpatched contralateral eye. The values of the unpatched contralateral eye are indicated as filled symbols (•). The shaded area indicates normal range for corresponding age groups. (Figure published in Vision Research 2003:43(24):2559–2571).

Full-field ERGs after 24 hours of extremely prolonged DA were performed to evaluate the capacity of recovery of the whole retinal area and different cell types in BD disease. Six young cases (age 15–30 years) underwent full-field ERGs after 24 hours of DA in one eye and standard DA in the fellow eye. The results could be compared with the effect of the ERG after 10 hours' prolonged DA from a previous study (Burstedt et al., 2003, 2008). Enhanced rod-isolated b-wave after extremely prolonged DA (24 h) shows a sufficient number of rods able to function, generating responses of normal amplitudes even in young BD patients, although still with prolonged peak times (Fig. 14). Since the b-wave of the ERG is a glial response reflecting a depolarization of the Müller cells (Miller & Dowling, 1970), these findings may be correlated to an affected CRALBP function in the Müller cells of the retina or possibly a reversible effect on the second-order ON-bipolar cell function, as a consequence of a change in photoreceptor function.

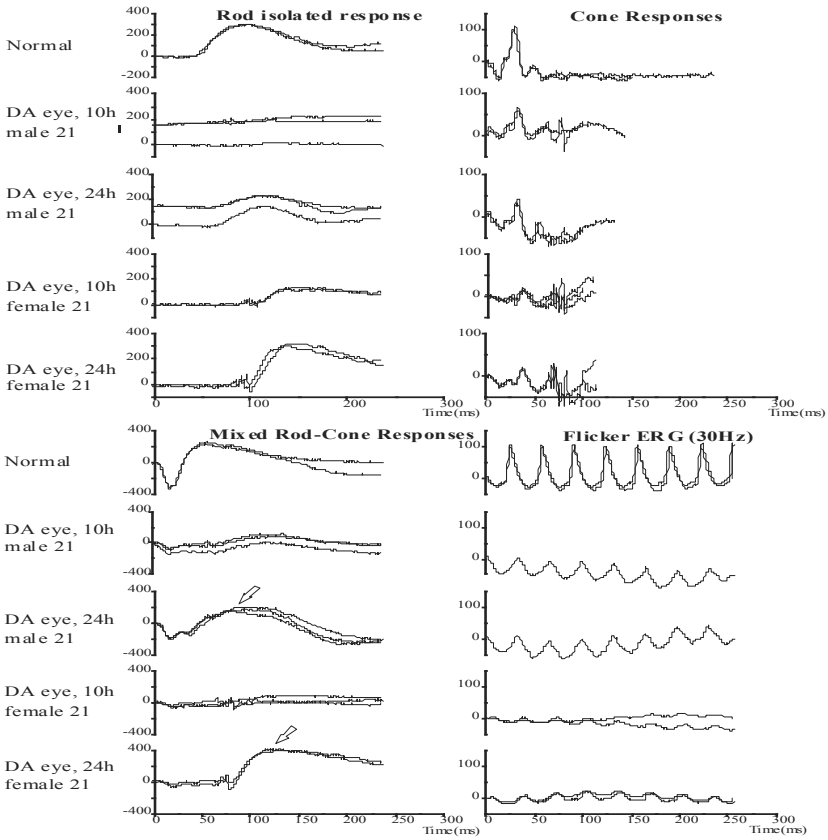

Fig. 14. Full-field electroretinograms of one eye, recorded after prolonged DA (10 h) and after extremely prolonged DA (24 h) in two BD patients (both 21 years old). A 'second', comparatively slowly rising positivity was observed in the mixed rod-cone response (arrows). For comparison, recordings of a normal subject are shown. (Figure published in Doc Ophthalmol. 2008;116(3):193–205).

The mixed rod-cone b-wave amplitude created by depolarization of the Müller and ON-bipolar cells in the inner retina is increased but still subnormal in the majority of patients.

After extended (24 h) DA, the mixed rod-cone a-wave response increases in amplitude to normal values in 4/5 cases with normal or somewhat delayed peak times. As the mixed a-wave shows normalized responses in the majority of the young BD cases examined, and the leading edge of the a-wave mainly represents a light-evoked hyperpolarization of the photoreceptors (Brown, 1968; Jamison et al., 2001; Robson et al., 2003; Tomita, 1965), these data suggest an additional, extremely slow regeneration of photopigments occurring even after 10 h DA. No obvious recovery of the cone b-wave is noted after the extremely prolonged DA (24 h); therefore, a relatively early damage to the cone system in BD patients cannot be excluded. Even though regeneration of opsin photopigments has been demonstrated in cone-dominant retinas, suggesting an interaction between Müller cells and cones in the recycling of visual chromophore (Mata et al., 2002), these electrophysiological results cannot confirm these findings.

In three younger BD patients a late evolvement in the mixed rod-cone response is observed (Fig. 14, arrows). The amplitudes are within the normal range of a mixed rod-cone b-wave, but the peak is extremely delayed (115 ms) compared to normal. This can be related to an enhanced scotopic activity associated with the slow and disturbed regeneration of photopigments. However, the exact origin of this late positive potential observed in BD patients is not known.

In summary, the continuous but slow regeneration of rod photopigments in *RLBP1* mutants presents an additional capacity for recovery of rod function and gain in activity in the inner retinal layers with extremely prolonged dark adaptation, possibly as a consequence of a change in photoreceptor function (Burstedt et al., 2003, 2008).

2.4 Outcome of visual function

Visual loss is an early sign of the BD disease, and individuals of working age may experience important socioeconomic consequences and interference with education as a result of their visual impairment. To provide insight into the perceived visual function of retinitis pigmentosa of Bothnia type, measurements of visual function were associated with the patients' self-assessment of their total self-reported visual function and health-related quality of life, measured with a questionnaire in 49 BD cases (Burstedt et al., 2010). Significant correlation was found between objective visual functions studied, and the subjective visual function. Almost 70% of the variability of the composite score could be explained by WVA and age alone. BD patients' responses to a majority of the questionnaire subscales significantly correlated with several of the clinical vision measures, especially those depending on central vision. Notably, the progressive declines in visual field area did not seem to affect significantly the self-perceived quality of life in patients with this phenotype. This finding might be an indication of ability to adapt to this type of gradual progressive visual field area loss, probably due to use of paracentral preserved areas. The expression of the disease has a significant impact on multiple domains of daily living, but there are no signs of worsening depression related to the increasing visual impairment.

2.5 Tinted contact lenses in BD

Could visual function be improved in BD? With the knowledge of an extremely prolonged dark adaptation (5–12 h) and even further gain of the ERG responses up to more than 12 h in

this phenotype, outcome of wearing of tinted contact lenses during daylight was tested (Jonsson et al., 2007).

Twelve patients with BD were fitted with soft contact lenses tinted dark brown. Outcome of visual parameters, and visual-function questionnaire, were tested before the contact lens fitting and after one month. Visual function was improved by dark-tinted contact lenses, and it was observed that the BD cases with the lowest visual acuity described the most obvious improvement of their visual function and preferred the darker tinted contact lenses; the majority of BD cases from this study have also chosen to continue wearing the brown-tinted contact lenses for several years following the study, possibly indicating a continuous benefit in their daily life over time (authors' comments).

Fig. 15. Contact lenses with clear and different grades of tint were evaluated in retinitis pigmentosa of Bothnia type.

3. Conclusions

The RP population of northern Sweden has given us a unique opportunity to evaluate and compare the phenotypical expression of different *RLBP1* mutations over time. Despite genetic heterogeneity, the clinical expression of different *RLBP1* mutations in northern Sweden presents a unique phenotype of the retinal disease, clearly directing the molecular diagnosis and search for *RLBP1* mutations. It became possible to offer genetic testing among the families related to BD patients and also to the patients with a hereditary form of the recessive form of RP. In BD families we can offer risk assessment to future generations, providing genetic counselling based on molecular testing and clinical findings. There are several approaches to treatment of RP patients, although there are no established standards. Several drugs and nutritional supplements such as vitamin A palmitate, ascorbic acid, docosahexaenoic acid and others were evaluated with contradictory outcomes in different

studies. Vitamin A palmitate, the most-used nutritional supplement, is shown to slow the rate of retinal degeneration, but this type therapy is not without controversy (Shintani et al., 2009). Gene therapy, which replaces or turns off the mutant disease-causing gene, represents another option for treatment. Several years of basic research of *RPE65*-Lebers congenital amaurosis, a retinal disease affecting the visual cycle, by several independent research groups, resulted in clinical trials of human gene therapies during recent years, demonstrating short-term evidence of visual gain (Jacobson & Cideciyan, 2010; Musarella & MacDonald, 2011). Therefore, we suggest that for treatment of BD patients, gene therapy is the most promising option among other concepts in the treatment of retinitis pigmentosa.

4. Acknowledgments

We acknowledge all BD patients and their families for their participation in all our studies. The authors express their thanks to all collaborators, and especially to Dr. Sandgren, for being a source of initiative and interest, and an engine in valuable discussions. This research was supported by funding from Crown Princess Margaretha's Foundation for Vision Research (KMA), the Swedish Medical Research Council, and grants from the County Council of Västerbotten.

1. Introduction

Retinal dystrophies are characterized by the degeneration of vision-supporting photoreceptor cells of the retina, leading to irreversible blindness. It is a heterogeneous group of diseases that can be caused by mutations on more than 150 identified genes with diverse functions (http://www.sph.uth.tmc.edu/Retnet/home.htm). Retinal dystrophies can be classified based on whether the rod or the cone photoreceptor cells are affected first, and based on the onset and progression of vision loss [1]. Leber congenital amaurosis (LCA) is in clear contrast with other inherited retinal dystrophies in that both rod and cone photoreceptor cells are affected from the onset of the disease [1]. The second major characteristic of LCA is that the progression to complete blindness is fast, making it the most devastating form of inherited retinal dystrophies [1]. In most cases, visual handicap is diagnosed before one year of age and progresses to legal blindness in early adulthood [2]. Other signs of the disease are an extinguished or severely reduced scotopic and photopic electroretinogram, absent or diminished pupillary response to light, and nystagmus (roaming eye movements) [3]. It is a rare disease, affecting approximately 1:30,000 people worldwide but it is the first cause of inherited blindness in children [2].

During the past 15 years, our understanding of the genetic basis of LCA has greatly progressed [1]. Today, 14 different genes causing LCA have been identified [1]. Together they are responsible for approximately 75% of LCA cases, the remaining 25% of LCA cases being caused by mutations in unidentified genes. The identified LCA-causing genes are expressed in various cell types of the retina and are involved in a wide variety of developmental and physiological pathways [1]. Because the disease is induced by mutation on a single gene, LCA patients are potentially good candidates for gene replacement therapy. In recent years, exciting results have been obtained in clinical trials for LCA caused by mutations on the *RPE65* gene (LCA2), representing 3 to 16% of LCA cases [4]. Several other LCA-causing genes have received proof-of-concept validation for gene therapy in animal models [1]. We can anticipate that in the following years, patients with LCA induced by mutations on these genes will undergo clinical trials for gene replacement therapy.

In this chapter, we will concentrate on LCA13 caused by mutations in the *RDH12* gene. This gene encodes for an enzyme of the short-chain dehydrogenase/reductase superfamily. It was named retinol dehydrogenase 12 (RDH12) based on its similarity with the RDH11 enzyme (Figure 1) [5]. Gene replacement therapy is not currently available for LCA13 patients and may not be for several years. Thus, any alternative therapeutic approach would be beneficial. We will review our and other's findings regarding the function of RDH12, providing new insight into the mechanism of RDH12-induced LCA. We will discuss how understanding the role of RDH12 is allowing the development of alternative therapeutic strategies to gene replacement therapy for patients with LCA13. Finally, we will describe our encouraging preliminary results obtained in a mouse line with disrupted *Rdh12* gene, using an imidazole-containing peptide derivative, which could be rapidly developed into an effective therapeutic strategy to preserve retinal structure and function in LCA13 patients.

Fig. 1. **Alignment of human RDH12 and RDH11 sequences.** Residue numbers are shown on the *right.* Identical residues are *boxed. Overbars* denote the two signature sequences for the superfamily of short-chain dehydrogenase/reductases [6]. GenBank™ accession numbers for human RDH12 and RDH11 are NP_689656 and CAG33461, respectively. Stretches of NH2-terminal hydrophobic residues predicted to be inserted in the membrane are underlined.

2. RDH12 and Leber Congenital Amaurosis

In 2004, mutations in the *RDH12* gene were found in a subset of LCA patients [7, 8]. Since then, more than 30 *RDH12* mutations have been found in the homozygous or compound heterozygous state in LCA13 patients [7-11]. LCA13 is inherited in an autosomal recessive manner and represents about 4% of all LCA cases [2]. LCA13 appears to share a common clinical picture with other types of LCA characterized by a poor visual function in early life, followed by a progressive decline due to both rods and cones degeneration [9].

Interestingly, when compared with the RPE65-mutant retina that has a relatively well preserved structure with a disproportionate loss of photoreceptor function (as measured in 4 LCA2 patients; ages 17, 19, 19 and 23), the structure of RDH12-mutant retina appears disrupted at much younger ages (measured in 4 LCA13 patients; ages 8, 11, 13 and 21) [12].

A number of RDH12 mutations leading to LCA have been biochemically evaluated by expressing the mutants in cultured cells and by measuring the enzymatic activities of the recombinant enzymes [7-11]. These studies have shown that mutations in RDH12 result in decreased or abolished enzymatic activity due to a lower affinity for the substrate or a lower affinity for the coenzyme and/or to a decreased specific activity. In addition, most of RDH12 mutations resulted in low steady-state levels of the mutant proteins in cells [11, 13]. It was hypothesized that these mutants could be recognized as misfolded and targeted for accelerated degradation by the ubiquitin-proteasome system [13]. These studies strongly suggest that the loss of RDH12 function is the primary event causing the development of LCA13 phenotype (i.e. rapid loss of photoreceptor function and disruption of retinal structure). Thus, to determine the triggering event in LCA13 pathogenesis, and because RDH12 is an enzyme, the fundamental question is: what is the nature of the RDH12 substrate?

3. Enzymatic activity of RDH12

RDH12 is an oxidoreductase enzyme of the short-chain dehydrogenase/reductase superfamily [5]. Its substrate and coenzyme specificities have been elucidated *in vitro* [5, 14]. RDH12 was found to reduce all-*trans* retinal and other retinaldehydes (in *cis* configurations) to corresponding retinols, using the reduced form of nicotinamide adenine dinucleotide phosphate as cofactor [5, 14]. In addition, various aldehyde-containing molecules, including 4-hydroxynonenal (4-HNE), were found to be reduced by RDH12 to corresponding alcohols [14]. Thus, RDH12 has a double substrate specificity for all-*trans* retinal (and other retinaldehydes) and for 4-HNE (and other toxic aldehydes). In addition, the possibility that RDH12 could have other -yet unknown- substrates cannot be ruled out.

The existence of two groups of substrates for RDH12 suggests that this enzyme could have two distinct physiological functions *in vivo*. As mentioned, mutations of RDH12 associated with LCA resulted in a decreased enzymatic activity of RDH12, inhibiting the reduction of all-*trans* retinal and 4-HNE to the corresponding alcohols *in vitro* [7, 10, 11, 15].

4. Possible RDH12 function(s) in the retina

RDH12 is abundantly expressed in rod and possibly cone photoreceptor cells in the retina [16-19]. These cells are photosensitive; they detect the presence of photons through the 11-*cis* retinal chromophore bound to opsin protein (forming the photosensitive rhodopsin). When photobleaching of rhodopsin occurs, light isomerizes 11-*cis* retinal to all-*trans* retinal, which then dissociates from opsin. This photoisomerization is the initial event that triggers the visual transduction pathway, activation of second order neurons, and eventually transmission of the signal to the brain. Under constant illumination, 11-*cis* retinal has to be

replaced (recycled) and all-*trans* retinal has to be removed from the surrounding of opsin so that photoreceptor cells continue to have an optimum sensitivity to light. The retinoid or visual cycle is the multi-step biochemical pathway that allows the recycling of 11-*cis*-retinal. The retinol dehydrogenases RDH8 (expressed in photoreceptor cells) and RDH5 (located in retinal pigment epithelium cells) were shown to directly participate in this essential pathway for maintenance of normal vision [20]. A possible function for RDH12 could thus be to reduce all-*trans* retinal, duplicating the RDH8 function, to keep photoreceptor cells in a state of high sensitivity to light.

We proposed another possible function for RDH12 in photoreceptor cells, in relation with its ability to reduce 4-HNE [15]. Reactive oxygen species formed within the mitochondria as byproducts of the electron transport chain can directly attack polyunsaturated fatty acids and initiate an auto-amplified chain reaction of lipid oxidation in cellular membranes. This causes the degradation of polyunsaturated fatty acids into a variety of oxidized products, including short- and medium-chain reactive aldehydes such as malondialdehyde, 4-hydroxyhexenal, and 4-HNE [21]. 4-HNE is the oxidation product of ω-6 arachidonic and linoleic fatty acids and is the most abundant and toxic end-product of lipid oxidation found in tissues [21-23]. It reacts readily with histidine, cysteine, and lysine to form Michael's adduct with these residues [24]. Oxidative modification of protein by 4-HNE leads to a variety of effects including inhibition of enzymatic activities; inhibition of protein functions; targeting of modified proteins for degradation; inhibition of protein, RNA, and DNA synthesis; cell cycle arrest; and apoptosis [21, 22, 25, 26]. When 4-HNE is reduced to the corresponding alcohol dihydroxynonene, its ability to form toxic adduct with proteins is abolished. Thus, we proposed that a possible function for RDH12 in the retina could be to detoxify 4-HNE by reducing it to dihydroxynonene [15].

When there is a loss of enzymatic function in cells, the substrate of the inactivated enzyme accumulates while the product of the reaction decreases. The next question is then whether it is the accumulation of substrate(s) or the disappearance of product(s), or both, that triggers the LCA13 phenotype. All-*trans* retinol, the product of all-*trans* retinal reduction, is not absolutely required for visual function because it is constantly supplied to the retinal pigment epithelium cells from the circulating blood. Therefore the most probable hypothesis is that accumulation of the substrate (all-*trans* retinal) rather than lack of product (all-*trans* retinol) might cause the retinal phenotype in LCA13 patients. Dihydroxynonene, the product of 4-HNE reduction, is not known to mediate any crucial biological function therefore in this scenario also, it seems that accumulation of the toxic substrate (4-HNE) rather than lack of product (dihydroxynonene) would cause the LCA13 phenotype.

5. Utilization of the *Rdh12* knockout mouse to determine the physiological substrate of RDH12

Identifying possible substrates for an enzyme *in vitro* is not enough to demonstrate that they are physiological substrates. *In vivo*, other considerations such as the localization and concentration of substrate relative to that of the enzyme are very important. Locations of the enzyme and substrate have to overlap and the substrate concentration has to be within a specific range for the enzymatic reaction to take place *in vivo*. The next step is thus to determine if there is accumulation of all-*trans* retinal and/or 4-HNE in the retina, in absence

of RDH12. Mice with disrupted *Rdh12* gene have been generated [16, 19] and they have been useful to determine what substrate of RDH12 accumulates in the retina.

After bleaching of rhodopsin, a moderate delay in all-*trans* retinal clearance was found in the *Rdh12* knockout retina [19, 27, 28]. To explain the existing but surprisingly small delay in all-*trans* retinal clearance, it has been argued that RDH12 is located only in the inner segment of photoreceptor cells, while rhodopsin is located only in the outer segment. Thus, it was proposed that instead of participating directly (with RDH8) to the reduction of all-*trans* retinal released in the outer segment, RDH12 could reduce only a small portion of all-*trans* retinal overflowing to the inner segment after bleaching of rhodopsin [27, 28].

In our study, we found that retinas of both albino [15] and pigmented *Rdh12* knockout mice (Figure 2) accumulated more 4-HNE-modified proteins than the corresponding wild-type animals on the same genetic background. As shown in Figure 2, pigmented knockout mice have significantly more retinal 4-HNE-protein adduct than the wild-type when exposed to bright light, a condition that induces oxidative damage. Similarly, in the BALB/c albino mice, 4-HNE-protein adduct was 60% higher in *Rdh12* knockout than in wild-type retinas in 2-month old animals raised under dim cyclic light [15]. These results support the hypothesis that 4-HNE is a physiological substrate of RDH12 in rod inner segments.

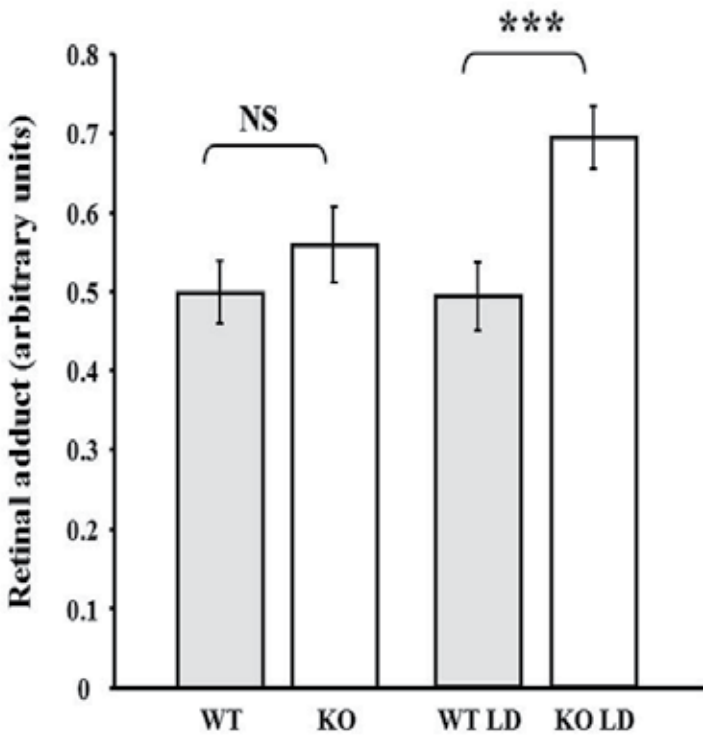

Fig. 2. **RDH12 protects against light-induced adduct formation in pigmented mouse retina.** Graph shows results for 6 mice per group. Littermates of wild-type and *Rdh12*

knockout mice were raised under dim (5-10 lux) cyclic light for 8 weeks. Control wild-type (WT) and knockout (KO) mice were killed 5 h after the (dim) light started. Light damaged (WT LD and KO LD) mice were killed after 48 h exposure to bright light (3,000 lux), without prior dilation of the pupils. Dissected retinas were homogenized in T-PER buffer (Pierce), according to the manufacturer's instructions. Protein concentrations were measured and dot blot analyses were carried out as described to quantify retinal adduct [15]. Equal aliquots (5 μg) of retinal protein were applied to a 96-well dot blot apparatus (Bio-Rad) and then transferred to a nitrocellulose membrane by vacuum filtration. Sample loading was monitored by staining the membrane with Ponceau red (Sigma). Membranes were blotted over night with a 1:1000 dilution of anti-HNE antibody coupled with horseradish peroxidase (abcam). Signals were quantified using SuperSignal West Femto Chemiluminescent Substrate (Pierce) and the digital Kodak Image Station 4000R.
Error bars denote SEM and Student's *t* test was used for significance.
NS, not significant ($p>0.05$); ***, $p<0.0001$.

The conclusion of these studies is that at least two physiological substrates of RDH12 coexist in photoreceptor cells; namely all-*trans* retinal and 4-HNE. The clearance of both of these substrates is delayed in the *Rdh12* knockout retina and it is now of crucial importance to determine which one, or if they can both, trigger the LCA13 phenotype.

6. Limitations of the *Rdh12* knockout mouse model to determine what substrate mediates photoreceptor damage

The main limitation to further determine whether accumulation of all-*trans* retinal or accumulation of 4-HNE is the triggering event in LCA13 is that, unlike LCA13 patients, the *Rdh12* knockout mouse does not develop a retinal phenotype [16, 19]. Thus the *Rdh12* knockout mouse is not an appropriate model for LCA13. We propose two possible explanations for the differences between mouse and human phenotypes.

6.1 Perhaps in mouse -but not in human- another enzyme is compensating for the loss of RDH12

In addition to RDH12, RDH11 and RDH13 are located in the inner segment of mouse photoreceptors. RDH11 and 12 are integral membrane proteins. Both enzymes are inserted in the membrane through a stretch of ~20 NH2-terminal hydrophobic residues (Figure 1) [5, 29]. RDH13 does not contain this stretch of hydrophobic residues and is a peripheral membrane protein. In previous studies, we showed that RDH11 is localized in the Golgi apparatus in spermatocytes [29] and in various cultured cells (unpublished observation). We performed a subcellular fractionation of mouse retinal tissues through ultracentrifugation on sucrose gradient [30]. RDH12 was found in Golgi- and endoplasmic reticulum-enriched fractions and RDH11 was detected only in the Golgi-enriched fractions [31]. Another study showed that RDH13 is a mitochondrial enzyme, localized within the intermembrane space, and associated with the inner mitochondrial membrane [32]. These different subcellular localizations suggest a specific role for RDH13 in the mitochondria, another specific role for RDH12 in the endoplasmic reticulum, but a possible redundant function for RDH11 and RDH12 in the Golgi. In the *Rdh12* knockout mouse photoreceptors, RDH11 may functionally compensate for RDH12 because these enzymes have overlapping localization and they have similar enzymatic activities and substrate specificities [17]. In humans on the other hand, RDH11 may not be

expressed in photoreceptor cells [5] and thus may not compensate for the loss of RDH12 activity, possibly explaining the more dramatic phenotype in LCA13 patients.

6.2 Perhaps bright light is triggering the phenotype resulting from disruption of RDH12 enzymatic activity

Patients with LCA13 show an early disruption of their retinal structure [12]. The distorted laminar architecture of RDH12-mutant retinas seems to be a specific feature of some subtypes of LCA [12]. It has been suggested that such dysplastic retinal response could be triggered by some forms of photoreceptor damage induced by environmental conditions [12]. For example, light exacerbates the retinal dysplasia in a mouse model of LCA caused by *CRB1* mutations (LCA8) [33, 34]. Interestingly, the *Rdh12* knockout mice do not have a retinal phenotype when they are raised under a controlled dim (5-10 lux) cyclic light environment [15, 16, 19]. However, when they are challenged by exposure to bright light (3,000 lux for the *Rdh12* knockout mice under the BALB/c background), the *Rdh12*-null photoreceptors appear significantly more sensitive than the wild-type cells to light-induced apoptosis [15, 19]. Since *Rdh12* knockout photoreceptors degenerate only after exposure to bright light but do not have a spontaneous degeneration when raised under controlled dim cyclic light, it is possible that similarly, the LCA13 patients have retinal degeneration because they are regularly exposed to very bright light intensities (i.e. outdoor light during a sunny day). Anticipation of dysplastic retinal response and greater understanding of the pathway that triggers it could lead to specific therapy to prevent this process in LCA13 patients. Without such prevention, the amount of salvageable retina might quickly become so low that any gene replacement therapy would not be worth attempting.

It is likely that the compensation by other RDHs combined with the controlled lighting environment, and anatomical differences between mouse and human retinas explain the absence of retinal phenotype in the *Rdh12* knockout mouse, as opposed to the dramatic phenotype in LCA13 patients. In any case, it is difficult to use the *Rdh12* knockout mice to determine what substrate of RDH12 accumulating in absence of enzyme induces a retinal phenotype, because there is no phenotype. Retinal damage can be induced by exposure to bright light but this treatment exacerbates the production of both substrates of RDH12 simultaneously so it is impossible to distinguish which one triggers the hypersensitivity of *Rdh12*-null photoreceptor cells to light-induced damage. In addition, we cannot exclude the alternative possibility that the hypersensitivity to light of the *Rdh12*-null photoreceptors is not the specific result of accumulation of RDH12 substrate(s) but rather due to a non-specific effect of the gene inactivation.

7. Alternative strategy to determine what substrate mediates photoreceptor damage

An alternative strategy is to experimentally induce the production of all-*trans* retinal and 4-HNE simultaneously by exposure of the *Rdh12* knockout mice to bright light, while at the same time decreasing the level of 4-HNE using a molecule that can specifically scavenge 4-HNE and lower its concentration in the retina (Figure 3). This strategy allowed us to distinguish the relative participation of each substrate to the photoreceptor hypersensitivity to light.

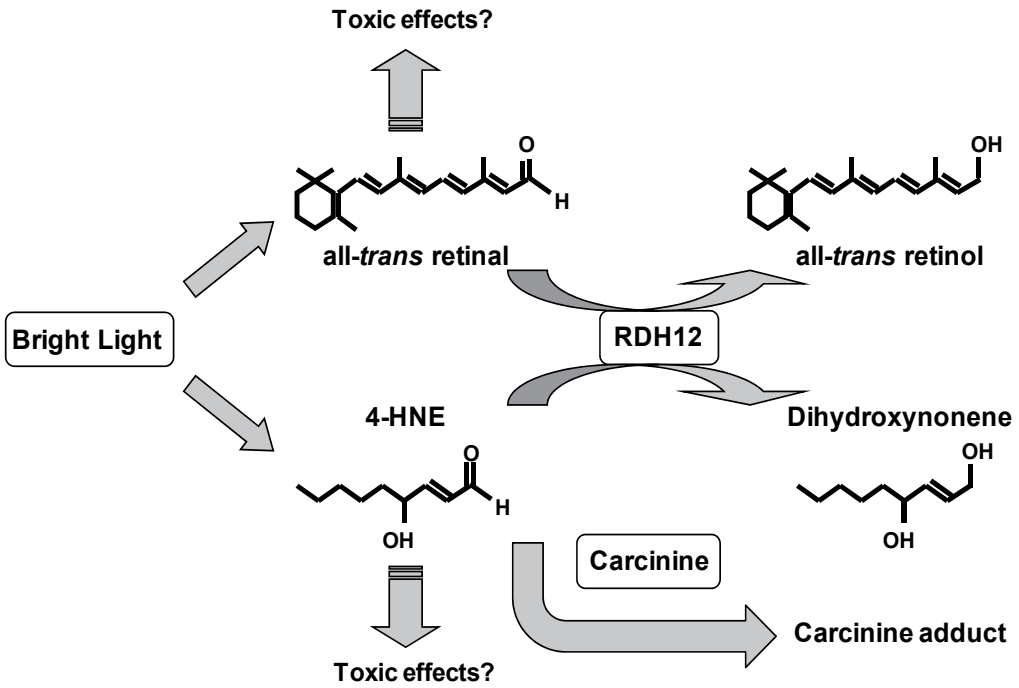

Fig. 3. **Experimental strategy to determine what substrate of RDH12 mediates photoreceptor hypersensitivity to light-induced damage.** Exposure to bright light exacerbates the production of both substrates (all-*trans* retinal and 4-HNE) simultaneously. In absence of RDH12, both substrates accumulate so it is impossible to distinguish which one triggers the hypersensitivity of photoreceptor cells to light-induced damage. Carcinine scavenges 4-HNE, forming 4-HNE-carcinine adduct, and thus can be used to lower 4-HNE independently of all-*trans* retinal. This allowed us to dissociate the effects of 4-HNE and all-*trans* retinal in the *Rdh12* knockout mouse retina.

Carcinine (β-alanyl-L-histamine) is a natural imidazole-containing peptide derivative that has antioxidant properties and can scavenge reactive aldehydes produced by lipid peroxidation [35, 36], thus preventing them from reacting with cellular proteins (manuscript submitted for publication). We have shown that intravitreal injection and systemic administration of carcinine protect wild-type photoreceptors from light-induced damage (manuscript submitted for publication). Photoreceptors are the first retinal cell type to show signs of damage after exposure to bright light. Light-induced apoptosis of photoreceptor cells is preceded by an increase of oxidative modification of retinal proteins [17, 37] and can be blocked by various types of antioxidants [38-40] including carcinine (manuscript submitted for publication).

We used carcinine to lower 4-HNE independently of all-*trans* retinal and dissociate the effects of these two molecules in mouse retina. Incubation of carcinine with all-*trans* retinal *in vitro* does not lead to any modification of the all-*trans* retinal molecule as determined by high-performance liquid chromatography analysis (unpublished observation) but incubation with 4-HNE leads to the formation of an adduct between carcinine and 4-HNE as determined by high-performance liquid chromatography and mass spectrometry (manuscript submitted for publication). Thus, carcinine is not expected to lower the retinal level of all-*trans* retinal or other retinoids under normal conditions or during exposure to bright light.

As shown in Figure 4A, without carcinine treatment (phospate buffered saline-injected eye), exposure of wild-type mice to bright light induces a decrease of rod-mediated visual function by approximately 50% for both a- and b-waves (black bars). As expected, the *Rdh12* knockout mice are more sensitive than the wild-type to light-induced damage, as shown by the 80 to 90% decrease of rod-mediated visual function for both a- and b-waves under the same conditions of light exposure (white bars). This result is consistent with previously published studies showing hypersensitivity of these knockout mice to light-induced damage [15].

Carcinine is expected to prevent light-induced damage mediated by oxidative stress and lipid peroxidation in photoreceptors. As shown in Figure 4A, with carcinine treatment (carcinine-injected eye), exposure of wild-type mice to bright light induce the decrease of rod-mediated visual function to about 25% loss instead of 50% loss without carcinine. In the *Rdh12* knockout mice, carcinine completely prevents the decrease of rod-mediated visual function. The remaining rod-mediated visual function after light damage goes from 10% without carcinine to 100% with carcinine, demonstrating a considerably beneficial effect of carcinine in these mice. The reason(s) why carcinine seems to protect more efficiently *Rdh12* knockout than wild-type photoreceptors is unknown. However, we can speculate that the disruption of *Rdh12* creates a "mild stress" in photoreceptors, inducing maybe some alternative protective mechanisms. The combination of enhanced compensatory protection and carcinine protection could be a possible explanation for this apparent higher efficiency of carcinine in the knockout than in the wild-type photoreceptors.

As shown in Figure 4B, cone-mediated visual function is more affected in the knockout than in the wild-type mouse by exposure to bright light (in phospate buffered saline -injected eye), and complete protection was provided by carcinine in both wild-type and knockout mice (carcinine-injected eye).

The fact that carcinine completely prevents light-induced damage in the *Rdh12* knockout mouse photoreceptors strongly suggests that the damage induced by light is mostly -if not only- mediated by oxidative stress and lipid peroxidation products accumulating in the *Rdh12* knockout photoreceptor cells. However, a mirror experiment in which all-*trans* retinal is specifically lowered independently of 4-HNE would further confirm our conclusion, if there was no protection. To specifically lower all-*trans* retinal independently of 4-HNE, a possible approach could be to overexpress the RDH8 enzyme in the *Rdh12* knockout photoreceptors because, as we have shown before, 4-HNE is not a substrate of RDH8 [29].

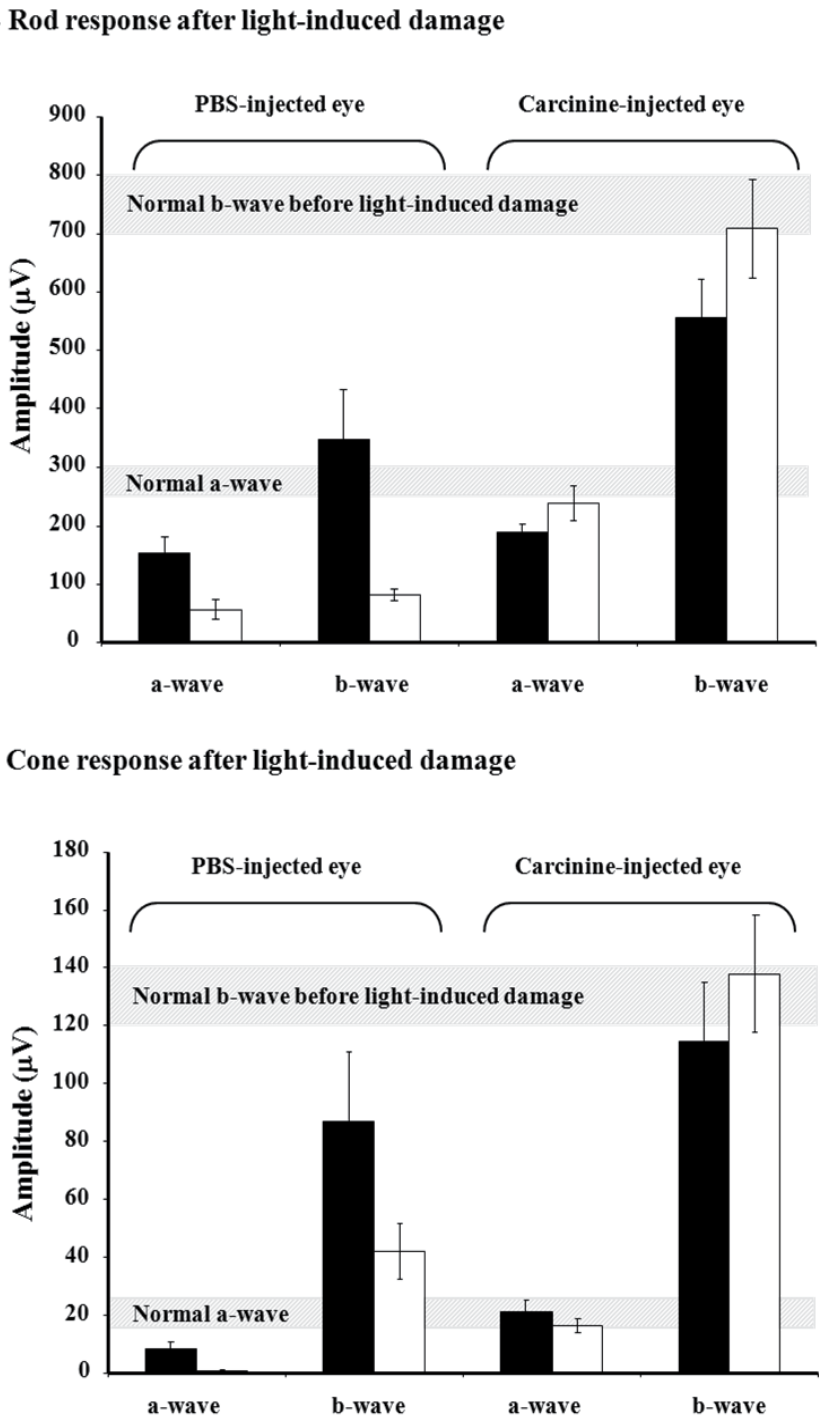

Fig. 4. **Carcinine protects visual function against light-induced damage in wild-type and *Rdh12* knockout mice.** BALB/c mice were raised in dim cyclic light for 8 weeks. Each

mouse was injected intravitreally in one eye with 1 μl phospate buffered saline (PBS) and in the other eye with 1 μl of 2 M carcinine diluted in PBS. Mice were returned in dim cyclic light for 48 h before light damage was initiated. Light damage was then induced in mice by 5 h exposure to 4,000 lux of white fluorescent light. After light exposure, mice are returned in dim cyclic light for 7 days to allow the retina to clear all dead cells. A. Scotopic electroretinographies were performed using saturating flash intensity. The a- and b-wave amplitudes of wild-type (black bars) and *Rdh12* knockout (white bars) are plotted to quantify rod-mediated visual function. B. Photopic ERGs were then performed to measure cone-mediated visual function. The a- and b-wave amplitudes are plotted to quantify cone-mediated visual function. Graphs show averaged results from 7 mice and error bars indicate SEM. Grey boxes show normal a- and b-waves recorded from PBS-injected eyes in mice that were not exposed to bright light.

8. Could decrease clearance of 4-HNE have toxic effects in photoreceptors?

Effects of 4-HNE in cells and its association with disease states have been increasingly well documented [23, 41]. Studies have shown that low, basal levels of the lipid aldehyde are present in cells (<5 μM), and at these concentrations, 4-HNE acts as a signaling molecule [42, 43]. It can activate cell growth and survival as well as stress response mechanisms, such as mitogen activated protein kinases, detoxification mechanisms, and inflammatory response, and by this way prepare the cells to overcome acute stress (protective effects) [41]. Under conditions of oxidative stress, 4-HNE concentrations increase above physiological levels; in membranes it accumulates at concentrations of 10 μM to 5 mM in response to oxidative insult [22, 23]. At such concentrations, the protective effect is lost; 4-HNE forms adduct with proteins inactivating their physiological functions, and activates intra cellular pathways promoting cell death [22, 23, 41].

The presence of 4-HNE-derived epitopes, including 4-HNE-protein adduct, has been reported in a growing number of diseases, including diabetes, cardiovascular, autoimmune, and neurodegenerative diseases, such as Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis [23]. The consistently growing evidence of increased 4-HNE tissue/blood levels in a great variety of human diseases certainly suggests a pathogenetic involvement of the aldehyde in their clinical expression and possible progression [41]. Recent studies have implicated 4-HNE in the pathogenesis of atherosclerosis and Alzheimer's disease [22, 41].

Oxidative stress, which induces lipid peroxidation and 4-HNE production, has been abundantly described to induce photoreceptor cell death [44-47]. Whether toxicity is mediated by 4-HNE and other lipid peroxidation products is unknown. We hypothesize that 4-HNE-mediated toxicity is inducing the rapid loss of vision in LCA13 patients. This hypothesis is based on the following evidences: (1) in cell culture, enzymatically active RDH12 protects against 4-HNE-induced cell death, while enzymatically inactive RDH12 does not [15, 37]. (2) Photoreceptor cells are particularly predisposed to oxidative stress because the retina has a high oxygen consumption, is chronically exposed to light, and contains several photosensitizers. This leads to an active production of reactive oxygen species. Furthermore, photoreceptors have a high content in polyunsaturated fatty acids, making their membranes particularly susceptible to lipid oxidation induced by reactive oxygen species. (3) In photoreceptor cells, 4-HNE production is induced by exposure to

bright light, specifically in the inner segment, the compartment where RDH12 is located [15, 37]. (4) Disruption of RDH12 induces accumulation of 4-HNE-modified proteins in mouse retina, correlated with a hypersensitivity to acute light damage [15].

Taken together these results show a correlation between accumulation of 4-HNE in photoreceptor inner segments and loss of visual function, suggesting a possible cause-effect relationship. The cause-effect relationship has not been demonstrated but the mechanisms of 4-HNE toxicity have been abundantly documented in other cells types and disease states.

In LCA13 patients, it is likely that the loss of retinal structure and function is triggered by accumulation of RDH12 substrate(s). Two physiological substrates of RDH12 have been identified *in vitro* and *in vivo*. In absence of RDH12, accumulation of each of these substrates could theoretically mediate unwanted effects in photoreceptor cells.

9. Carcinine – A possible therapeutic agent for LCA13?

If 4-HNE is indeed involved in the LCA13 disease mechanism, then carcinine would clearly be beneficial based on its antioxidant and 4-HNE scavenging activities. Additionally, we recently found that carcinine has another effect that might be of significant interest for LCA13.

9.1 Carcinine protects RDH12 from degradation

In a previous study, we have shown that exposure to bright light induces a specific decrease of RDH12 protein level in the mouse retina while the closely related RDH11 protein remains stable [17]. This effect is not accompanied by a decrease of the *Rdh12* mRNA level so we hypothesized that the protein reduction was due to increased degradation rather than decreased production of RDH12 [17]. We further hypothesized that RDH12, like any other protein could be modified by 4-HNE (or maybe even more so because it has specific affinity for this molecule) and targeted for degradation [17]. Bright light would increase the endogenous production of 4-HNE and modification of RDH12, and the adduct would be quickly degraded. If not compensated by an increase in RDH12 synthesis, this would result in a net decrease of RDH12.

We used mouse retinal explants to test this hypothesis (Figure 5). Incubation of mouse retinas in a media containing 4-HNE leads to a 40% decrease of RDH12 in 4 h, while RDH12 level remains stable in retinas incubated in the same media without 4-HNE (Figure 5A). Total 4-HNE-modified proteins were then immunoprecipitated with anti-HNE antibody and immunoblotted using an RDH12 antibody. RDH12 was immunoprecipitated by the anti-HNE antibody (Figure 5B), demonstrating the modification of RDH12 by 4-HNE. The 4-HNE-RDH12 adduct accumulates first (at 1 and 2 h incubation with 4-HNE) and then decreases (at 4 and 6 h incubation with 4-HNE), supporting the hypothesis that the adduct is targeted for degradation. When compared with the total amount of 4-HNE-modified protein, the modification of RDH12 does not seem to happen significantly faster than the modification of the other proteins (Figure 5C). This result invalidates the idea that the specific affinity of RDH12 for 4-HNE would increase the rate of adduct formation. By contrast, the decrease of 4-HNE-RDH12 adduct is significantly faster than the decrease of the total amount of 4-HNE-modified protein (Figure 5C). This result suggests that RDH12 is particularly unstable (compared with other proteins) when subjected to oxidative modification.

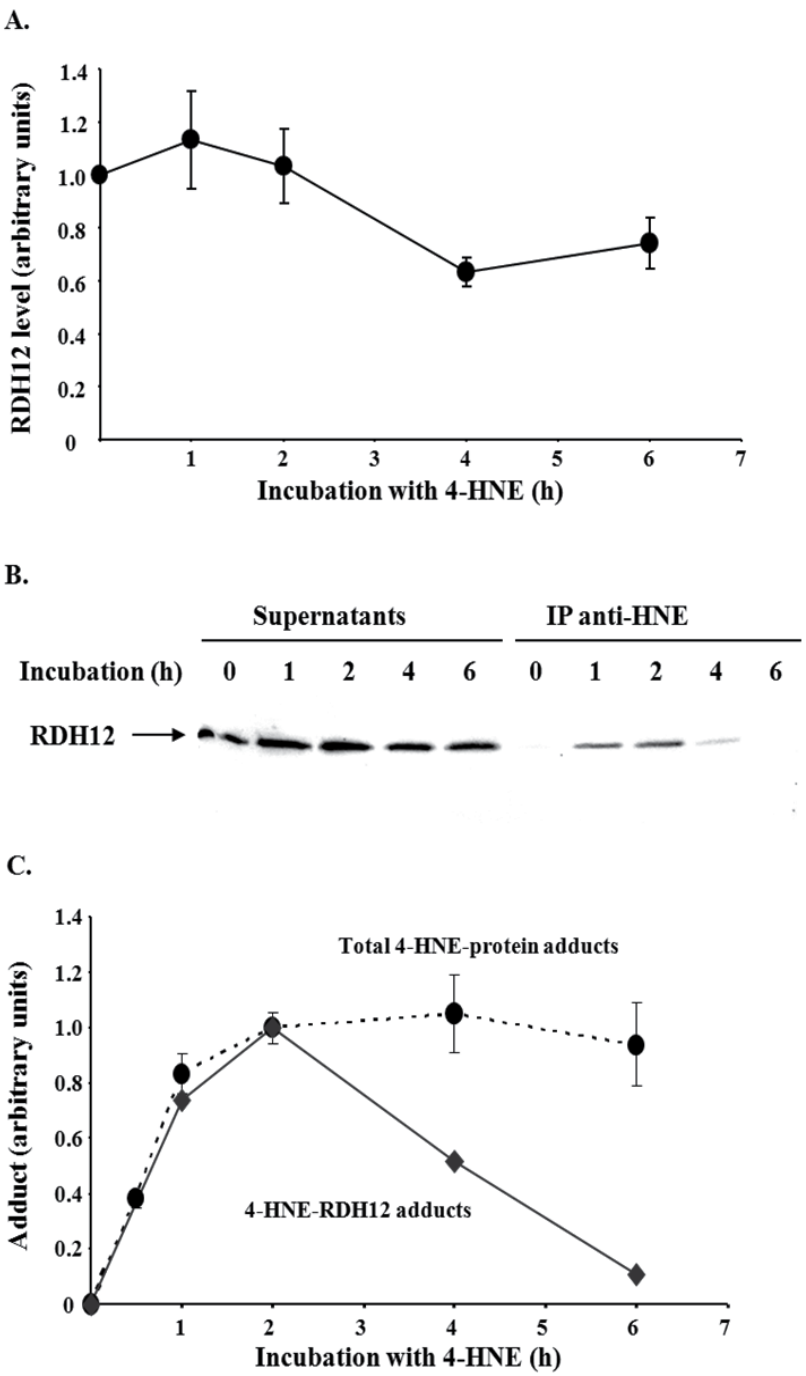

Fig. 5. **4-HNE modifies RDH12 and induces its degradation in retinal explants.** Retinas were dissected from 4- to 6-weeks-old pigmented wild-type mice. Retinas were incubated in Dulbecco's modified Eagle's medium, with or without 200 μM 4-HNE, at 37°C under 5% CO_2.

At indicated times, 6 retinas were removed from incubation, immediately washed in phosphate buffered saline, and frozen in liquid nitrogen for subsequent protein preparation. Frozen retinas were homogenized in T-PER buffer (Pierce), according to the manufacturer's instructions. A. Protein concentrations were measured and immunoblot analysis using anti-RDH12 antibody was performed using 30 μg of protein. The levels of RDH12 in retinal explants incubated with 4-HNE were expressed relative to those of RDH12 in retinal explants incubated without 4-HNE, arbitrarily defined as 1.0. B. Immunoprecipitation of 4-HNE-modified proteins was carried out as follow: equal amounts of protein were pooled from 6 retinas. 100 μg of pooled protein were incubated with 5 μl of anti-HNE antibody coupled with biotin (abcam) over night at 4°C, in a volume of 100 μl T-PER. 50 μl of streptavidin agarose resin (Pierce) was then added to each sample and incubated for 1 h at 4°C. After 3 washes with 1 ml T-PER, proteins were eluted in 50 μl Laemmli buffer and immunoblot analysis of supernatant and immunoprecipitated proteins were carried out with the anti-RDH12 antibody. C. Dot blot quantification of total 4-HNE-protein adduct was carried out as described in Fig. 2. with 2.5 μg of protein. The results from B were quantified and plotted on the same graph. At each time point the amounts of adducts are expressed relative to the highest level of adduct, arbitrarily defined as 1.0. Signals were detected using SuperSignal West Pico chemiluminescent or West Femto Maximum Signal Substrate (Pierce) and quantified using Kodak Molecular Imaging Software.

Interestingly, following intravitreal injection (Figure 6A) or systemic administration of carcinine (Figure 6B), the RDH12 protein level in mouse retina is stabilized and completely resistant to light-induced degradation. *In vivo*, the amount of 4-HNE-RDH12 adduct was undetectable (unpublished observation) so we could not determine whether carcinine was protecting RDH12 because it was opposing the 4-HNE-modification of RDH12 or through another mechanism. Absence of detectable 4-HNE-RDH12 adduct *in vivo* might be explained by the fact that endogenous production of 4-HNE as well as formation and degradation of adduct is an ongoing process, by contrast with the single dose of 4-HNE applied to the retinal explants creating a detectable "pulse" of 4-HNE-RDH12 adduct.

The stabilization of RDH12 protein by carcinine could enhance its therapeutic benefits for LCA13 patients. As discussed before, the RDH12 mutants associated with LCA are not only poorly active, but are also particularly unstable. The stabilizing effect of carcinine could keep the level of mutant RDH12 high enough to allow residual RDH12 enzymatic activity in photoreceptor cells. This, in addition with 4-HNE scavenging and antioxidant properties, could preserve the retinal structure and function in LCA13 patients.

9.2 Carcinine can be administered topically for chronic treatment

Treatment with carcinine would have to be started at the time of diagnosis and applied chronically to protect against 4-HNE and oxidative damage, which are ongoing processes in cells. We have investigated various modes of administration that could be compatible with a chronic treatment and measured the resulting level of carcinine in the retina (manuscript submitted for publication and unpublished results). Interestingly, topical administration through eye drop leads to detectable levels of carcinine in the retina (Figure 7). This result suggests that carcinine migrates from the cornea to the retina, following topical administration. The mechanisms of migration (simple diffusion versus transport) as well as the routes of

migration (trans-corneal versus trans-conjonctival penetration, migration through the vitreous humor or by lateral diffusion through the sclera, etc) are currently under investigation. The possibility to administer carcinine through eye drops is promising because it is a non-invasive and particularly easy route of administration, compatible with chronic treatment.

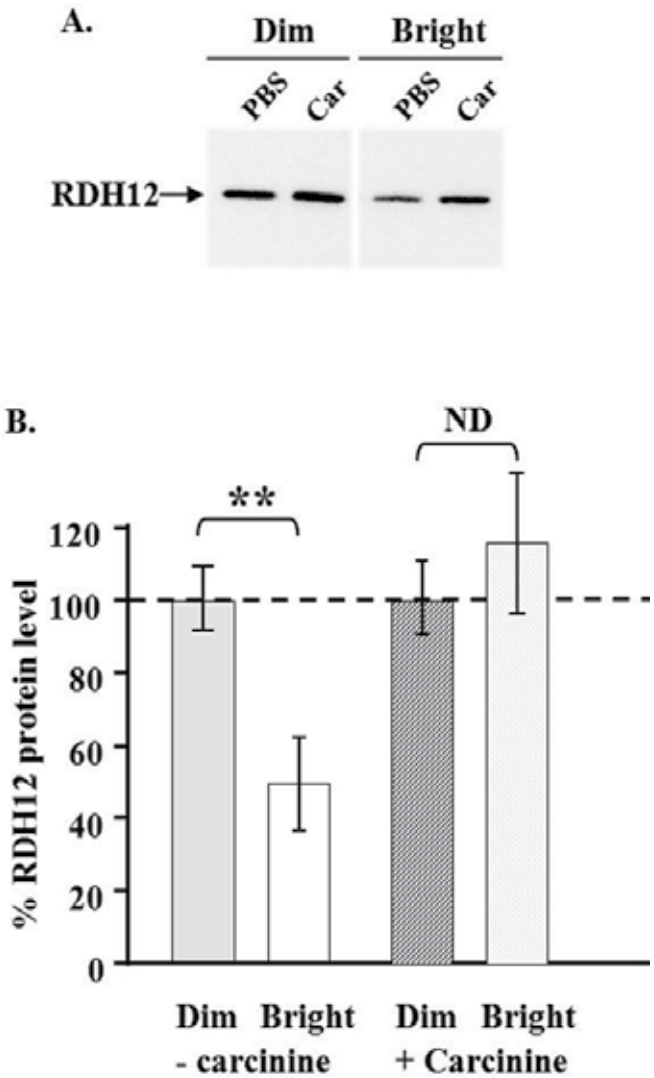

Fig. 6. **Carcinine protects RDH12 from light-induced degradation in mouse retina.** BALB/c mice were raised in dim cyclic light for 8 weeks before carcinine treatment. A. Mice were injected with carcinine or PBS and exposed to bright light as described in Fig. 4. For each group, 10 µg protein extract from 6 mice were pooled (60 μg final) and immunoblotted with anti-RDH12 antibody. B. Carcinine was administered through gavage (0 or 20 mg / mouse/ day) once a day for 5 days before light exposure. Mice were then exposed to bright white fluorescent light (3,000 lux) for 4h. Retinas were immediately frozen and proteins were extracted from one retina from each mouse (4 mice per group) using T-PER reagent. Protein

extracts from each mouse were individually quantified by immunoblot. RDH12 levels were normalized to β-actin first and expressed relative to the level of RDH12 in retinas of dim untreated mice, defined as 100%. Graph shows average and SEM values for 4 mice per group. Student's *t* test was used for significance; NS, not significant (>0.05); **=p<0.001.

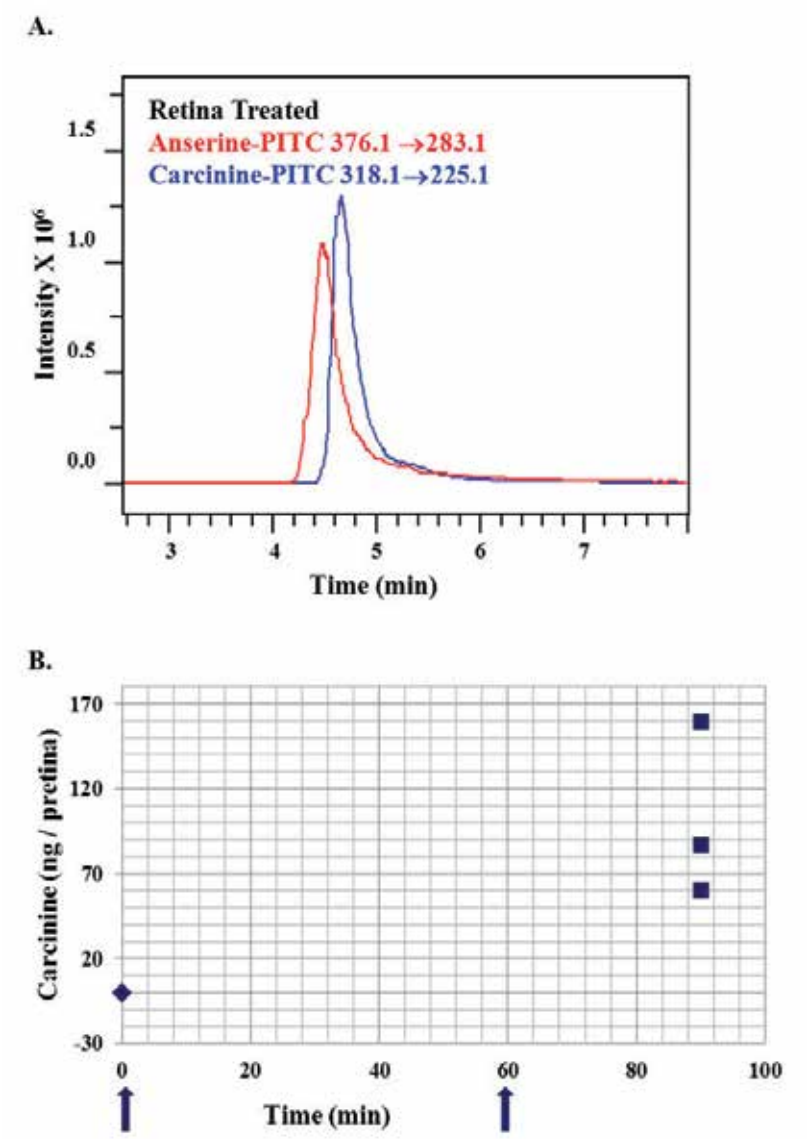

Fig. 7. **Topical administration of carcinine leads to detectable levels in the retina.**
Mice received carcinine (0.2 M) dissolved in Can-C eye drop solution (Innovative Vision Products, Inc). To analyze and quantify retinal carcinine, 2 retinas were homogenized in 1ml of cold 0.01M HCl with polytron. One μg of internal standard anserine was added to the samples. Samples were extracted with acetonitrile and derivatized with phenylisothiocyanate (PITC). Samples were analyzed by high-performance liquid chromatography / mass spectrometry

(Michrom Bioresources Paradigm MSRB capillary HPLC, Bruker Daltonics HCT Ultra Ion trap MS). High-performance liquid chromatography was run on column Magic MS C18, 5m, 200 A, 0.5 x 150 mm with Solvent A (0.09% formic acid, 0.01% TFA, 2% acetonitrile, 97.9% water) and Solvent B (0.09% formic acid, 0.0085% TFA, 95% acetonitrile, 4.9% water). An isocratic program (15% B for 10 min) was used. The flow rate was 20 ml/min and detection wavelength was 215 nm. An ion trap mass spectrometer (HCT Ultra PTM discovery system, Bruker Daltonics) equipped with an electrospray ion source and operating under an Esquire data analysis system was used. The spray voltage was set at 4 kV in the positive mode. The heater temperature was maintained at 300 ° C. A, 0.2 M carcinine was administered in Can-C eye drop solution at 0 min and mice were killed 30 min later to collect retinas. B, Another set of mice received 0.2 M carcinine at 0 and 60 min (indicated by arrows) and were killed 30 min following the second administration (at 90 min) to collect retinas.

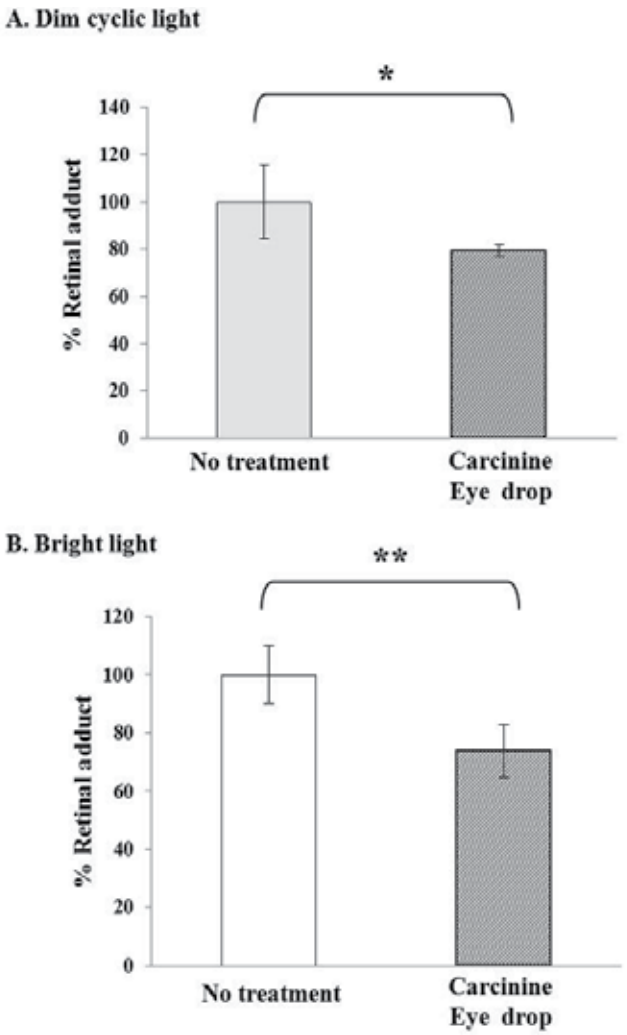

Fig. 8. **Carcinine decreases total 4-HNE-modified protein in mouse retina.** BALB/c mice were raised in dim cyclic light for 8 weeks before carcinine treatment. 0.2 M carcinine was

administered in Can-C eye drop solution (1 drop each 60 min, for 6 h) and mice were kept in dim light (A) or exposed to bright light (3,000 lux) for 4 h, starting right after administration of the second drop (B). Immediately after exposure to bright light, retinas were collected. Whole retinal homogenates were prepared and equal aliquots (10 μg) of retinal homogenates were analyzed by dot blot using anti-HNE coupled with HRP to quantify total 4-HNE-protein adduct. Five mice were used in each group, and the mean and SEM are plotted. Values were compared using Student's *t* test for significance; *=$p<0.05$; **=$p<0.001$.

9.3 Carcinine decreases the amount of 4-HNE-protein adduct in the retina

After administration of carcinine through eye drop, we found that the total amount of protein modified by 4-HNE in mouse retina is significantly decreased, both under dim and bright light (Figure 8). This result suggests that carcinine can scavenge 4-HNE *in vivo* after topical administration through eye drop. This implies that carcinine levels within the retina are adequate and that carcinine can enter the retinal cells to scavenge 4-HNE produced endogenously. Thus, carcinine could prevent the accumulation of toxic 4-HNE in RDH12-mutant retinas. We predict that carcinine, administered through eye drops, will prevent light-induced retinal damage in the wild-type and *Rdh12* knockout but these experiments have not been completed at this time.

10. Future directions

10.1 Developing therapeutic strategies

As shown by our preliminary experiments with carcinine, it is possible to start developing appropriate therapeutic strategies from the information already available on the function of RDH12. As discussed, exposure to bright light, as well as increased all-*trans* retinal levels, and increased oxidative damage particularly through 4-HNE modification are suspected to play a role in the disease mechanism. Accordingly, protection against these triggers can be developed with the goal to protect the retinal structure at least long enough to allow LCA13 patients to be eligible for gene replacement therapy.

10.1.1 Protection from light-induced damage

As discussed, the *Rdh12* knockout photoreceptors are more sensitive than the wild-type photoreceptors to light damage in mouse and exposure to bright light might be a trigger for the early dysplastic retinal response in LCA13 patients. Therefore, protection against light-induced retinal damage is an appropriate strategy.

Physical protection from bright light by wearing sun glasses should be encouraged for patients with LCA13. Compounds such as retinoid-like small molecules that provide chemical protection against light-induced retinal damage could also be beneficial [48, 49]. A number of studies have identified that photobleaching of rhodopsin is the essential trigger for retinal light damage [50, 51]. Genetically-modified mice that lack the opsin apoprotein or that have the opsin apoprotein but lack the ability to generate 11-*cis*-retinal are both protected against light damage [50-52]. A steady state rhodopsin level is achieved by the balance between its bleaching and regeneration. Therefore, the rate of rhodopsin regeneration is an important factor in light damage susceptibility. Fast regeneration of

functional rhodopsin after bleaching increases retinal sensitivity to light damage, whereas slowing the flux of retinoids through the visual cycle increases the resistance of photoreceptors to light-induced insult. For example, slowing rhodopsin regeneration and inhibiting the visual cycle with 13-*cis*-retinoic acid prevents light damage in albino rats [53]. More recently, it has been shown that retinylamine provides efficient protection from light damage through a similar mechanism [48].

Most of the small molecules inhibiting the visual cycle are structurally similar to retinoids [49]. However, we recently identified α-phenyl-N-*tert*-butyl nitrone, a commonly used free radical spin trap, as another type of compound with no structural similarity with retinoids that interferes with rhodopsin regeneration during continuous illumination and protects against light-induced retinal degeneration [54]. The advantage that α-phenyl-N-*tert*-butyl nitrone may have over these retinol-related compounds is that it is not structurally similar nor a derivative of any of the visual cycle components and therefore may not have adverse effect by interacting with retinoid receptors and other components of the visual cycle.

10.1.2 Protection from oxidative damage

Because oxidative damage is likely to contribute to the LCA13 disease mechanism, compounds that inhibit oxidative damage or enhance endogenous protection against oxidative damage would be appropriate candidates for LCA13 treatment.

A wide variety of antioxidants are available as oral supplementations. Specific advantages of carcinine would be to combine antioxidant and 4-HNE scavenging activities. Thus, carcinine can offer an additional line of defense against oxidative damage by decreasing 4-HNE, a secondary product of oxidative stress that mediates and amplify the oxidative damage triggered by reactive oxygen species and that was shown to accumulate in mouse retina in absence of RDH12.

In addition, the main limitation for therapeutic utilization of antioxidants in retinal diseases is usually the poor targeting of the posterior segment of the eye (choroid, retinal pigmented epithelium, and retina) due to anatomical and physiological barriers that normally protect the eye. Most molecules cannot reach the posterior segment tissues upon topical administration in the form of eye drops. Periocular or intravitreal injections are more efficient routes of administration but they are invasive procedures, which are not compatible with a chronic preventive treatment. Oral supplementation of antioxidants is usually preferred but oral bioavailability and the necessity to cross the blood-retinal barrier limits the amount of compound reaching the target tissues, and therefore limits the prevention of oxidative damage in these tissues.

Carcinine is one of the very few compounds that can reach posterior segment tissues upon topical administration (less than 10 of such compounds have been reported to date) [55]. This method of administration represents the great advantages of being non-invasive, safer because it is used locally no systemic side effects are expected, and cheaper because it is used locally the amount needed is smaller than with systemic administration than any other methods. It is also compatible with a chronic treatment that could be administered by the patients themselves, or by their parents.

Drugs that upregulate the body's natural defense against oxidative stress would also be appropriate. Reactive oxygen species are constantly generated in cells as unwanted by-

products of aerobic metabolism. A wide variety of enzymatic as well as non-enzymatic cellular defense systems prevents and repair reactive oxygen species-induced damage to tolerable levels. Under ideal circumstances, the rate of production of oxidative damage should be comparable to that of its removal or repair. In LCA13, absence of the cellular defense mediated by RDH12 could perhaps be compensated by the enhancement of other cellular cytoprotective mechanisms through dietary or pharmaceutical manipulations. A wide variety of dietary polyphenols and other classes of phytochemicals have been reported to induce the expression of enzymes involved in cellular antioxidant defenses and detoxification mechanisms [56]. Such compounds would be appropriate candidates for LCA13 treatment as well.

11. Conclusion

Although generally described in the literature as an enzyme involved in all-*trans* retinal reduction, in this chapter we presented evidences for an additional detoxification role of RDH12 in photoreceptor inner segments, reducing the 4-HNE produced by lipid oxidation that takes place constantly in mouse retina. Loss of this function in patients with inherited retinal dystrophy due to mutations in *RDH12* might contribute to the dramatic and early onset loss of retinal structure and function in these individuals. Our preliminary experiments with carcinine show that this compound might be beneficial in LCA13 because it has antioxidant, 4-HNE scavenging, and RDH12 stabilizing effects in the retina. In addition, we showed that carcinine can be conveniently administered through eye drops to target the retina. Additional therapeutic strategies are developed for protection against bright light and all-*trans* retinal toxicity. Finally, the recent impressive clinical accomplishment of gene therapy for LCA2 patients laid the ground for using similar approaches to treat various types of LCA, including LCA13.

12. Acknowledgment

The authors thank Dr. Debra A. Thompson for her critical review of this manuscript. This work was supported by grants from the National Center for Research Resources (P20RR017703), the National Eye Institute (R21EY018907 and P30EY012190), the Oklahoma Center for the Advancement of Science and Technology, the University of Oklahoma College of Medicine Alumni Association, and by an unrestricted Grant from Research to Prevent Blindness, Inc. to the Ophthalmology Department of the University of Oklahoma Health Sciences Center.

Eyelid and Orbital Infections

Ayub Hakim
Department of Ophthalmology, Western Galilee - Nahariya Medical Center, Nahariya, Israel

1. Introduction

The major infections of the ocular adnexal and orbital tissues are preseptal cellulitis and orbital cellulitis. They occur more frequently in children than in adults. In Schramm's series of 303 cases of orbital cellulitis, 68% of the patients were younger than 9 years old and only 17% were older than 15 years old.

Orbital cellulitis is less common, but more serious than preseptal. Both conditions happen more commonly in the winter months when the incidence of paranasal sinus infections is increased. There are specific causes for each of these types of cellulitis, and each may be associated with serious complications, including vision loss, intracranial infection and death. Studies of orbital cellulitis and its complication report mortality in 1- 2% and vision loss in 3-11%. In contrast, mortality and vision loss are extremely rare in preseptal cellulitis.

1.1 Definitions

Preseptal and orbital cellulites are the most common causes of acute orbital inflammation. Preseptal cellulitis is an infection of the soft tissue of the eyelids and periocular region that is localized anterior to the orbital septum outside the bony orbit. Orbital cellulitis (3.5 per 100,00) is an infection of the soft tissues of the orbit that is localized posterior to the orbital septum and involves the fat and muscles contained within the bony orbit. Both types are normally distinguished clinically by anatomic location.

1.2 Pathophysiology

The soft tissues of the eyelids, adnexa and orbit are sterile. Infection usually originates from adjacent non-sterile sites but may also expand hematogenously from distant infected sites when septicemia occurs. Preseptal cellulitis usually originates from skin infection with or without local trauma. It may also originate from structures inside the eyelid that are connected to the surface and become infected such as external and internal hordeolom. Chalazion is an example of internal hordeolom and these are all infected glands with surface connections. Glands with even partial preseptal location such as the lacrimal gland, in which the palpebral lobe is located preseptally, may also cause preseptal cellulitis.

Orbital cellulitis occurs in the following three situations:

- Spreading of an infection from the periorbital structures, usually from the paranasal sinuses, but also from the face, the globe and the lacrimal sac.

- Direct inoculation of the orbit from surgical trauma.
- Hematogenous spread from distant sites (bacteremia).

In case of local cutaneous infection, preseptal cellulitis can arise from the spread of a contiguous anterior eyelid infection such as a chalazion, local trauma resulting in infection such as insect bite, or a foreign body. The skin and, in some instances, the sinuses and lacremal mucosa, are colonized by various microorganisms. Orbital cellulitis following trauma is the consequence of a direct exposure of the orbital contents to these microorganisms. Open periorbital fractures, as well as closed fractures involving the sinuses or the nasal bone, may be a risk factor for orbital infections.

Orbital cellulitis, in contrast, usually arises from spread of infection from the paranasal sinuses. The ethmoid sinus is the most common source that extends to the orbit in children. In adults, pansinusitis is often accompanied by orbital cellulitis and its spread is believed to be caused through the ethmoid or frontal sinuses. The ethmoid sinus separeated from the orbit medially by the thinnest orbital bone – lamina papyracea. Often, the lamina contains congenital dehiscences through which sinus infections can easily spread into the orbit. This may support the frequency of orbital cellulitis secondary to ethmoiditis. The anterior and posterior ethmoidal foramina may also serve as potential passages for infection.

The orbital roof borders the frontal sinus. It is a diploeic bone and is thicker than the lamina papiracea. Infection may spread more easily through the valveless facial veins. Since the frontal sinus is adjacent to the anterior cranial fossa, it may serve as an intermediary for the spread of infection.

The orbital floor that borders the maxillary antrum also contain congenital dehiscences through which infection from the maxillary sinus can enter and facilitate infection spreading.

The posterior medial wall of the orbit borders the sphenoid sinus. Isolated sphenoiditis is rare. The sphenoid may be involved secondary to ethmoiditis. Sphenoethmoidal sinusitis has distinct clinical characteristics. Marked visual loss with or without ophthalmoplegia usually precedes the findings of proptosis and inflammatory orbital signs. This condition is rare due to the thick bony barrier and firm attachment of periorbita to the posterior orbital wall.

One dehiscence or more is often present in orbital walls, particularly in the thin-walled lamina papyracea and this facilitates the spread of infection to the orbit. Posteriorly, the optic nerve within the optic canal is adjacent to the lateral wall of the sphenoidal sinus. Dehiscence can also be found in the lateral wall of the sphenoidal sinus adjacent to the optic canal. The free valveless venous communication between the orbit and the sinus is another reason predisposing the orbit to the spread of adjacent sinus infection.

However, not all orbital cellulitis infections caused by sinus disease are secondary to acute sinusitis. Orbital fracture involving sinuses may allow spreading of an existing chronic sinus infection. Open fractures may also result in orbital cellulitis due to direct contact with the environment. Foreign bodies, such as a glass, wood or orbital floor implants, can cause orbital cellulitis. Infection can extend to the orbit from the eye, teeth, middle ear, or in neglected cases of preseptal cellulitis, from the eyelids and face.

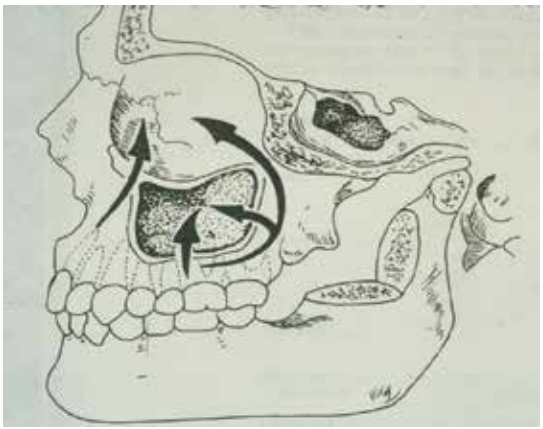
Uncomplicated eyelid, strabismus, cataract surgery, glaucoma valve and retinal surgery may all expose the orbit to infection. Orbital implants that are imbedded and other foreign bodies,

such as Molteno valve implant, may carry a risk for infection, especially if they are colonized or exposed. Orbital cellulitis secondary to keratitis may develop after radial keratotomy.

Advanced carries with secondary infection, poor dental work or an infected root or dental cyst can cause orbital cellulitis. Extraction of maxillary premolars, molars or canines exposes the patient to orbital infection. The most common pathway for odontico-orbital infections is through the paranasal sinuses. The apices of maxillary molars and premolars are in close proximity to the floor of the maxillary sinus and are, in fact, in direct contact with the maxillary mucosa. Direct fistula to the antrum may be caused by a floor fracture during dental extraction or maxillary mucosa disruption. Infection spreading from the sinus to the orbit can occur through congenital dehiscences in the medial orbital wall or through communication between the venous plexus of the maxillary mucosa and the ophthalmic veins, thereby causing thrombophlebitis.

Another pathway for the spread of infection is the thin buccal cortical plate of the alveolar processes.

Finally orbital cellulitis can occur secondarily from embolic spread in subacute bacterial endocarditis and from other distant organs.



Pathway for odontico-orbital infections

Dental abscess.Predisposing factors:poor dental care, advanced caries, root treatment, following dental extraction.

1.3 Classification

In 1970, chandler described a spectrum of progressive infectious changes in orbital cellulitis.

Chandler's Classification:

Stage I – Preseptal cellulitis

Ocasionally, edema may spread secondarily to preseptal cellulitis posterior to the septum without infection. In these cases chemosis may be present, but the extraocular movements and visual acuity remain intact.

Stage II – Orbital cellulitis

Diffuse edema of orbital contents, with leukocytosis, fever, proptosis and impaired extraocular motility without discrete abscess formation.

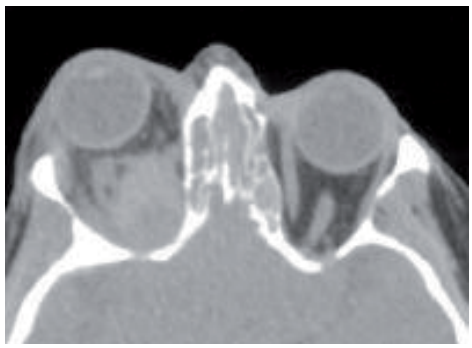
Examples are shown in the images below:

A male with left orbital cellulitis presented with proptosis, ophthalmoplegia, and edema and erythema of the eyelids. The patient also exhibited pain on eye movement, fever, headache, and malaise.

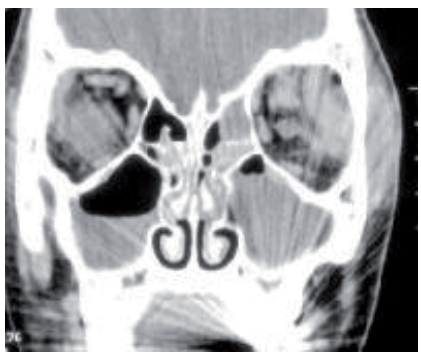
A male with left orbital cellulitis with proptosis, ophthalmoplegia, and edema and erythema of the eyelids. The patient also exhibited chemosis and resistance to retropulsion of the globe.

Stage III - Subperiosteal abscess

The globe is often displaced and limited in the field of gaze of the abscess.



An axial computed tomography scan in a patient with a right orbital infection caused by streptococcus pneumoniae and a right superior orbital subperiosteal abscess that resulted in blindness.



A coronal computed tomography scan of a child with pansinusitis as well as a left orbital and subperiosteal abscess.

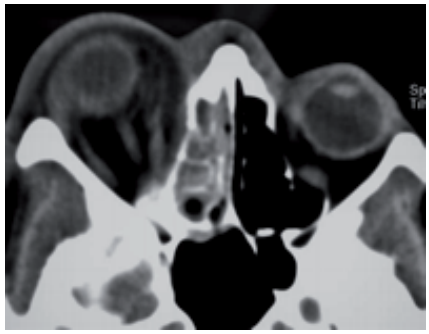
A coronal computed tomography scan in a patient with sickle cell disease. In this image, the patient has a left subperiosteal bleeding that mimiced the appearance of an infectious subperiosteal abscess.

Stage IV – Intraorbital abscess, purulent collection:

These patients have severe proptosis, chemosis, ophthalmoplegia and often visual loss.

Frontal view of the patient with a right orbital abscess showing periorbital redness, swelling and proptosis.

Coronal computed tomography scan in a pediatric patient with pansinusitis sinusitis and left orbital abscess.



Axial computerized tomography scan shows a right classic proptosis associated with an abscess of the orbit, as well as displacement of the medial orbital tissues and tenting of the posterior.

Stage V – Cavernous sinus thrombosis (septic abscess)

In these instances, the orbital signs evolve in the fellow eye (bilateral) and other central nervous system signs supervene.

A T1 weighted coronal MRI demonstrating asymmetry between the caverenous sinuses with obliteration of the right cavernous sinus.

2. Preseptal cellulitis

Preseptal cellulitis is more common than orbital cellulitis. It can present with swelling and erythema of tissues surrounding the orbit, with or without fever. Preseptal cellulitis most commonly occurs from a contiguous infection of the soft tissues of the face and eyelids

secondary to local trauma, foreign bodies or insect or animal bites. It is rare for untreated preseptal cellulitis to progress to orbital cellulitis by local extension. Defining the exact location of inflammation is essential for proper diagnosis and treatment.

2.1 Symptoms and signs

Patients with preseptal cellulitis often have a short history (days) of painless swelling of the eyelids. A history of early upper respiratory tract infection, trauma, insect or animal bite, conjunctivitis, or chalazion may be disclosed. Fever is an inconstant feature. The eyelid characteristically is erythematous, edematous, tender and warm. Vision and pupillary response are always unaffected and proptosis, globe displacement and limitation in ocular motility are never present. Concurrent preseptal cellulitis was discovered in the presence of many systemic diseases including, varicella, asthma, nasal polyposis and neutropenia. Preseptal cellulitis is more common among children than in adults.

Preseptal cellulitis is more common in children than in adults.

swelling and erythema of soft tissues surrounding the orbit.

Eyelid swelling, erythema, local warmth, tenderness.no proptosis, limited ocular motility or optic nerve involvement.

2.2 Microbiology

The most common inciting microorganisms include *Streptococcus pneumoniae*, *Staphylococcus aureus*, other Streptococcus species and anaerobes. *Haemophilus infuenzae* type B was the most common cause in children under four years old. However, routine vaccination with conjugate *Haemophilus influenzae* vaccines since 1985 has dramatically decreased this infection in young children. Less commonly implicated microorganisms include Acinetobacter spp., *Nocardia brasiliensis*, *Bacillus anthracis*, *Pseudomonas aeruginosa*, *Neisseria gonorrhoea*, Proteus spp., *Pasteurella multocida*, *Mycobacterium tuberculosis* and Trichophyton spp.

2.3 Differential diagnosis

Conditions that might masquerade as preseptal cellulitis include allergic edema (anaphylactoid reaction) of the eyelids, severe blepharitis with scruffs (seborrheic),

collarets(staphylococcal), sleeves(demodex) with or without erythema but no local warmth. The meibomianitis is characterised with eyelid swelling, pouting of meibomian gland orisices and discharge from orifices but no local warmth.

In addition dacryoadenitis, blunt trauma, thyroid eye disease, leukemic infiltrates, blepharochalasis syndrome and autoimmune inflammatory disorder such as lupus. Other disorders of less resemblance include orbital tumors/pseudotumours (, orbital vasculitis, necrotising fascitis and others.

2.4 Management

Treatment regimens cover the most likely organisms to cause infection in this setting and according to case series. Outpatient treatment should include broad-spectrum oral antibiotics and close observation. The author came to a conclusion that most cases of preseptal cellulitis can be safely managed as outpatients with oral antibiotics and follow-up until improvement is documented. If the condition does not improve or deteriorates 48 hours or more after oral antibiotic treatment, the patients should be admitted for intravenous antibiotic treatment and close observation. The average time of hospitalization is four days.

The appropriate antibiotics in adults include Amoxicillin–clavulinate (Augmentin) 875 mg every 12 h, and in children 90 mg/kg/day amoxicillin and 6.4 mg/Kg/day of clavulanate divided to two doses. Another option includes Cefpodoxime (Vantin) 200 mg every 12 h in adults, and 10 mg/kg/d divided every 12 h in children with maximum daily dose of 400 mg. Cefdinir (Omnicef) 600 mg daily in adults, and 14 mg/kg/d divided every 12 h in children with maximum daily dose 600 mg is another option.

Pediatric patients under 1 year of age and all more severe cases require the same approach as patients with orbital cellulitis, namely, intravenous broad-spectrum antibiotics and hospital observation .Blood cultures should be obtained if the systemic fever increases. The recommended duration of antimicrobial therapy is for 7-10 days. Occasionally, patients will continue to have local signs of cellulitis at end of treatment. Oral antibiotic therapy is recommended to be continued in these patients until resolution of the erythema. Children with preseptal cellulitis, no orbital involvement, and who do not appear toxic can be treated with intramuscular or oral antibiotics on a daily basis as outpatients. Preseptal cellulitis in adults can be managed on outpatient basis with oral antibiotics with frequent monitoring for progression.

3. Orbital cellulitis

Orbital cellulitis occurs in three settings:

i. Extension of infection from periorbital structures, such as the face, lacrimal sac and globe, but particularly from the paranasal sinuses. Acute sinusitis is complicated by orbital cellulitis in 1-3% of cases and the coexisting sinusitis is present in 73-94% of patients with orbital cellulitis. Ethmoid sinusitis and pansinusitis are most likely to progress to orbital cellulitis. The first ocular sign of sinusitis may be preseptal inflammation only. This can then quickly progress to the classic clinical picture of orbital cellulitis. Other causes include – orbital trauma, with fracture or a foreign body, dacryocystitis, and infection of teeth, middle ear or face.

ii. Direct inoculation from accidental trauma or from surgery. Orbital cellulitis is uncommon complication of ophthalmic surgery, being reported after strabismus surgery, blepharoplasty, radial keratotomy, retinal surgery and following peribulbar anesthesia. A special case is fungal orbital cellulitis, a relatively rare condition occurring in two principal forms – 1. Subacute infection due to genera of Zygomacetes (mucormycosis). 2. A more chronic orbital infection caused by species of Aspergillus. The distinction between these two may be difficult on clinical observation alone.
iii. Hematogenous spread (endogenous from bacteremia). The microorganisms responsible for most cases are aerobic non-spore forming bacteria.

3.1 Symptoms and signs

Orbital cellulitis as preseptal cellulitis can present with swelling and erythema. The cardinal signs and symptoms are proptosis, ophthalmoplegia and globe displacement. Pain on eye movement, vision loss (indicates orbital apex involvement), diplopia, conjunctival chemosis and elevated intraocular pressure are common but variable accompanying signs.

3.2 Microbiology

S. aureus and Streptococci are the most commonly identified organisms in culture-positive orbital cellulitis. Less common causes are *H. influenza* and non-spore forming anaerobes. However, many other common and rare bacterial pathogens include *Eikenella corrodens*, *Aeromonas hydrophilia*, *P. aeroginosa*, fungal and mycobacterial pathogens, including *Scedosporium apospermum*, *M. tuberculosis* and *Mycobacterium avium* complex. The prognosis of aspergillosis is poor. More than 80% of reported patients have died from this causative.

3.3 Differential diagnosis

Conditions that may mimic orbital cellulitis include:

- Anaphylactoid reaction can be characterised with eyelid swelling and erythema but no local warmthand no proptosis, limited ocular motility or optic nerve involvement.
- Cavernous sinus syndrome that is characterised by proptosis, complete ophthalmoplegia, optic nerve involvement, V2 involvement, evolve to bilateral condition and usually in debilitated patients (diabetics, drug abusers, HIV).
- The orbital apex syndrome is characterised with complete external ophthalmoplegia, optic nerve and V1 involvement with/without proptosis.
- Superior orbital fissure syndrome is a condition that is characterised with complete external ophlmoplegia, V1 involvement with or without proptosis.
- The orbital compartment syndrome and the orbital tumors can present with proptosis, limited ocular motility, optic nerve involvement and increased intraocular pressure but no local warmth.

3.4 Diagnosis

There have been no controlled trials examining the utility of radiologic studies (e.g. computed tomography scanning, orbital ultrasound, or magnetic resonance imaging) in the diagnosis of orbital cellulitis or in distinguishing preseptal from orbital cellulitis.

Computed Tomography scanning (CT)

CT can confirm extension of inflammation into the orbit, detect coexisting sinus disease, and identify an orbital or subperiosteal abscess. Whether every patient with suspected orbital cellulitis needs a CT scan is controversial. Some experts suggest that a CT scan be performed only in those patients who deteriorate or fail to respond to 48 hours of IV antibiotics, as the majority of patients with orbital cellulitis do well with conservative medical management. It is suggested that patients with suspected orbital cellulitis – those with proptosis, globe displacement, limitation of eye movements, double vision, vision loss, and those patients in whom the physician cannot accurately assess vision – usually patients less than one year of age, at presentation have a baseline CT scan.

Orbital Ultrasunography(US)

US provides higher-resolution details of orbital contents and is useful when sequential follow-up of an abscess or drained abscess is required. However, orbital sonography is not widely available and is dependent on the expertise of the sonographer.

Magnetic Resonance Imaging (MRI)

MRI is superior to CT in the resolution of soft tissue disease. However, it is not usually performed because of the need for sedation in pediatric patients and because MRI is rarely immediately available.

Microbiologic studies

The causative microorganism in orbital cellulitis may be difficult to identify due to normal flora contaminants, mixed infection, and prior antibiotic therapy. Cultures for aerobic and anaerobic organisms may be obtained from blood, sinus aspirates, and abscess. Because blood cultures are usually negative, some clinicians obtain cultures of eye secretions or pharyngeal culture. However, these cultures are likely to be contaminated with normal oropharyngeal flora and should not guide the choice of antibiotic therapy. Microbiologic data limited to microorganisms recovered by surgical drainage from orbital abscesses or involved sinuses and/or positive blood culture are the most reliable information. It is recommended that in patients with suspected orbital cellulitis, blood cultures should be obtained before the initiation of antibiotic treatment. If surgery is performed, culture of abscess material or sinus contents should be sent for aerobic, anaerobic and fungal cultures.

3.5 Complications

The complications of bacterial orbital cellulitis may be orbital or intracranial. Orbital complications of orbital cellulitis include subperiosteal or orbital abscess formation in 7-9%, permanent globe displacement, limited ocular motility that may cause diplopia, and vision loss in 1%. Orbital abscess may be clinically indistinguishable from orbital cellulitis. Proptosis and globe displacement tends to be more severe with orbital abscess than in orbital cellulitis, and patients are more likely to be systemically ill. The diagnosis of orbital abscess is confirmed by imaging or at surgery. The identification of an orbital abscess on the baseline CT scan is important since these patients almost always require surgery. Intracranial complications, which are encountered in 4% of orbital cellulitis secondary to sinusitis include meningitis in 2%, cavernous sinus thrombosis in 1%, intracranial abscess

formation, epidural or subdural abscess or parenchymal brain abscess in 1%, and carotid artery occlusion. Intracranial involvement may be heralded by ophthalmoplegia, changes in mental status, contralateral cranial nerve palsy, or bilateral orbital cellulitis. Cavernous sinus thrombosis has become relatively rare in developed countries because of prompt and adequate treatment of most cases of acute sinusitis, but it still poses a major threat. The mortality rate of cavernous sinus thrombosis may exceed 50%.

Permanent vision loss may occur because of:

1. Corneal ulcer and perforation secondary to exposure or neurotrophic keratitis.
2. Destruction of intraocular tissues following neovascular or inflammatory glaucoma, endophthalmitis, septic uveitis or retinitis and exudative retinal detachment.
3. Various other mechanisms affecting the globe or posterior orbit, such as secondary glaucoma due to elevated orbital pressure, infectious optic neuritis or inflammatory optic neuritis , pressure effects the optic nerve, thrombophlebitis of ocular veins and central retinal artery occlusion.

Blindness can result from elevated intraorbital pressure causing optic neuropathy or extension of the infection to the optic nerve from the sphenoid sinus.

3.6 Management

Prompt administration of appropriate antibiotics is the key for successful treatment of orbital cellulitis. After appropriate workup, all periorbital and orbital infections should be treated with broad-spectrum antimicrobial agents. There have been no controlled trials examining the required duration of antimicrobial therapy in orbital cellulitis. Treatment regimens are based upon coverage of the most likely organisms to cause infection in this setting and treatment of case series. The initial empiric antibiotic treatment should consist of parenteral broad-spectrum therapy. Infection due to methicillin-resistant *S. aureus* is best treated with vancomycin, clindamycin and cefotaxime.

Fungal orbital cellulitis occurs and is primarily due to mucor and aspergillums species. It requires antifungals, such as amphotericin. Corticosteroids may be helpful in bacterial infections, but they should not be started before surgery and until the patient has been on appropriate antibiotics for 2-3 days to ascertain eradication of the microbial agents.

If secondary glaucoma develops, ocular anti-hypertensive agents should be initiated promptly. Prompt diagnosis and therapy are important since delayed intervention can result in sustained vision loss.

3.6.1 Antibiotic treatment

Due to increasing incidence of Methicillin-resistant *S. Aureus*, empiric therapy with Vancomycin (Vancocin) (15 mg/kg IV every 12 hours in adults, 10 to 15 mg/kg IV every 6 hours in children, maximum daily dose of 4gr) is recommended. If susceptibility testing reveals Methicillin-sensitive *S. aureus*, Vancomycin should be replaced with Nafcilin (Unipen), or Oxacillin (Bactocill) - (both agents are dosed at 2gr IV every 4 hours in adults, and 200 mg/kg per day IV in 4-6 divided doses in children, maximum daily dose of 12gr) since these agents have better CNS penetration than vancomycin.

One of the following should be added:

1. Ampicillin-sulbactam (Unasyn) 3gr IV every 6 hours in adults, 300 mg/kg per day in 4 divided doses in children, maximum daily dose of 12 gr.
2. Ticarcillin-clavulanate (Ticar), which covers most of the Gram-negative bacteria as well as Gram-positive organisms, including atypical *H. influenza*, and has also excellent anaerobic coverage. The dosage is 3.1gr IV every 4 hours in adults, 200-300 mg of ticarcillin component per kg per day in 4-6 divided doses in children of less than 60 kg. The maximum daily dose of ticarcillin component is 18 gr.
3. Piperacillin-Tazobactam 4.5gr IV every 6 hours in adults, 240 mg/kg per day in 3 divided doses in children, with a maximum daily dose of 16gr of piperacillin component.
4. Ceftriaxone (Rocephin) is effective agpenicillinase-producing *S. aureus*, most Gram–positive organisms, and most Gram-negative organisms except for Pseudomonas. Ceftriaxone also crosses the blood-brain barrier; therefore, it is an excellent choice if there is a suspicion of concurrent intracranial infection. 2gr IV every 12 hours in adults, 80-100 mg/kg per day in 2 divided doses in children, maximum dose of 4gr daily may be given.
5. Cefotaxime (Claforan), a third-generation cephalosporin that covers most of the common sinus pathogens with the exception of *Clostridium difficile*, may be given 2gr IV every 4 hours in adults, 150-200 mg/kg per day in 3-4 equally divided doses in children, with a maximum daily dose of 12gr.

Patients allergic to penicillin and/or cephalosporins may be treated with a combination of vancomycin and a flouroquinolon. For patients over 17 years of age, ciprofloxacin 500 mg twice a day or levofloxacin 500 mg daily may be prescribed. Flouroquinilones are not recommended for use in pediatric patients as first-line therapy for any infection because of the musculoskeletal side effects - The mildest side effects include muscle pain, called fibromyalgia. A more serious side effect, though also less common, is tendon damage. Fluoroquinolones can, in high doses, cause tendon damage, which can ultimately lead to rupture of the Achilles tendon (in addition gastrointestinal effects predominating (nausea, vomiting, diarrhea, or abdominal pain in 1.0%–5.0% of thepatients), followed byeffects onthecentral nervous system (dizziness, headache, and/or insomnia in 0.1%–0.3% of the patients) and skin (0.5%–2.2% of the patients). Elevation in levels of hepatic enzymes occurred in 1.8%–2.5% of thepatients, azotemia in 0.2%–1.3%, and eosinophilia in 0.2%–2.0%. Initial antibiotic therapy should be administered IV under hospitalization. Generally switching to oral therapy is done after the patient is afebrile and skin findings have begun to resolve, which usually take 3-5 days.

The duration of treatment depends on the response. Patients should be treated with parenteral antibiotics until they show clear evidence of clinical improvement as manifested by decrease in orbital congestive signs such as proptosis, gaze limitation, cellulitis and edema. Intravenous therapy should continue for a minimum of 3 days. Then oral antibiotic therapy may be instituted for a total course of 10 days to 3 weeks, depending on the severity of infection. Associated bacteremia, however, should be treated with 7-10 days of IV therapy.

As aforesaid, the oral regimen should be tailored based upon the results of the cultures. If the results are not available, reasonable empiric oral antibiotic choices include 1. amoxicillin

– clavulinate – 875 mg twice daily for adults or children over 40 kg, and 45 mg/kg/day divided every 12 hours for children over 3 moths and under 40 kg or 2. fluoroquinolone – (levofloxacin 750 mg once daily in adults). Linezolid (ZYVOX) - (600 mg twice daily in adults and children over 12 years of age, 10 mg/kg three times daily for children under 11 years) should be added if MRSA is suspected.

Careful follow-up is indicated in all patients who present with orbital cellulitis. This should include twice-daily examinations with attention to visual acuity, confrontation visual fields, exophthalmometry, motility and pupillary examination.

3.6.2 Antifungals

(Amphotericin B- Ambisome) 1 mg/kg IV q24h or Voriconazole (VFEND, Pfizer) 6 mg/kg IV q12h for 2 doses, then 4 mg/kg IV q12h or Voriconazole 200-300 mg PO q12h

Antifungal is the treatment of choice for fungal orbital cellulitis. It is administered IV and may be appropriately administered before laboratory confirmation of fungal infection in cases of severe infection and debilitated patients (diabetes mellitus, drug abusers, human immunodeficiency disease, metastatic cancer, prolonged administration of antibiotics and/ or corticosteroids).

3.6.3 Surgery

The timing for surgical intervention is critical. In cases of orbital cellulitis without abscess formation, in which visual acuity is 20/60 (Snellen notation), 6/15 (metric equivalent) or less, or declines with appropriate medical management, orbital exploration should be emergent. In cases in which the acuity is better than 20/60, the patient should be followed, expectantly, and frequently while more conservative management is initiated.

Orbital surgery is indicated if the patient:

1. Fails to respond
2. Deteriorates clinically despite treatment
3. Has worsening visual acuity or develops afferent pupillary defect
4. Develops an abscess, except selected pediatric cases with medial subperiosteal abscess, which may be successfully treated medically.

In patients older than 14 years of age, the author favours the latter approach because the risks of surgery are negligible compared with the visual and life-threatening risks of no intervention. In patients 9 years of age or younger, 25% of the subperiosteal abscesses are likely to resolve with antibiotic therapy alone. Several indications have been suggested for drainage of subperiosteal abscesses. These include age of 9 years or older, large abscess, frontal sinusitis, non-medial abscesschronic sinusitis, dental infection, optic nerve involvement, suspicion of anaerobic infection and recurrence after drainage. All other cases may be managed conservatively by intravenous antibiotics.

1. Introduction

There has been significant evolution over time from external headlight sinus surgery to endoscopic sinus surgery(ESS). ESS was pioneered by Messenklinger, who discovered that the sinuses had a predetermined mucociliary clearance pattern towards the natural ostium irrespective of additional openings into the sinuses. This philosophy of opening the natural ostium of the diseased sinus was then popularized by Stammberger and Kennedy. ESS is now accepted as the surgical management of choice for chronic sinusitis. Furthermore, as our knowledge of the anatomy of the sinuses has improved, other anciliary surgeries such as endoscopic lacrimal surgery, orbital decompression, applications to the pterygopalatine and infratemporal fossa, approaches from the sphenoid/sella extending to the cribriform, parasellar and clival region have evolved. Moreover, innovation in instrumentation has led to the acceptance of endoscopic management of benign endonasal tumors and more recently, on endoscopic management of malignant tumors of the nose and sinuses.

The current interest in ESS stems from several developments. The first is the advent of compact, multi-angled telescopes that allow excellent visualization of the nasal cavity for examination and of the sinuses during procedures, including such areas as the maxillary ostia and the frontal recess. Secondly, is the acceptance and appreciation of the great work of Messerklinger(1967) demonstrating that the anterior ethmoids are usually the key to persistent sinusitis. Thirdly, is the advent in radiological imaging. Endoscopic diagnostic examinations in conjunction with modern imaging methods, particularly CT scan, have proven to be an ideal combination and have been accepted as the "Standard of Care' for sinus disease. The CT scan can clearly identify anterior ethmoids disease which can easily be missed on a plain paranasal sinus X-ray. These developments make it possible to diagnose more accurately and treat sinusitis refractory to non-invasive therapy.

The technique of ESS was developed in Europe by Messerklinger and Wigand, who had two different goals designed for extremes of disease. The Messerklinger technique advocated in 1985 is an anterior to posterior approach which involves only the anterior ethmoids and the maxillary sinus ostium and can be extended into the posterior ethmoids, sphenoid and the frontal sinus anteriorly if necessary. Thus, the Messerklinger technique is ideal for patient with anterior ethmoid disease with or without maxillary or frontal sinus disease. On the contrary, the Wigand approach advocated in 1978 is posterior-to-anterior and routinely involves all the sinuses on the ipsilateral side and is ideal for patient with pan-sinusitis who

has or is apt to fail the more limited Messerklinger approach. Both techniques are based on the assumption that the sinus mucosa is most likely reversibly diseased and will return to normal once ventilation has been established. No attempt is made to eradicate the sinus mucous membrane, as in the Caldwell-Luc procedure, but rather to reestablish drainage so the mucosa can return to normal and restore its proper function.

Although telescopes give the surgeon a clearer and magnified view of the nose and sinuses, the picture on the video monitor is not three-dimentional and depth perception and orientation can be difficult. Consequently there is a risk of getting lost and this may result in an injury to the orbit, its contents, the optic nerve and the intracranial cavity. To reduce this risk, surgeons should ensure that they are thoroughly familiar with the anatomy and the anatomical variations that can occur in the nose and sinuses. Therefore, radiological imaging is essential prior to surgical intervention.

A significant development for soft-tissue removal was the development of "through-cutting" instrumentation. Powered instrumentation using soft tissue shavers (Metronic, Xomed, USA) offer another significant advancement to the endoscopic sinus surgeon but with some risk to the orbit and cranium in inexperienced hands (Fig 1). Setliff and Parsons were the first to report the use of soft-tissue shavers in endoscopic sinus surgery (Setliff , 1994). ESS with its minimally invasive technique often reduces pain, bleeding and length of hospital stay and avoids external incision and thus reduces surgical cost compared to conventional techniques. Endoscopic surgery cannot replace every conventional external approach and we should never be embarrassed to employ or convert to these conventional approaches when necessary (Gendeh et al, 2007). However, not all cases are suitable for an endoscopic approach and the surgeon must be experienced in the full range of surgical options, the patho-physiology and natural history of disease processes, if optimum results are to be achieved. This is particularly true in the controversial area of sinonasal neoplasia.

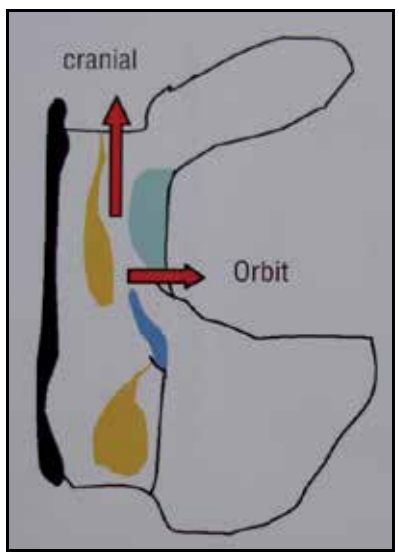

Fig. 1. Diagrammatic coronal section of paranasal sinuses showing the anatomical proximity of orbit and cranium to the nasal cavity in utilization of powered instrumentation and the risk involved.

This chapter will briefly outline the future trends in endoscopic skull base surgery. The Expanded Endonasal Approach(EEA) is a an extended endoscopic transnasal approach, providing access to the entire skull base from the epicenter, the sphenoid sinus.

It is important to define the word "endoneurosurgery" (Kassam et al, 2007). This is a new and emerging field and represents the use of the endoscope as the sole and only tool used to visualize the entire neural axis. In the case of EEA, only the endoscope is used to access the ventral skull via a completely transnasal route. As a joint team effort, this extended applications beyond the sphenoid sinus/sella needs a lot of surgical skills, planning and coordination for proper patient selection and optimal care. The EEA provides surgical access to the ventral skull base to resect a wide variety of intra-dural and extra-dural pathologies and allows the reconstruction of the resulting defect using a naso-septal flap. The evolution of these techniques has been enabled by technological advances including the design of specific endonasal instrumentation, surgical navigation technology and the development of new biomaterials for reconstruction. The incidence of tumor recurrence will be very much reduced with this minimally invasive ventral skull base technique. The use of powered instruments with navigational fusion imaging is most beneficial especially in revision cases.

2. Endoscopic dacryocystorhinostomy

Dacryocystorhinostomy(DCR) involves the formation of a bypass from the lacrimal sac into the nose. It is essential that with proper history and examination including syringing and probing, a correct diagnosis is made. Syringing and probing is performed only in congenital and acquired nasolacrimal duct obstruction (NLDO) and are indications for the procedure. They are not performed in acute and chronic dacryocystitis.

2.1 Indications (Table 1)

The main indication is when there is distal outflow obstruction to the nasolacrimal system which can clearly be demonstrated on a dacrocystogram. Endoscopic surgery is not indicated for obstruction of a punctum or a canaliculus for which there are other procedures. Often distal obstruction is mixed with varying degree of proximal obstruction and this need to be explained when counseling the patient. Syringing and probing is helpful in defining the site of obstruction. It is expected that in congenital and acquired NLDO, the epiphora would resolve and in acute and chronic dacryocysitis, the infection would be resolved without recurrences.

1. Primary acquired NLDO
2. Secondary acquired NLDO
    a. Infectious causes of secondary acquired lacrimal duct obstruction
    b. Inflammatory causes of secondary lacrimal obstruction
    c. Neoplastic causes of lacrimal obstruction
    d. Traumatic causes of lacrimal obstruction
    e. Mechanical causes of lacrimal obstruction

Table 1. Indications for Endonasal DCR(EDCR)

A dacrocystogram (Fig 2) is indicated if there is any mass within the sac and scintigraphy helps to define a functional problem. A functional problem is one issue for which a dacryocystogram is helpful. Lacrimal sac mass is another indication for dacryocystogram. A bloody discharge from the punctum is a symptom that needs investigating to exclude malignancy in the sac. The common symptoms are epiphora, recurrent dacryocystitis or swelling from a mucocele. It is unusual for intranasal pathology like Wegener granulomatosis and sarcoidosis to be the causative factor. Nasolacrimal duct obstruction can occur following a middle-third facial fracture. Distal nasolacrimal obstruction can be secondary to endoscopic sinus surgery if the Stammberger Rhinoforce Antrum Punch (Stortz, Germany) used to remove the uncinate process is placed too far forward.

Fig. 2. A dacrocystogram showing distal obstruction of right nasolacrimal system on failure of penetration of dye into the inferior meatus in a patient with unilateral unresolving tearing.

2.2 Contraindications (Table 2)

A contraindication to DCR is the presence of a benign or malignant lesion in the lacrimal system or the surrounding tissues and active Wegener granulomatosis. Other causes are lacrimal sac diverticulum,, canalicular stenosis, lacrimal calculi and extensive midfacial trauma.

1.	Known or suspected lacrimal system neoplasm
2.	Large lateral lacrimal sac diverticulum
3.	Common canalicular stenosis
4.	Lacrimal system stones
5.	Extensive midfacial trauma

Table 2. Contraindications for Endonasal DCR(EDCR)

2.3 Anatomy and pre-operative assessment

The lacrimal system comprises the lacrimal gland and its drainage system which commences with a punctum in each eyelid for 1mm at right angles to the lid margin. It continues as the upper and lower canaliculus which run parallel to the lid margin and then join to form a common canaliculus that drains into the lacrimal sac (Fig 3). Inferiorly the sac forms the nasolacrimal duct, which drains into the inferior meatus about 1cm posterior to

the anterior end of the inferior turbinate (Fig 4). The lacrimal sac sits in the lacrimal fossa which is a very thin bone. Unlike its anterior margin, the anterior lacrimal crest, is made of very dense bone. In about 8% of patients, an anterior ethmoidal air cell lies medial to the lacrimal fossa which needs to be transverse before a rhinostomy can be created.

Topical anesthetic drops such as amethocaine are placed in the eye followed by dilatation of the upper and lower puncta performed with punctual dilator. The puncta are initially dilated with the instrument perpendicular to the lid margin, rotating it for the first 1 mm with the lid margin taut, before turning it medially parallel to the lid. Upon dilatation of the punctum, a "0" Bowman probe is passed through the dilated punctum and angled medially. As the probe enters the common canaliculus, a slight resistance may be felt as a "soft stop" and as it touches the medial wall of the sac, there is a "hard stop". The probe is then angled vertically down to feel whether there is any sac pathology or distal obstruction. This is a description for probing in children, which is preferably performed under general anaesthesia. It is avoided in adults because of the intolerable pain. Rigid 0.7 mm dacryocystoscopes can be used to inspect the fine obstructing membranes that can be found at the medial aspect of the upper and lower canaliculi (Wormald, 2002). These proximal membranes are the main cause of proximal obstruction, and a DCR is not indicated if this is the site of the obstruction. For surgeons becoming familiar with intranasal anatomy or a history of previous sinonasal surgery, it may be helpful to introduce a 20-gauge fiberoptic endoilluminator(Stortz, Germany) through the superior or inferior canaliculus after punctual dilator. The endoilluminator is then advanced gently until a hard stop signifying the lacrimal bone is identified (Woog, 2004). The location of the lacrimal sac may then be visualized endoscopically by transillumination (Fig 5 a, b).

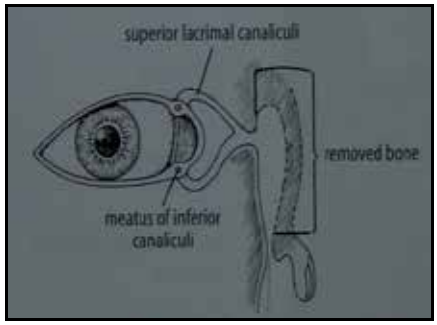

Fig. 3. Diagrammatic anatomical picture of nasolacrimal drainage system

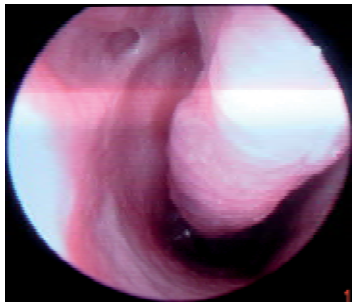

Fig. 4. Endoscopic view of a right nasolacrimal duct opening into an inferior meatus

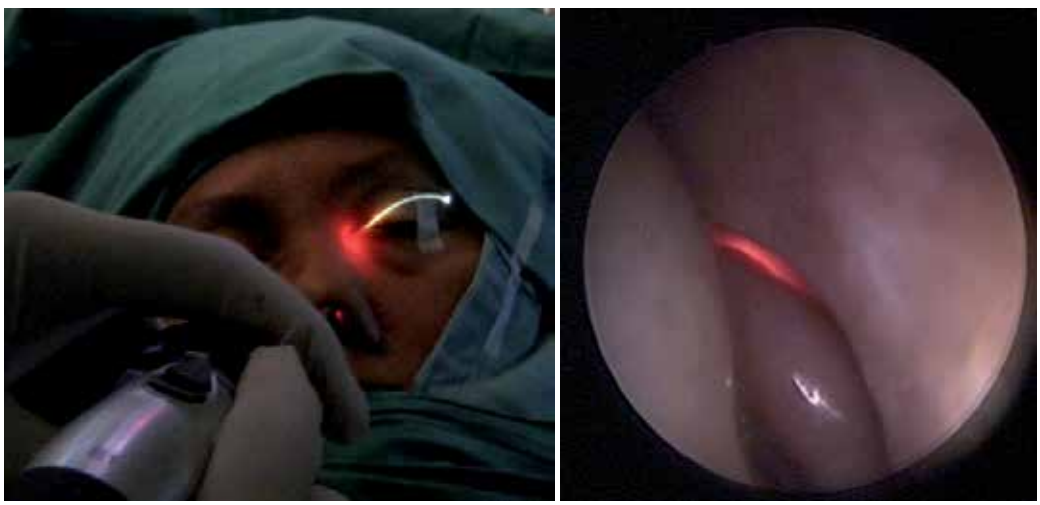
Distal obstruction is diagnosed by probing and then syringing to see whether the fluid can initially pass through the canaliculi into the nose. If it refluxes through the other punctum, it indicates that there is distal obstruction. On the contrary, if there is reflux through the same punctum, then there is canalicular or common canalicular stenosis and this can be confirmed by gentle probing. There are many causes of dysfunction that requires a different treatment than DCR. The most common site of distal obstruction is where the sac becomes the duct. Some surgeons will offer a DCR to patients with a functional blockage where there is free flow on syringing but on scintigraphy the pump system does not work. Only 70-75% of the tears are drained through the inferior canaliculus. Lester-Jones Pyrex tube is required only in bi-canalicular extensive obstruction that cannot be managed by other procedures such as forced probing and silicone intubation.



(a) (b)

Fig. 5. A picture showing a fiber-optic endoilluminator being introduced via the left inferior cannaliculus to illuminate the nasolacrimal sac(a) and a zero degree endoscopic view identifying the location of the illuminated lacrimal sac(b) in the same patient.

2.4 Surgical technique

Upon nasal decongestion with neuropatties and infilteration with lidocaine and adrenaline, a 15 scalpel blade is used for initial mucosal incisions. The first incision is made horizontally 1 cm above the axilla of the middle turbinate, commencing 3 mm posterior to the axilla and coming forward 1 cm onto the frontal process of the maxilla. The blade is then turned vertically and incision made about two thirds of the vertical height of middle turbinate, stopping just above the insertion of the inferior turbinate into the lateral nasal wall. The blade is then turned horizontally and the inferior insertion commenced at the insertion of the uncinate process and brought forward to meet the vertical incision.

A suction Freer's dissector (Stortz, Germany) is used to elevate the mucosal flap, ensuring that the tip of the sucker always maintains contact with the bone. Meanwhile the bone should be palpable so that the junction of the soft lacrimal bone and hard bone of the frontal process can

be identified. The thin lacrimal bone is 2 to 5 mm wide before the insertion of the uncinate process is reached. The dissection stops at the uncinate. A round knife (Stortz, Germany) is used to flake the soft lacrimal bone away from the postero-inferior region of the sac.

A forward-bitting Hajek Koeffler punch (Stortz, Germany) is used to remove the lower portion of the frontal process of the maxilla (Fig 6). The tip of the punch is used to push the lacrimal sac away where the lacrimal bone has to be removed. The punch is engaged in the hard bone of the frontal process and this bone is removed. Care should be taken not to grasp the sac as the punch is closed during bone removal. Removal of the frontal process of the maxilla uncovers the antero-inferior portion of the lacrimal sac. Bony removal with punch is continued as far superiorly as possible until the bone becomes too thick for the punch to engage. At this juncture the 15 degree curved 2.9 mm rough diamond burr(Medtronic Xomed, Jacksonville, Florida, USA) is attached to the micro-debrider and used to remove the rest of the bone up to the superior mucosal incision (Jones,1998). Often, an agger nasi cell is present and the mucosa of this cell will be exposed as the sac is followed superiorly above the axilla of the middle turbinate thus exposing the frontal recess (Fig 7). The diamond burr can be brought into light contact with the lacrimal sac lining without damaging the sac. A cutting burr will remove the bone faster but may cause significant damage to the sac wall with development of hole in the sac wall.

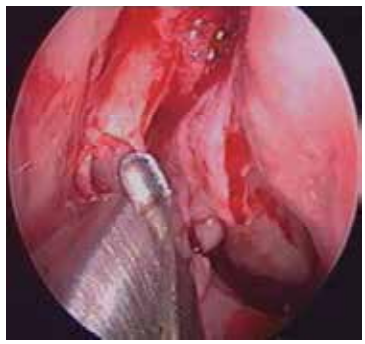


Fig. 6. Intraoperative endoscope view showing right dacrocystorhinostomy with initial removal of the thin lacrimal bone with Hajek Koffler sphenoid punch and subsequently the hard frontal process of maxilla with a microdrill

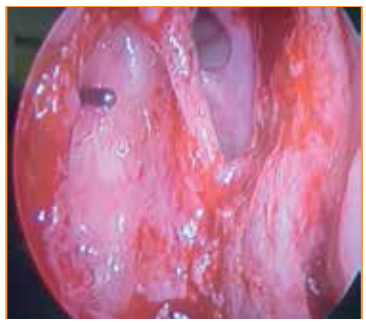

Fig. 7. Intraoperative endoscopic view showing a right dacrocystorhinostomy with wide exposure of the nasolacrimal sac with visible end of eye probe and removal of agger nasi cell exposing the frontal recess

Next, the inferior punctum is dilated with a punctum dilator and a Bowman's canalicular probe is passed into the sac. If the tip of the probe is not seen to move behind the thin sac wall, the probe is not in the lumen. The exposed sac is incised vertically with a DCR minisickle knife (Metronic Xomed, USA). Belucci scissors (Stortz, Germany) are used to make upper and lower releasing incisions in the posterior flap which is rolled out on the lateral nasal wall. The sac should now be completely marsupialized and lie flat on the lateral nasal wall. Approximating the lacrimal and nasal mucosa should result in a first intention healing rather than a secondary intention healing and should reduce the formation of granulation tissue and scarring. The puncta are dilated and Silastic lacrimal intubation tubes(O'Donoghue tubes) are placed through the upper and lower puncta and retrieved endonasally. Ligar clips are placed to secure the tubes in place (Fig 8). Before placing the clips ensure a loop of tubing is pulled in the medial canthus of the eye so that the tubes are not tight. If the loop is tight the tubes can cheese-wire through the punctum (Khairullah and Gendeh, 2011). A square of Gelfoam(Pharmacia NSW, Sydney, Australia) or Merogel (Metronic Xomed) is slid up the tubing and placed over the flaps to hold them in position.

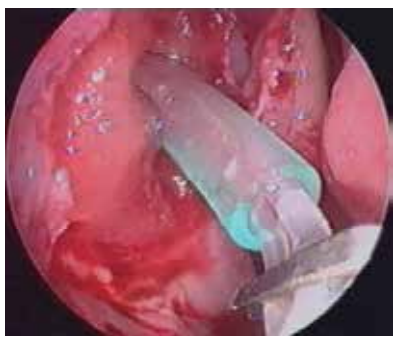

Fig. 8. Intraoperative endoscope view showing right dacrocystorhinostomy with stent in situ an adult patient presenting with unresolving right tearing.

Saline irrigation is started within 3 to 4 hours of surgery. The patient is commenced on broad spectrum antibiotics for 5 days and eye drops are used for 3 weeks. The O'Donoghue tubes are removed in the clinic after 4 weeks. It is rare to see any granulation tissue but if they are present they should be removed. The patient is reviewed for a further 18 months before discharge.

2.5 Laser assisted DCR

For osteotomy, laser was used exclusively in the early part of the series in 1992 and 1993. The preferred site for osteotomy was the thinnest bone located in the infero-posterior parts of the lacrimal fossa, which corresponds to the brightest area in the nasal cavity as demonstrated by the transilluminator. The authors concluded that the success rate of laser-assisted DCR was around 78%, which was much lower than that of conventional DCR. Beginning in 1999 and 2000, osteotomy was performed with either a drill, a punch, or both, which enabled removal of thicker bone. The site of the osteotomy was moved to the level of medial canthus, which was anterior and superior to that of previous surgeries. When the osteotomy was completed, the common internal punctum was visible on endoscopy. With this approach, the success rate improved to 92%(Lee et al, 2004).

In another interesting study in 65 patients with a mean follow-up of 74 months, the authors found the success rate of endoscopic laser assisted DCR has gradually declined over the years to 56%. The authors do not advocate the use of laser in endonasal DCR with epiphora (Umapathy et al, 2006).

3. Endoscopic applications in orbital surgery

3.1 Endoscopic blow out fracture repair

Fractures of the roof of the maxillary sinus with herniation of the orbital content (blow-out fracture), often produce strangulation of the inferior rectus or inferior oblique muscles and thereby impairing movement of eyeball (Fig 9). They can present with periorbital ecchymosis and subconjunctival hemorrhage. Those with fracture of medial wall of orbit without prior surgical intervention can present with enopthalmos.

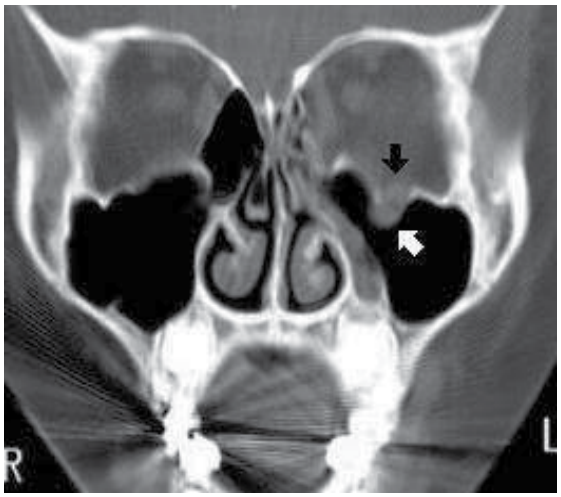

Fig. 9. Coronal CT scan of the paranasal sinuses showing a 'tear drop' sign resulting from a blunt trauma to the left eye in a patient presenting with diplopia

Passage of the endoscope through the intranasal maxillary antrostomy may provide superb visualization of the posterior orbital floor which is the most difficult area to view by transconjunctival or subciliary approach. Anatomically, this area of the orbital floor commonly lies behind the middle half of the globe on axial view. This posterior view may furthermore be obscured because the orbital floor angulates 15 degrees superiorly as one proceeds from the orbital rim toward the orbital apex. Therefore, the endoscope is an extremely useful means of safely and definitely identifying the posterior edge of the defect and ensuring that the posterior edge of the orbital implant do not compromise the optic nerve or other structures at the orbital apex (Hartstein et al, 2004). In many small fractures for which an implant is not required, endoscopic examination and reduction may be sufficient, thus avoiding an external incisional approach.

It is doubtful that endoscopy alone will replace standard CT scanning in the evaluation of orbital fractures. Thus, combining forced duction testing with endoscopic visualization of a fracture may prove to be useful diagnostic tool.

3.1.1 Indications

This include fractures with extension to the middle and posterior portions of the orbital floor, in delayed or secondary fracture repair.

3.1.2 Surgical technique

Orbital fracture repair is normally performed using general anaesthesia. Some author's have reported the use of purely endoscopic approach for the repair of orbital floor fracture (Ikeda et al, 1999). The procedure is commenced by enlarging the maxillary ostium and then introducing an angled endoscope. Bony fragmenst in the fracture site are removed endoscopically until an improvement in forced duction testing is noted. Subsequently, a uretheral balloon catheter is introduced through the ostium into the maxillary sinus. In some patients with trap-door-type fractures, successful fracture repair may be possible with endoscopic approach alone, with removal of the displaced bony fragment and relieve of the entrapment. Saline is used to inflate the balloon which elevates the contents out of the fracture site. The balloon is removed approximately two weeks after surgery.

Tips for successful surgery

Endoscopic visualization of fractures of the posterior aspect of the orbital floor and medial orbit may facilitate safe and secure implant placement and ensures that no residual orbital soft tissue is entrapped within the fracture site or beneath the implant. The endoscopic technique minimizers the uncertainty of implant placement posteriorly in both primary and secondary repairs. It may help to minimize the number of additional incisions required in the medial orbit, maxillary sinus and even the eyelid. The increased accuracy of implant placement may help to reduce the risks of residual exopthalmos postoperatively. This technique is useful in the more complex fractures involving the posterior orbital floor and medial wall.

3.2 Endoscopic orbital decompression of complications of thyroid-related orbitopathy

Graves' disease is an autoimmune disorder affecting the thyroid, orbit and skin. Approximately 50% of patients with this disorder develop orbital manifestation of dysthyroid orbitopathy. Fewer than 5% of such patients have disease that is severe enough to require surgical decompression of the orbit (Metson and Samaha, 2004). The extensive muscle enlargement limits globe movement in extremes of gaze which will cause diplopia. Visual loss in Grave's disease is uncommon, occurring in only 2 to 7% of patients (Kountantakis et al, 2000; Kuppersmith et al, 1997). Exopthalmos in Grave's disease is thought to result from the deposition of immune complexes in the intraocular mucles and fat which in turn leads to edema and fibrosis (Tandon et al, 1994). The resultant increase in intraorbital pressure pushes the globe forward causing proptosis. If this proptosis become severe enough, the eyelids cannot close properly and chemosis with or without exposure keratitis of the cornea may occur. Furthermore, the crowding of the orbital apex by the obviously enlarged extraocular muscles places pressure on the optic nerve. Stretching of the optic nerve by increasing proptosis may result in the development of optic neuropathy and visual loss. If medical treatment fails (high dose steroids with or without low-dose radiotherapy) , surgical decompression of eyelid is indicated(Cook et al, 1996).

Removing one or more of the bony walls can decompress the contents of the orbit. The least amount of decompression would be achieved with medial wall removal , but the most physiologic and least to cause complications like globe displacement and diplopia. Endoscopic orbital decompression affords maximal orbital decompression at the orbital apex, an area that is not fully accessible via the external or transantral routes (Metson et al, 1994). Many techniques have been described for decompressing the orbit but the order of the procedures is that orbital decompression first, then strabismus and lastly the eyelid.

3.2.1 Indications and contraindications

The primary indication for the surgery is exopthalmos, either for cosmetic reasons or when vision is deteriorating and steroids and radiotherapy treatment has failed. The most common indications for such surgery are exposure keratopathy and optic neuropathy that have been refractory to conservative measures. Patients with diplopia from dysthyroid orbitopathy may require decompression before strabismus surgery to reaccess the globe and improve the predictability of muscle adjustments. Some surgeons who consider aesthetically undesirable proptosis to be an indication for orbital decompression have performed such surgery for its cosmetic benefits.

Contraindications to endoscopic orbital decompression include acute sinusitis and anatomic abnormalities of the maxillary bone. Endoscopic decompression may be technically difficult in patients with very small maxillay sinuses or thick orbital walls. These features are easily identified on computed tomography(CT) scan of the orbit and sinuses, which should be obtained on all patients before surgery.

3.2.2 Useful instruments

- A long-shanked drill with a course diamond burr (Medtronic Xomed, Jacksonville, Florida, USA) and good irrigation system to keep the bone cool.
- Image guided surgery

3.2.3 Endoscopic technique

The patient is placed in a supine position with head slightly elevated. Packing that has been soaked in a 4% cocaine solution is placed in the nasal cavity to initiate mucosal vasoconstriction. Both eyes are exposed in the surgical field. If general anaesthesia is used, the corneas are covered with protective shells. Under endoscopic visualization, submucosal injections of 1% lidocaine with epinephrine are administered along the lateral nasal wall and middle turbinate. If a septal deviation precludes endoscopic access to the middle meatus region, a septoplasty is performed before orbital decompression.

The bones removed in endoscopic decompression include the medial wall of the orbit and the portion of the floor that is medial to the infraorbital canal. The procedure is initiated with an incision through the uncinate process. This incision is made just posterior to the maxillary line, a bony eminence that extends from the anterior attachment of the middle turbinate to the root of the inferior turbinate(Fig 10). The maxillary sinus ostium is then generously enlarged to provide optimal exposure of the orbital floor to prevent obstruction of the maxillary sinus by the decompressed globe. Bone is removed in the posterior

direction to the level of the back wall of the sinus. Anterior removal is terminated at the thick bone of the frontal process of the maxilla, which protects the nasolacrimal duct. The ostium is enlarged superiorly to the level of the orbital floor and inferiorly to the root of the inferior turbinate. A 30-degree endoscope is used to identify the infraorbital nerve along the roof of the sinus (Fig 11).

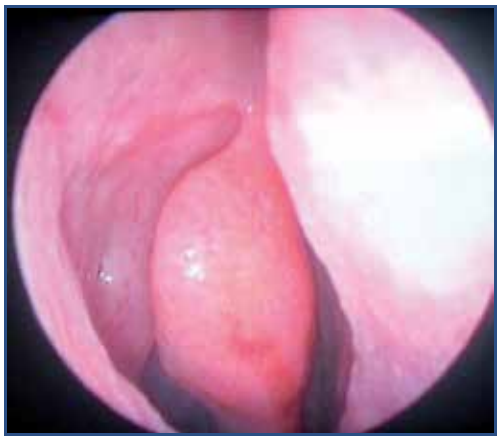

Fig. 10. A zero degree endoscopic view of left lateral nasal wall showing the maxillary line and uncinate process

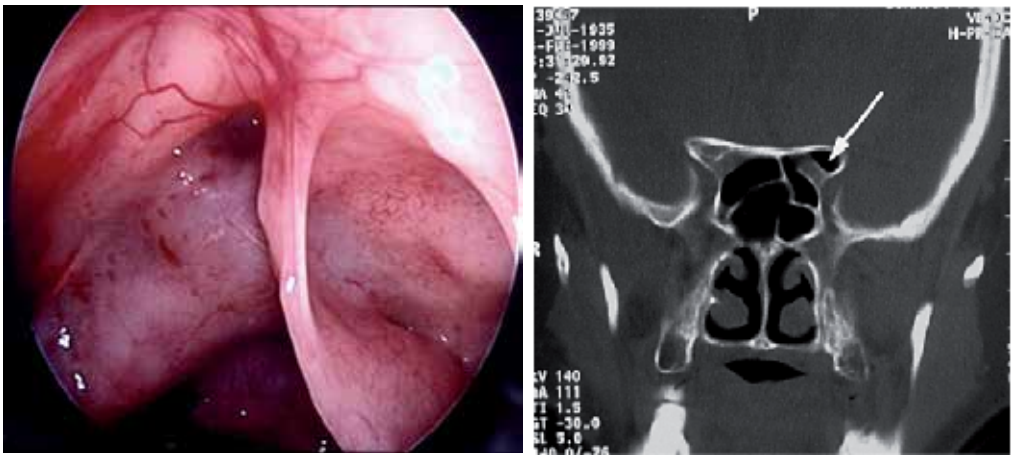
Fig. 11. A 30 degree endoscopic view showing evidence of wide right middle meatal antrostomy with infraorbital indentation in the roof of the maxillary sinus

An endoscopic sphenoethmoidectomy is then completed as described by Stammberger (1991) and Kennedy (1985). The degree of pneumatization of the sphenoid determines whether the optic nerve indents or even dehiscent in its lateral wall. Similarly, if the posterior ethmoid sinuses envelop the optic nerve before it reaches the sphenoid sinus, am Onodi cell may be present (Fig 12).The anterior and posterior ethmoid arteries are identified along the ethmoid roof. The middle turbinate that serves as a landmark during the sphenoethmoidectomy is removed before opening the lamina papyracea to optimize

exposure to the medial orbital wall and facilitate postoperative cleaning. The skeletonized lamina papyracea is gently penetrated with a small spoon curette. Bony fragments of lamina papyracea is lifted in a medial direction to avoid perforation of the underlying periorbita. This elevation may also be performed with a periosteal elevator or delicate Blakesley forceps(Stortz, Germany). If surgery is performed using local anaesthesia, additional injections may be necessary to desensitize the medial orbital wall. Anaesthetic agent is injected just deep to the periorbita through the bony opening in the lamina.



(a) (b)

Fig. 12. An intra-operative endoscopic view (a) and coronal CT scan view (b) showing an Onodi cell

Bone of the lamina papyracea is removed in a superior direction toward the level of the ethmoid roof. The frontal recess is the most anterior superior portion of the ethmoid sinus, which communicates with the frontal sinus. Removal of the lamina papyracea in this region can cause postoperative obstruction of the frontal sinus by herniated fat. As dissection continous in a posterior direction toward orbital apex, thicker bone and underlying periorbita are generally encounterd within 2 mm of the sphenoid face. This thickening represents the annulus of Zinn, from which the extra ocular muscles(EOMs) originate and through which the optic nerve passes (Fig 13). This landmark represents the posterior limit of dissection and does not need to be removed. In cases of neuropathy, bone removal proceeds more posteriorly and may extend to the lateral wall of the sphenoid sinus.

Fragments of bone are cleared from the anterior end of lamina papyracea where it joins the lacrimal bone. Dissection in this region may be facilitated by use of an angled spoon curette and 30-degree endoscope (Stortz, Germany). The thick white fascia of the lacrimal sac may be uncovered but should not be opened. Firm bone anterior to the maxillary line protects most of the sac, so it should not be removed. Removal of the bone along the medial orbital floor can be most technically challenging aspect of this surgery. A spoon curette is used to fracture the bone in a downward direction. This bone may break apart in several small fragments with a natural cleavage plane along the infraorbital canal. Use of a 30-degree endoscope may facilitate visualization within the maxillary sinus and aid in the identification of the infraorbital nerve which serves as the lateral limit of bone removal.

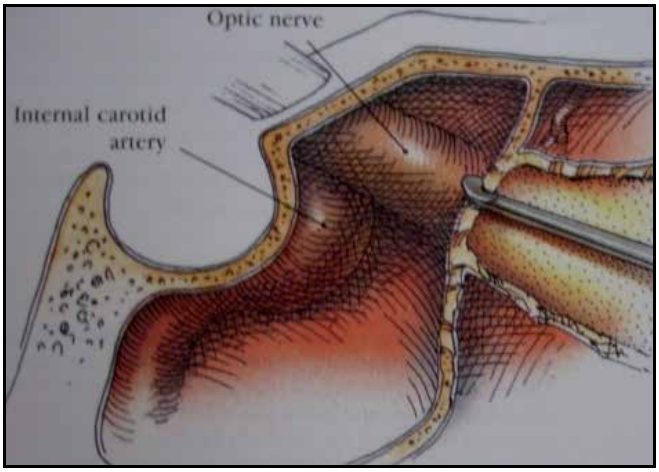


Fig. 13. A diagrammatic sagittal section of left sphenoid and posterior ethmoids showing the thick bone at the annulus of Zinn at the junction of the orbital apex and sphenoid sinus

After the periorbita has been fully exposed and cleared of bony fragments, it is opened with a sickle knife(Stortz, Germany). The incision is usually commenced in front of the sphenoid sinus. Care is taken to keep the tip of the blade superficial to avoid injury of the underlying orbital contents especially the medial rectus muscle, which may be enlarged secondary to dysthyroid orbitopathy. Incision of the periorbita is extended along the ethmoid roof and the orbital floor. A horizontal strip of periorbita overlying the medial rectus muscle is preserved (Fig 14). This fascial sling serves to decrease prolapsed of the muscle and is thought to reduce the incidence of postoperative diplopia (Metson and Samaha, 2002). However, in patients with optic neuropathy, maximal decompression is needed and the fascial sling is sacrificed to allow for wider excision of the periorbita which is removed eventually with angled Blakesley forceps. At the completion of the procedure, the generous prolapsed of the orbital fat into the opened ethmoid and maxillary sinuses should be observed(Fig 15)

Fig. 14. A 70 degree endoscopic view showing an emergency horizontal orbital decompression incisions of the periorbita extending from the ethmoidal roof to the orbital floor for thyroid related orbitopathy

Fig. 15. A 30 degree endoscopic view showing prolapsed of orbital fat into the nasal cavity on balloting the right eye

A lateral orbital decompression may be performed at this time, depending on the extent of patient's disease and the degree of additional decompression desired. Due to the prior medial decompression, the orbital contents are easily retracted in a medial direction to provide excellent exposure of the lateral bony wall, which is removed or contoured. Concurrent excision of excess intraconal fat may also be performed if necessary. Bilateral orbital decompressions may be performed concurrently or as a staged procedure.

Nasal packing is avoided in order to prevent compression of the optic nerve, which is rendered increasingly vulnerable by the decompression. The patient is discharged the morning after surgery with a prescription for oral antibiotics and instructions to begin twice-daily nasal saline irrigations with a bulb syringe. During postoperative visit a week later, residual debri is cleared from the nasal cavity under endoscopic guidance.

In some cases, local anaesthesia may be preferred to general anaesthesia. These situations include patients who have an only-seeing eye, significant medical comorbidity, or a strong preference for local anesthesia.

The use of local anesthetic enables the surgeon to monitor the patient's vision on a continuous basis during the surgery and reduces the likelihood of occult injury to the optic nerve (Metson et al, 1994). Ideal sedation is achieved with intravenous bolus of propofol, 0.4 to 0.8mg/kg, administred before local injection, followed by maintenance infusion of 95 to 75 ug/kg during the procedure. Submucosal infilteration of 1% lidocaine with epinephrine 1:100,000 is performed exactly as described for the procedure utilizing general anaesthesia. Patients may report discomfort during removal of the lamina papyracea, and this may require a small additional infiltration of anaesthetic solution into the periorbita.

3.2.4 Complications

Diplopia is a relatively common sequela of endoscopic orbital decompression reported in 15 to 30 % of postoperative patients. This complication can be the result of change in the vector of pull of the EOMs. Diplopia that is present preoperatively is usually not improved by this surgery. Patients with preexisting or new-onset post-operative diplopia frequently require

strabismus surgery. It is essential that all patients be informed of the possibility of postoperative double vision before undergoing orbital decompression.

Techniques to decrease the incidence of new-onset postoperative diplopia, including the preservation of the fascial sling of periorbita to prevent prolapsed of the medial rectus muscle, have been mentioned (Metson and Samaha, 2002). To decrease the incidence of postoperative diplopia, the use of balanced decompression technique is advocated. This technique involves performing external lateral wall decompression at the time of endoscopic medial wall decompression to reduce pressure on the medial rectus muscle while simultaneously increasing the degree of ocular recession.

Postoperative bleeding after endoscopic orbital decompression is managed by direct caurterization of the bleeding site. Nasal packing is avoided in these patients to avoid pressure in the region of the optic nerve. The incidence of sinonasal infection post-surgery is minimized with the routine use of postoperative antistaphylococcal antibiotics.

Postoperative epiphora may occur if the nasolacrimal duct is transected during the maxillary antrostomy. This complication is readily treated with an endoscopic DCR. Blindness and cerebrospinal fluid rhinorrhea are also potentially serious complications of orbital decompression but rare.

Endoscopic orbital decompression should be performed only by surgeons with extensive experience in endoscopic intranasal techniques. A team approach, which uses the skills of both an Otolaryngologist and an Opthalmologist during the performance of this procedure is highly recommended.

Tips for successful surgery

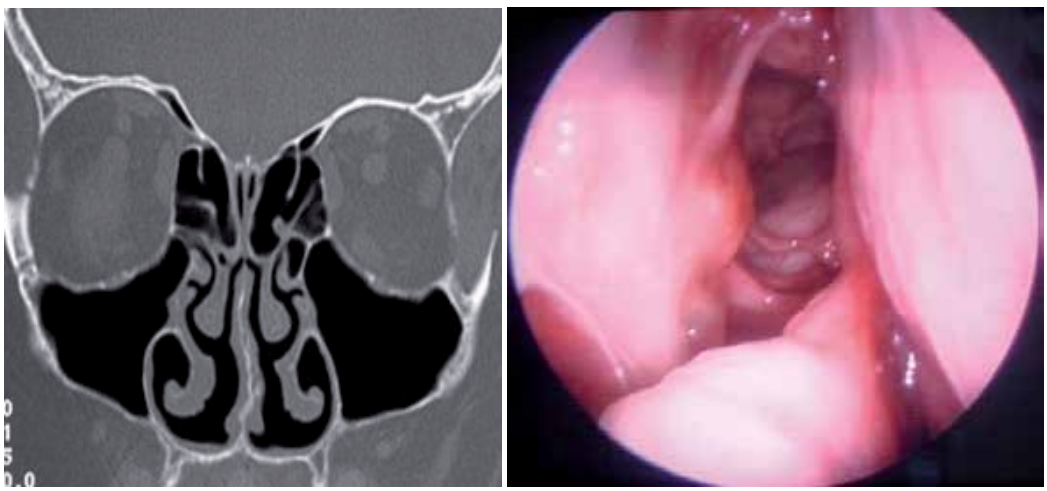
Orbital decompression for thyroid-related orbitopathy is an effective method for reduction of proptosis for cosmetic proptosis, eye complications from exposure of the cornea and visual loss. The amount of regression of proptosis is related to the number of walls removed during surgery. It is believed that three-walled decompression may give a more balanced decompression with less likelihood of postoperative diplopia.

3.3 Endoscopic orbital decompression for acute orbital hemorrhage

The procedure of choice is lateral canthotomy and inferior cantholysis with of course cold dry compresses as tolerable. This is performed for 'orbital compartment syndrome' due to orbital bleeding, emphysema or tumor. For orbital decompression, lateral canthotomy alone is not sufficient and the inferior eyelid should be completely free to allow anterior displacement of the globe. Drainage of any kind is only indicated if this is not helpful. The problem with drainage is that the bleeding is diffuse and not confined to one compartment. Endoscopic drainage is actually performed to remove adjacent orbital wall and open the periosteum to allow decompression of orbital soft tissues. It is important to note that the same can be achieved with the faster canthotomy and inferior cantholysis.

Invariably the anterior ethmoidal artery(AEA) can be located one cell behind the frontal recess(Fig 16 a, b). The size of the so called supra-orbital cell (Bolger & Mann, 2001) varies: it can be small or large. The AEA can often be seen on CT scan, (Fig 10) particularly as it enters

the orbit where it produces a fluted defect in the lamina papyracea(LP). The more pneumatized the supra-orbital recess, the more vulnerable it is to damage. Often the ethmoidal bulla (EB) attaches to the skull base and the AEA lies within the roof and is 1-2 mm behind the attachment of the anterior wall of the EB to skull base. If the frontal recess (FR) does require opening, it is best approached anteriorly, away from AEA if the landmarks are poor owing to previous surgery or bleeding. As the AEA is sometimes dehiscent, it is advisable not to grasp polyps in this area if one is unable to identify the anatomy clearly. Often the FR can be found by following the intact anterior wall of the ethmoidal bulla superiorly.



(a) (b)

Fig. 16. A coronal CT imaging showing an indentation of right anterior ethmoidal artery at the region of frontal recess (a) and a 70 degree endoscopic view showing indentation of the artery in the same patient(b).

The AEA is dehiscent at some point in the majority of patients (Lang, 1989). It is essential to avoid tearing it for it can cause marked bleeding. If it is transected and retracts into the orbit, a marked increase in pressure in the posterior compartment of the eye can occur and place the retinal artery and its supply to the retina at risk. If it is torn, gentle bipolar diathermy will arrest the bleeding but this should be performed with great care to avoid transecting the remaining segment of the artery.

3.3.1 Bleeding

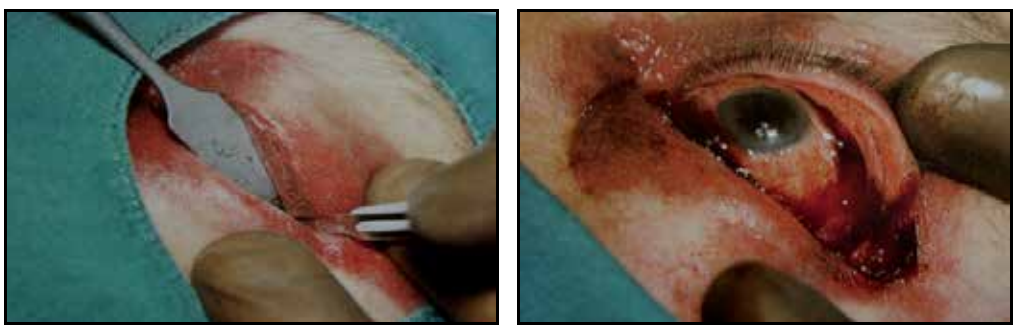
If there is obvious bleeding into the posterior compartment of the eye, the eye will prop out, the orbit will become very firm and within a few minutes the swinging flash light test will reveal an afferent defect. An awake patient will complaint of discomfort and loss of vision. An orbital tourniquet should be tried on immediate recognition. This involves placing a cotton wool over the closed eyelid and applying an orbital tourniquet over the cotton wool and around the head and then inflating it to systolic pressure. This is performed for one minute and then it should be removed and the pupil reflexes and/or the vision checked. If

the vision or pupil reflex has improved, the orbital tourniquet should be reapplied and the process repeated every minute for up to 5 minutes. If this is performed soon after injury, it may be sufficient to stop bleeding into the orbit and it can arrest the process.

It is advisable to monitor vision for 6 hours postsurgery to ensure that no further bleeding occurs into the posterior compartment. If this maneuver fails then the orbit must be decompressed. A lateral canthotomy and inferior cantholysis is quick and efficient technique for up to one hour and it is best to decompress the orbit as early as possible (Jones, 1997). Moreover, one should not wait for an opthalmological colleague to arrive unless they do so within an hour. Assessing the vascular supply of the retinal vessels with an opthalmoscope is inadequate.

3.3.2 Lateral canthotomy and inferior cantholysis

Local anesthetic is placed around the lateral canthus of eye and it is divided using small straight scissors down to the bone of the orbital rim and to the depth of the lateral sulcus of the conjunctiva. A corneal abrasion or conjuctival damage can be avoided by protecting the globe. The lower lid is then retracted downward for good expose. The scissors is angled at 45 degree to the horizontal axis and the lateral ligament and septum is divided and the globe and contents of the orbit will then prolapse forward (Fig 17). The pupil reflexes, the pressure of the orbit and vision should all be checked. The orbit will retract to its normal position over the next 2-3 days. Suturing is usually performed a week or so after the procedure.



(a) (b)

Fig. 17. Picture showing an emergency left lateral canthotomy (a) and subsequent cantholysis (b) being performed in the same patient for iatrogenic orbital hemorrhage

This procedure is normally sufficient to decompress the posterior compartment of the eye. If inadequate a surgical decompression should be undertaken. It can be done either endoscopically by removing the LP widely and incising the orbital periosteum or externally via a Lynch-Howarth incision. Preserving vision takes priority over producing an external scar. If the orbit is decompressed by an external approach, the AEA will not be found as it will have retracted into substance of the orbit.

3.3.3 Medial rectus damage

Medial rectus damage occurs when there is disinsertion of the muscle, damage to the muscle nerve or intramuscular bleeding. In damage encountered during enscopic sinus

surgery, a vigilant assistant should look out for movement of the globe which occurs unintentionally. As a precautionary measure, the assistant should repeatedly ballot the eye when the surgeon is operating on the lateral nasal wall. Anatomically the medial rectus muscle is located closer to LP posteriorly then anteriorly (Fig 18). The suction port of the powered shaver should preferably be directed medially away from the LP to minimize the risk of damaging the structures in the lateral nasal wall. Damage to medial rectus occurs through deeper penetration into the orbit. Unfortunately, it is very difficult to prevent the scarring and diplopia that are likely to occur if recognized then. Moreover, expert strabismus surgeons have difficulty in correcting the problems caused by damage to the medial rectus. It is a medical negligence and should preferably be settled out of court.

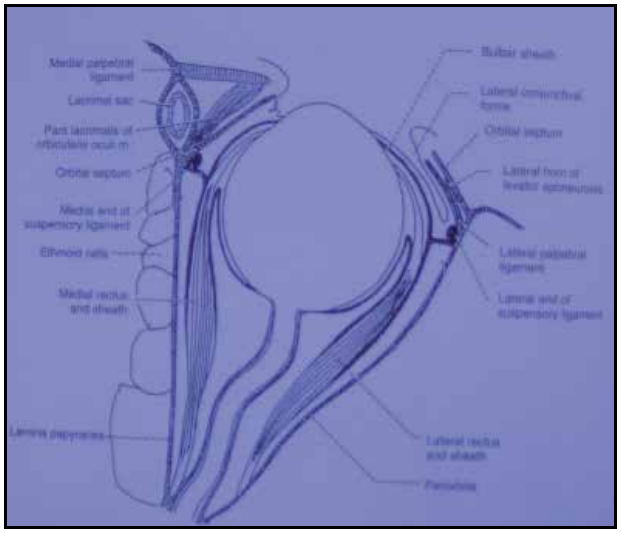


Fig. 18. Axial section of the relationship of right medial rectus and optic nerve to the lamina papyracea

3.3.4 Optic nerve damage

The optic nerve can be damaged by penetration of the orbit through the lamina papyracea. Therefore, it is important for the assistant to look for eye movements when the surgeon is operating on the lateral nasal wall. Moreover, the optic nerve can be damaged if it is exposed in a sphenoethmoid air cell(Onodi cell)(Fig 19). An Onodi cell should be identified on routine pre-operative imaging and care taken in removing polyps lateral to the sagittal plane of the medial wall of the maxillary sinus. It is advisable to identify the sphenoid sinus ostia medially and then work forward. The optic nerve indentation can be prominent in 20% of patients in the upper half of lateral wall of sphenoid sinus but is rarely dehiscent (Fig 20). The carotid artery lies in the lateral and inferior aspect of the sphenoid sinus. Therefore, it is advisable to avoid the lateral wall of sphenoid sinus by directing the suction port of the powered shaver medially away from the lateral wall of sphenoid sinus to minimize the risk of damaging the structures present there.

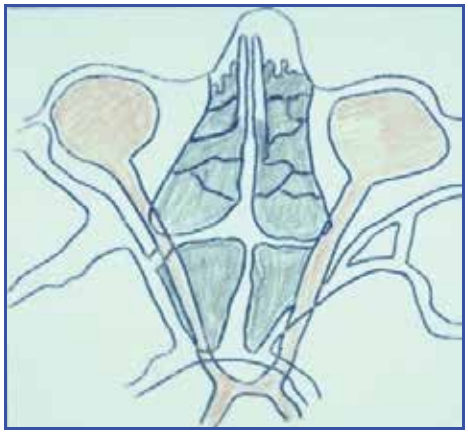

Fig. 19. A diagrammatic axial view of the paranasal sinuses showing a rare bilateral Onodi cell

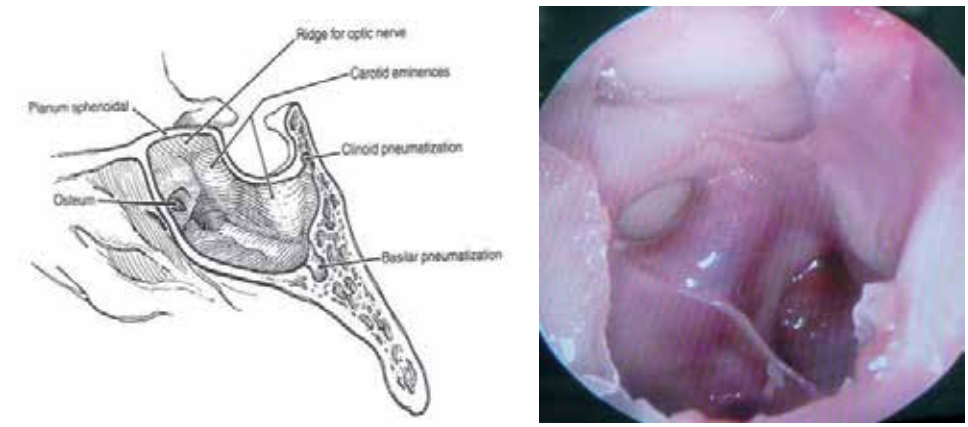

Fig. 20. Diagrammatic sagittal section and endoscopic view of the sphenoid sinus showing indentations of the lateral wall by internal carotid artery inferiorly and optic nerve superiorly

3.3.5 Post-operative complications

3.3.5.1 Bleeding

Sitting the patient 30% head up at end of procedure is often adequate for minor general ooze. Coughing during extubation will result in temporarily more bleeding due to increase in venous pressure. A nasal pack soaked in 1:10,000 epinephrine is helpful for more than minor ooze and removed in the recovery or left in position for 12 hours if oozing continues. Prophylactic antibiotics are advocated for nasal packs left in position for more than 24 hours. Rarely, torrential reactionary bleeding can occur in the first 12 hours due to these vessels initially going into spasm intra-operatively when the platelet plug and clotting factors block them but with due time either due to relaxation of artery or fibrinolysis reverses this process and bleeding commences. Usually it is impossible to locate the bleeding site. If a local nasal pack with vasoconstrictor and local anesthetic is not helpful to

control the bleeding, then bipolar caurtery of the offending vessel may be helpful. If this too fails, then reinserting a nasal pack and/or balloon may be necessary to tamponade the bleeding until the spheno-palatine artery(SPA) can be ligated under general anesthesia. If a large sphenoidotomy has been performed, the bleeding could be due to the damaged septal branch as it crosses the anterior wall of the sphenoid (Fig 21).

Fig. 21. Intraoperative Endoscopic view showing a right low sphenoidotomy with evidence of sphenopalatine bleed

3.3.5.2 Adhesions

Mucosal damage to adjacent surfaces can result in adhesions (Fig 22). Adhesions can be minimized by topical and local corticosteroids application. If adhesions are present pre-operatively, they need removal with a through-cutting punch followed by douching and debridement at one week.

Fig. 22. Endoscopic view showing adhesions between left septum and inferior turbinate after nasal surgery

3.3.5.3 Epiphora

The lacrimal sac or naso-lacriminal duct can be damaged if the middle meatal antrostomy(MMA) is extended too far anteriorly. If middle meatus needs to be enlarged anteriorly to allow improved access or drainage, then the uncinate process (UP) is removed retrograde with Stammberger Rhinoforce antrum punch (Stortz, Germany). If patient complaints of watery eyes post surgery, it is best not to intervene as it will often resolve on its own. If the epiphora is persistent, an endo-nasal DCR will be helpful.

3.3.5.4 Periorbital emphysema

Peri-orbital emphysema or air in the soft tissues around the eye is due to intra-operative breach of the LP and the patient unknowingly blown their nose(Fig 23).The anesthetist should be advice to take care on extubating the patient and not to use too much force if patient needs to be ventilated with face mask. The emphysema will resolve in due time provided the patient does not blow any more air into the area. Prophylactic antibiotics are administered for active sinusitis or history of sinusitis.

Fig. 23. Left periorbital emphysema post powered endoscopic sinus surgery which resolved spontaneously

3.3.5.5 Anosmia

Smell is a precious sense and every effort should be made to preserve or improve it. The olfactory mucosa extends from the cribriform plate to cover almost all the medial side of middle turbinate and the same area on the septum with a little inferior extension.

Pre-operative oral steroids are helpful in preventing damage to the mucosa, especially if polyps are medial to the middle turbinate (MT) when assessed as an outpatient. If the polyps remain medial to middle turbinate at surgery, perform an ethmoidectomy and then gently lateralize the MT to open the olfactory cleft which allows better access to topical steroid spray. If the patient has hyposmia or anosmia post-surgery and the MT is adherent to the septum, it is worth resecting and lateralizing the MT as an elective procedure when mucosal edema has settled down.

3.3.5.6 Frontal recess stenosis

The frontal sinus is often opaque on CT scan in nasal polyposis and it is normally due to retained secretions. It is rare to find polyps within the frontal sinus. Often opening the middle meatus and de-bulking polyps in region below the frontal recess with a shaver or through-cutting forceps (Stortz, Germany) followed by washing and topical nasal steroids may be adequate to allow the patients disease to be controlled.

It is essential not to denude the frontal recess of its mucosa since this may predispose to stenosis. If there is purulent disease within the frontal sinus causing symptoms, then it is advisable to open the recess, preserving as much mucosa as possible. This is ideally

performed by dissecting the mucosa off the agger nasi cells with a ball probe and pulling it down on the shell of the cell and removing the fragments of bone and carefully preserving the mucosa. Any loose fragments of mucosa are best left alone. Large fragments of redundant mucosa around the frontal recess can be trimmed using a shaver or through-cutting forceps (Stortz, Germany). If there is a bony partition between the supra-orbital cell and frontal recess or a high frontal cell, the partition between them should be removed sub-mucosally.

3.3.5.7 Crusting

Crust results from mucosal damage. If there is full thickness mucosal damage, the mucus produced stagnates because there is no functioning cilia to clear it and it may take up to a year for the cilia to start to function synchronously again. Therefore, mucosal damage should be minimized and a full thickness defect should be avoided at all cost.

3.3.5.8 Infection

Superficial infection of stagnant mucus is common and usually resolves with douching. Sometimes, staphylococci multiply in a sump of mucus that collects in the maxillary sinus and may be slow to clear with douching alone. Topical nasal mupirocin ointment sniffed liberally after douching 6 times a day for 3 weeks can be very helpful.

3.3.5.9 Osteitis

Local osteitis due to exposure of bone is a rare complication resulting in severe pain. It produces a very dull, severe crippling nagging ache that causes tears to the patient. This condition is very distressing to the patient and worrying for the surgeon. Major analgesics are required and local treatment appears to provide little relief. Patients undergoing surgery for inverted papilloma where mucosal preservation is not practiced are at risk.

Tips for successful surgery

Intraobital hemorrhage should be managed with lateral canthotomy and cantholysis followed by orbital decompression with removal of the medial orbital wall. Orbital decompression can be performed without canthotomy and cantholysis if the complication is notice intraoperatively

3.4 Endoscopic orbital decompression for orbital sub-periosteal abscess

Rhinosinusitis in children is not a surgical disease, and therefore the treatment is medical with systemic antibiotics such as clavulinic acid and ampicillin(Augmentin). The priority should be safety in any treatment as the problem usually resolves with time without intervention. Growth and maturation of the immunological response to pathogens play a major role in resolution of the disease (Jones, 1999; Howe & Jones, 2004).

Patients presenting with orbital complications of sinusitis commonly have a degree of cellulitis and edema (chemosis) around the eye with associated proptosis (Fig 24). This may be associated with some restriction of eye movement. Patients typically present with history of nasal obstruction, purulent rhinorrhea and facial pressure or pain. Nasal endoscopy reveals an inflammed and oedematous nasal mucosa with usually presence of pus in the middle meatus.

Fig. 24. Picture of a child with a left orbital cellulitis

If a subperiostal abcess is suspected, a CT scan of the parananasal sinuses with contrast will present a mass located on the lamina papyracea or in relation to the frontal sinus. The rim of the mass will enhance with the contrast. Moreover, the proptosis will be visible on the axial scans.

The external approach is quick and easy and the abscesss can usually be rapid and safely drained. If the surgeon is a skilled and experienced endoscopic sinus surgeon, endoscopic drainage of the subperiosteal abscess can be performed. The problem with this procedure is the significant vascularity that is associated with acute sinusitis. If the mucosal surface is touched with an instrument or endoscope, it will usually bleed and an inexperienced surgeon may lose orientation and complications may occur as a result of poor visibility during the surgery. Frequent packing with decongested soaked neuropatties throughout the procedure helps to minimize the bleeding but will not control it entirely. In a patient with acute sinusitis, the anaesthetist needs to optimize the patient's hemodynamics parameters to create an optimal surgical field.

The surgical approach is to perform an uncinectomy and enlarge the maxillary ostium to a moderate degree. Uncinectomy alone without antrostomy carries the risk of postoperative closure of the maxillary sinus because the inflammation and edema predisposes to scarring and adhesion formation. Clearance of the frontal sinus depends on whether the frontal sinus is thought to be the origin of the subperiosteal abscess. If the abscess is located adjacent to the ethmoidal sinuses, clearance of the bulla ethmoidalis and posterior ethmoids is performed with identification of the lamina papyracea. The lamina papyracea over the subperiosteal abscess is widely exposed and removed. If the abscess is related to the floor of the frontal sinus, it can still be drained endoscopically. A minitrephine is usually placed in the frontal sinus before dissection of the frontal recess. This aids in identification of the frontal outflow tract. The frontal recess is cleared and the frontal ostium identified. The lamina papyracea directly behind the the lacrimal sac is removed and using a curette, the orbital periostium is kept intact and gently pushed laterally while the curette advances into the subperiosteal abscess and the abscess drained (Wormald PJ, 2005).

A malleable suction (Medtronic Xomed, Jacksonville, Florida, USA) is introduced into the cavity and any fibrin within the cavity is removed. A corrugated Pendrose drain is slid into the abscess cavity and left in place, draining the abscess cavity into the ethmoid sinuses for 1

to 2 days before being endoscopically removed. Endoscopic removal of the subperiosteal abscess remains highly effective but it must be emphasized that the surgeon should be very experienced.

Although endoscopic drainage of subperiosteal and other orbital abcesses is becoming more common, the efficiency of narrow surgical drainage via an endoscopic approach has not been thoroughly been evaluated (Page and Wiatrak, 1996). Similarly, although endoscopic treatment of frontal sinus is less invasive than open frontal surgery, it also has a lower reported success rate (Metson and Gliklich, 1998).

Indications for CT scan

- Unable to accurately assess vision, gross proptosis, opthalmoplegia, deteriorating visual acuity or colour vision, bilateral edema, no improvement or deterioration at 24 hours or a swinging pyrexia that does not resolve within 36 hours

Tips for successful surgery

Endoscopic decompression of a subperiosteal abscess should only be performed by very experienced endoscopic sinus surgeons because the surgical field can be very bloody, which can significantly increase the degree of difficulty and the likelihood of complications. If the surgeon is not experienced, then the abscess should be drained via an external incision.

3.5 Endoscopic optic canal decompression

The most common indication for endoscopic optic canal decompression is traumatic optic nerve neuropathy(TON). Currently it is thought that 5% of severe head injuries will have concomitant injury to the optic nerve, optic tract or optic cortex (Tandon et al, 1994; Kountantakis et al, 2000; Kuppersmith et al, 1997). Since major brain injury takes precedence over traumatic optic neuropathy, it may result in the optic nerve injury being diagnosed somewhat later then the brain injury. Some authors feel that early diagnosis and treatment of traumatic optic neuropathy may be of greater benefit to the patient(Lubben et al, 2001, Sofferman, 1995) and advocate diagnosis of optic nerve deficit by the presence of an absolute or relative afferent pupillary defect supported by disc edema and congestion of the vessel walls. These findings in addition to CT scan and possibly MRI scan and visual evoked potentials are sufficient to undertake optic canal decompression. Currently there is no properly conducted randomized controlled trials comparing high-dose steroid therapy, surgical decompression and observation (Steinsapir et al, 2002).

Traumatic optic neuropathy is believed to result from two distinct injuries to the nerve. The primary injury is the result of either a direct contusive force on the optic canal and nerve or elastic deformation of the sphenoid, with transfer of the force on the intra-canalicular optic nerve disrupting the axons and blood vessels (Steinsapir & Goldberg, 1994). This primary injury may result in compression of the nerve by bony fragments or in hemorrhage into the nerve sheath. A secondary injury may occur if the primary injury is not treated in due time. Compression of the blood vessels occur if there is bleeding into the dura resulting in ischaemia and continued axon loss (Sofferman, 1995; Steinsapir & Goldberg, 1994).

We have adopted a conservative approach to traumatic neuropathy with all patients undergoing high-dose steroid treatment before being offered surgical intervention. The exception is when bony fragments are found to impinge on the optic nerve.

A randomized clinical trial demonstrated no benefit of either high-dose corticosteroids nor optic nerve decompression. Both are still employed because the alternative may be irreversible blindness. However, at the initial presentation, the visual performance of visual fields is correlated to the final outcome.

3.5.1 Medical therapy for traumatic optic neuropathy

Presently megadose intravenous methylprednisolone is helpful. Methylprednisolone 30mg/kg IV loading dose is given followed by 5.4 mg/kg/hr thereafter (Cook et al, 1996). The patient's visual acuity is monitored hourly and surgical intervention is considered if the patient shows or fails any of the criteria below:

- A dilated optic nerve on CT scan
- Fracture of optic canal on CT scan with vision less than 6/60
- Fracture of optic canal with vision more than 6/60 but the patient's vision deteriorates on steroids
- Vision is less than 6/60 after 48 hours of steroids with likely canal injury (indicated by the presence of fluid levels in the posterior ethmoids and sphenoids and/or the presence of fractures of the ethmoids, orbital apex and sphenoid).

3.5.2 Surgical therapy for traumatic optic neuropathy

Optic nerve decompression (OND) is an extension of orbital decompression when the optic nerve in the lateral wall of the sphenoid is decompressed.

3.5.3 Indications

Optic nerve injury is usually and should be recognized immediately by the existence of relative afferent papillary defect (RAPD) or inverse RAPD. It always appears in optic nerve injury even if visual acuity is relatively preserved initially. If it occurs in traumatic setting, the visual acuity will always deteriorate to no light perception. One should suspect this injury whether the ocular media are clear or opaque. It may be inappropriate for the patient to undergo surgery if they have a Glasgow coma scale of less than eight (Jones et al, 1997). Several studies suggest that with retro-orbital hemorrhage, decompression of the orbit needs to be done in less than one hour (Mason et al, 1998). However, where there is no hemorrhage, it is less understood under what circumstances it is beneficial to decompress the nerve pathway. If there is an anatomical constriction on CT scans affecting the course of the optic nerve and the patient is fit for anesthesia, then it seems reasonable to remove bone pressing on the nerve.

3.5.4 Useful instruments

- A long-shank drill with a course diamond burr and good irrigation system (Medtronic Xomed) to keep the bone cool.
- Image guided surgery

3.5.5 Surgical technique

The standard preparation of the nose is performed with decongestants and infilteration. An uncinectomy with exposure of the maxillary ostium is performed (Fig 25). An axillary flap is

performed and the agger nasi cell removed for acess to skull base. The fovea ethmoidalis is exposed in the region above the bulla ethmoidalis. If there is disruption of the cells of the frontal recess, then this will be cleared. In some patients with severe sinus fracture, the entire skull base may be mobile.

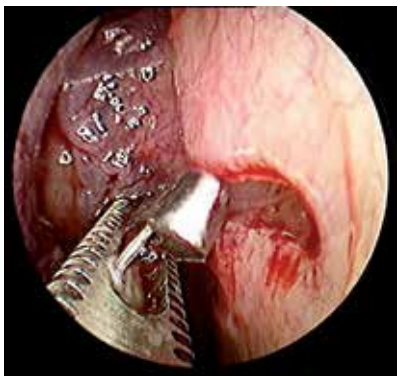

Fig. 25. A zero degree endoscopic view showing a left uncinectomy being performed

In majority of patients, the posterior ethmoid cells will be full of blood and when combined with mobility of lamina papyracea, the skull base surgeon can become disorientated. Thus, this surgery should be undertaken only by highly experienced endoscopic sinus surgeons. A posterior ethmoidectomy and sphenoidotomy should be performed. In the posterior ethmoids, the posterior lamina papyracea and fovea ethmoidalis should be identified. If significant disruption of the posterior ethmoids and lamina papyracea has occurred, then a large middle meatus antrostomy provides an extra reference point and lessens the likelihood of the surgeon becoming disorientated. The natural ostium of the sphenoid sinus should be identified and anterior face of the sphenoid widely opened.

The anterior face of the sphenoid needs to be taken as high as possible so that the roof of the sphenoid and the posterior ethmoids is continuous (Kuppersmith et al, 1997; Luxenberger et al, 1998; Chow and Stankiewicz, 1997). The sphenoid should be inspected and the optic nerve, carotid artery and pituitary fossa identified (Luxenberger et al, 1998; Chow and Stankiewicz, 1997). If there is significant disruption of the orbital apex or the lateral wall of the sphenoid, the identification of these basic structures can be difficult and image guidance may be helpful here.

The thick bone overlying the junction of the orbital apex and sphenoid sinus is known as the optic tubercle. This bone is normally too thick to flake off and an irrigated 15 degree angled diamond burr(Medtronic Xomed, Jacksonville, Florida, USA) is used to thin this bone down until it is almost transparent (Luxenberger et al, 1998; Chow and Stankiewicz, 1997). A blunt Free's elevator is pushed through the lamina papyracea 1.5 cm anterior to the junction of the posterior ethmoids air cell(s) and the sphenoid. While performing, care should be taken to keep the orbital periosteum intact, otherwise prolapsed of the orbital fat can severely obstruct the dissection of the optic nerve. The bone of the posterior orbital apex is flaxed off the underlying orbital periosteum (Luxenberger et al, 1998; Chow and Stankiewicz, 1997).

The bone over the optic canal is approached once the bone over the orbital apex is removed. This bone is usually quite thin and in majority of the cases can simply be flaked off the

underlying nerve (Fig 26). Sometimes, the bone over the nerve can be too thick and will need to be thinned with diamond burr prior to removal. When the bone is thin enough to be flaked off the underlying nerve, suitable instruments like the Beale's elevator and the House curette, both from the ear tray should be used.

Fig. 26. A 45 degree endoscopic view showing bone being cleared off the optic canal with underlying optic nerve sheath clearly visible in a patient with traumatic optic neuropathy

When all the bone has been cleared off the optic canal and underlying optic nerve sheath is clearly visible, the sheath should be incised (Luxenberger et al, 1998; Chow and Stankiewicz, 1997). The location of the ophthalmic artery should be noted for it usually runs in the posteriorinferior quadrant of the nerve. Occassionally, this artery can migrate around the lower edge of the nerve and potentially into the surgical field (Steinsapir et al, 2002). However, if the nerve is incised in the upper medial quadrant, the risk to this artery should be minimal(Luxenberger et al, 1998; Chow et al, 1995). A sharp sickle knife is used to incise the sheath of the optic nerve. Usually the swollen nerve is under pressure and the sheath splits as it is incised and nerve will protrude through the incision.. The incision is continued onto the orbital periosteum of the posterior orbital apex with resultant protrusion of orbital fat. The orbital fat covering this area of the medial rectus muscle is thin and care should be taken to avoid injuring this muscle (Fig 27). No packs are placed on the nerve or in the sinuses.

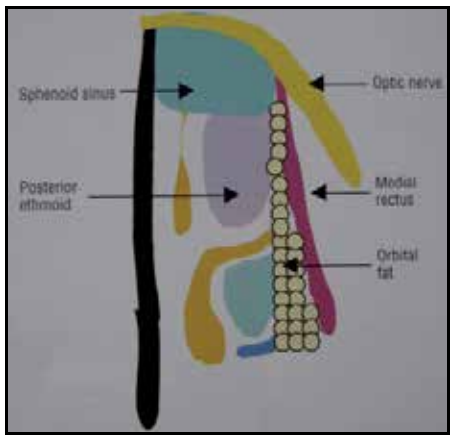

Fig. 27. A diagrammatic axial section of the paranasal sinuses and the orbit showing the anatomical relationship of the medial rectus muscle to fat and periorbita

It is vital to monitor the vision post-operatively quarter-hourly for one hour and then hourly for 4 hours. The immediate or early results of decompression are frequently extremely gratifying. The patient should be instructed not to blow their nose or sniffle sneezes for 4 days to avoid surgical emphysema.

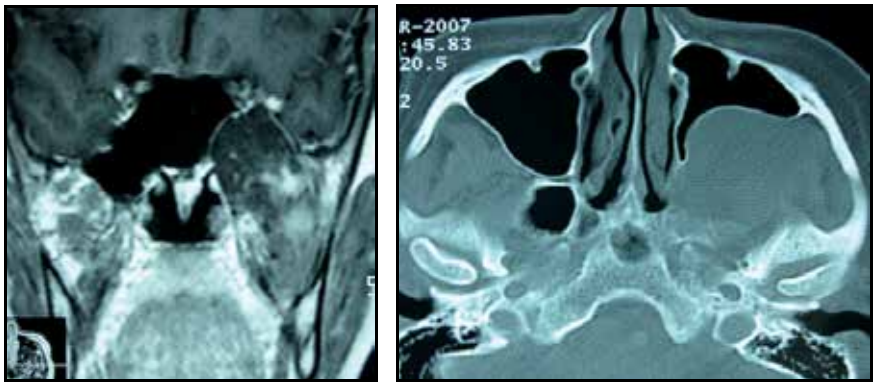
Tips for successful surgery

Optic nerve decompression is a highly complex procedure and should be undertaken by endoscopic sinus surgeon with significant experience and skill. Potential injury to the skull base with a resultant CSF leak may occur and in addition an associated injury to the internal carotid artery may be present. Injudicious manipulation of bony fragments may have catastrophic consequences for the patient. A trial of medical therapy should be advocated before surgery is contemplated unless there is an obvious bony fragment impinging on the optic nerve. Literature review suggests that patients should be operated upon if medical therapy fails to improve the vision within 24 to 48 hours. Significant delays would seem to lessen the potential for success of the surgery. Great care should be considered in exposing the optic nerve especially when flaking the bone from the nerve. Injudicious use of inappropriate instruments has the potential to worsen the vision. In the hands of an experienced endoscopic sinus surgeon, this procedure is relatively safe with low morbidity and has the potential to improve and in some cases restore lost vision, especially after blunt trauma.

4. Endoscopic applications to the pterygopalatine and infratemporal fossa for resection of benign pathological lesions

The most common benign tumor involving the pterygo-palatine and infra-temporal fossa is the juvenile angiofibroma(Fig 28). These tumors originate in the region of spheno-palatine foramen and expand into pterygo-palatine fossa. Large tumors may extend into infra-temporal fossa and usually have a large intranasal component that may extend into nearby sinuses especially the sphenoid sinus. Other benign tumors in this region are inverting papilloma extending from the nasal cavity or rare tumors arising from the nerve sheath (schwannomas)(Fig 29), cartilage or muscle. Meningoceles extending into this area from the middle cranial fossa are rare.

Fig. 28. Endoscopic view of a right juvenile angiofibroma in a teenage male presenting with recurrent epistaxis.



(a) (b)

Fig. 29. A coronal(a) and axial(b) MRI view of the paranasal sinuses showing a left maxillary nerve schwanomma

4.1 Surgical technique for endoscopic modified medial maxillectomy

The nasal cavity is prepared by placing cocaine and adrenaline-soaked neuropatties in the nasal cavity. The lateral nasal wall and septum are infiltrated with 2% lidocaine and 1:80,000 adrenaline. Using 2 ml of lidocaine and adrenaline, a pterygo-palatine fossa block is placed via the greater palatine canal which greatly helps to reduce vascularity during dissection of medial wall of the maxilla and pterygo-palatine fossa.

The initial step in endoscopic modified medial maxillectomy is to remove the uncinate process and perform a large middle meatal antrostomy. Moreover, the maxillary antrum is enlarged posteriorly up to posterior wall of maxillary sinus. This provides visualization of the medial orbital wall and aids in removal of residual medial maxilla without endangering the orbit. Majority of tumors of maxillary sinus and pterygo-palatine fossa will involve the posterior ethmoids and sphenoid. The bulla ethmoidalis is removed and a posterior ethmoidectomy and sphenoidotomy are performed. The inferior turbinate is medialized and its posterior two-thirds removed. A right angled phako-knife is used to make mucosal incisions from just below the orbit, through the anterior one third of the inferior turbinate onto the floor of the nasal cavity. The incision is continued along the floor of the nose to the posterior region of the inferior turbinate and on to the maxillary sinus. A sharp chisel is used to cut the bone under the mucosal incisions

If the bone forming the medial maxillary wall is mobilized, the naso-lacrimal duct will tether the bone anteriorly and the duct will be visualized which can be transected with a scalpel (Fig 30). Subsequently, a DCR spear knife (Metronic Xomed) is used to open the lower half of the sac, creating an anterior and posterior flaps and rolling these out (Wormald et al, 2003; Wormald & van Hasselt, 2003; Vrabac, 1994). This prevents stenosis of the sac postoperatively (Wormald et al, 2003; Wormald & van Hasselt, 2003). The edges of the resected maxilla are cleaned with micro-debrider (Metronic Xomed). Using a 70 degree endoscope the entire maxillary sinus can be visualized including the anterior wall and floor. The tumor can now be removed from the maxillary sinus under direct vision. A canine fossa puncture can be performed, if additional access is required which can be useful to access areas within the sinus

that may otherwise be difficult to access. Malleable suction dissector's are useful because these instruments can be bent to the required angle for dissection in difficult areas like the anterior wall or antero-lateral region of the lateral wall of maxillary sinus.

Fig. 30. A 30- degree endoscopic view showing evidence of right modified medial maxillectomy performed for an inverted papilloma.

4.2 Exposure of the pterygo-palatine fossa

Exposure of the pterygo-palatine fossa via a wide medial maxillary antrostomy is necessary for tumors the occupy the ptergo-palatine fossa and extending into the infra-temporal fossa. The mucosa from the posterior wall of the maxillary sinus is elevated and preserved and the exposed bone removed to access the pterygo-palatine fossa. A 45 degree through-bitting Blakesley forceps is used to remove the bone anterior to the spheno-palatine artery and continued to the posterior wall of the maxillary sinus exposing the contents of the pterygo-palatine fossa. Traction is vital for tumors that extend into the infra-temporal fossa because it allows the surgeon to identify the areas of attachment of the tumor to the surrounding tissues and to dissect these free with suction dissector. Thus the entire tumor can be mobilized and its pedicle identified.

Tumors that extend into the infra-temporal fossa will usually be closely associated with the maxillary nerve in the pterygo-palatine fossa. This nerve should be identified both distally and proximally early in the dissection and preserved. Suction dissection instruments are used to separate the nerve from the tumor. Fibrous tissue is easily divided with endoscopic soft tissue scissors.

Feeding blood vessels can either be caurterized with suction bipolar diathermy forceps or clipped and cut. Once the tumor is removed, the tumor bed can be closely inspected to ensure no tumor remnant remains. Once hemostasis is achieved with suction bipolar forceps, the preserved mucosa from the posterior wall of the maxillary sinus is replaced. Surgicel can be placed in the cavity if required. Finally, ensure that the lacrimal sac is adequately exposed to prevent postoperative stenosis and epiphora. The incidence of postoperative epiphora has been described as high as 30% (Bolger et al, 1992).

Endoscopic two-surgeon technique for tumors of the pterygo-palatine and infra-temporal fossa

The key to successful endoscopic removal of large tumors in this region is having two surgeons operating at the same time. This can be achieved by providing access to the tumor

bed for the second surgeon through the septum from the opposite nasal cavity. A hemi-transfixation(Freer's) incision is made on the opposite site of tumor. Using standard septoplasty techniques, the mucosa is elevated off the cartilage of the septum which is preserved but most of posterior bony septum is resected. A horizontal incision is made in the opposite septal mucosa to allow instruments placed through the opposite nostril and into the Freer's incision to cross the septum and access the tumor on the contra-lateral side of the nose.

During tumor removal, the second surgeon can provide significant traction on the tumor and when the feeding vessel from the maxillary artery is cut, large volume suction in the field can allow the suction bipolar cautery to be used to identify and cauterize the large bleeding vessel.

4.3 Juvenile angiofibroma with pterygo-palatine and infra-temporal fossa extension

Angiofibromas that significantly extend into pterygopa-latine fossa can be removed after endonasal endoscopic medial maxillectomy (Kennedy et al, 1990) and embolization within the preceding 24 hours. This reduces the vascularity of the tumor and allows dissection around the tumor without major hemorrhage. The second surgeon can keep the surgical field clear using a large suction in the area of dissection while the other surgeon holds the telescope and suction dissection instrument.

4.4 Schwannoma involving the pterygo-palatine and infra-temporal fossa

Endoscoopic medial maxillectomy also provides access to other tumors that may involve the pterygo-palatine and infra-temporal fossa. Schwannoma of the maxillary nerve involves the entire ptrygo-palatine fossa and extends significantly into the infra-temporal fossa. Endoscopic medial maxillectomy allows access to the entire posterior wall of the maxillary sinus and after its removal, to the tumor.

4.5 Post-operative care

Douching of the nose with saline is started immediately postoperatively. Local and systemic antibiotics and corticosteroids are usually helpful. Crusting will usually continue for a few weeks until the cavity epithelializers but has not proved to be problematic in the long run. Benign tumors do not usually need any adjuvant treatment but malignant tumors may require postoperative radiotherapy.

5. Endoscopic resection of benign pathological lesions of paranasal sinuses

5.1 Mucoceles

Mucocele is a chronic, expansile, benign cystic lesion limited by the mucosa of the paranasal sinus, with thick, translucent mucous secretions (Fig 31). The most common are the frontoethmoidal mucoceles which presents with headaches and orbital symptoms. The expansile character of the mucocele promotes slow erosion of the adjacent bone via compression and consequent bone absorption. This disease is usually secondary to obstruction to sinus drainage, leading to stagnation of the secretion within the cavity. The predisposing factors can be fractures, mucosal edema, polyps, tumors, surgical trauma and

chronic sinusitis. Mucoceles are classified according to the sinus of origin. The frontal sinus being the most common site, followed by the ethmoid, maxillary and sphenoid sinuses.

Fig. 31. Coronal CT imaging of the right frontal sinus with evidence of a right mucocele showing expansile erosion of right orbital floor with lateral extension

Fronto-ethmoidal sphenoidal and the rare maxillary sinus mucoceles are ideal cases for endoscopic approach provided wide marsupilization can be achieved (Hehar & Jones, 1997). Mucoceles accessible with the endoscope should be opened as widely as possible using through-cutting forceps in order to minimize the amount of scar tissue that forms around the edges and which might lead to recurrence. Coronal CT scan is helpful to show whether the lesion can be approached via the nasal cavity and whether it is unilocular or multilocular. In the frontal sinus, a small mucocele may be drained via the endoscopic approach (Fig 32) but mucoceles with lateral extension may be difficult to access via the nose. Therefore, an external and endoscopic approach can be usefully combined, preserving lateral support of the frontal recess and avoiding a stent.

Fig. 32. Coronal CT imaging showing a right iatrogenic frontoethmoid mucocele and intraoperative endoscopic drainage and follow up a 3 months post surgery showing a patent frontal sinustomy in an adult presenting with frequent right headaches and heavy eyes

Preoperative evaluation of patients with frontal mucoceles should include careful evaluation of the lesion relative to the skull base. Endoscopic decompression is probably the best initial therapy for these lesions. It is particularly true of mucoceles that have eroded the posterior table of the frontal sinus and become adherent to the dura.An uncinectomy is performed with an axillary flap as advocated by Wormald PJ(2005). Often in surgery of these lesions, the skull base is identified within the posterior ethmoids and then followed anteriorly until

the bone of the lesion is identified. The mucosal covered mass at the frontal recess area is opened with Blackesley's straight forceps (Stortz, Germany). As the lesion is approached or entered, mucoid or mucopurulent material is sucked out. The frontal sinustomy is enlarged upto about 2cm and the edges of exposed mucosa marsupilized. It is essential to remove all osteitic intersinus septa if recurrence of disease is to be avoided. If the bony margins are not flushed with the surrounding wall, narrowing of the opening, due to scarring and closure may occur (Kennedy et al, 1989). Once a frontal and/or ethmoid mucocele has been marsupilized, the expanded "shell" of bone that remains can be pushed manually to correct any bony swelling that may cause a cosmetic defect or displacement of the orbit intraoperatively. Sometimes a posteriorly placed mucocele may leave the orbit displaced even after marsupilization and then the orbit may need to be decompressed by removing its lateral wall (Conboy & Jones, 2003).

The majority of mucocels can be marsupilized endoscopically with minimal morbidity and long-term results as compared to other techniques. The wider the mococele is marsupilized, the better the result. Majority of mucoceles can be marsupilized well with the endoscope except those lying in the lateral aspect of the frontal sinus, those that are secondary to malignancy(require an en-bloc and a craniofacial resection) and those secondary to pathology like Paget disease of fibrous dysplasia (Kennedy et al, 1989; Beasley & Jones, 1995).

In the postoperative period, the mucosal lining the mucocele cavity may undergo significant hypertrophy and secretions may accumulate, necessitating suction from time to time. However, mucociliary clearance becomes reestablished, typically in a few weeks and the mucosal hypertrophy resolves over time (Kennedy et al, 1989). Hospitalization usually is less than 24 hours. As with other endoscopic sinus surgery, meticulous postoperative care is essential.

Relative contraindications for endoscopic marsupilization

- Abnormally thick bone (Paget's disease (Fig 33), fibrous dysplasia (Fig 34)).
- Revision surgery where an external fronto-ethmoidectomy was performed and if the recurrence is located lateral to area accessible via a median drainage procedure
- A laterally placed frontal mucocele
- Malignancy associated with a mucocele

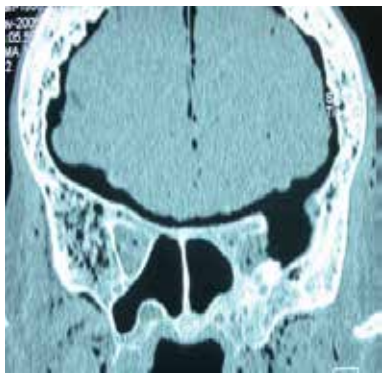


Fig. 33. A coronal CT scan view of paranasal sinuses and skull showing evidence of Pagets disease

Fig. 34. A coronal CT scan of the paranasal sinuses showing evidence of fibrous dysplasia involving the sphenoid sinus

6. Endoscopic applications to the sellar, parasellar and clival for resection of benign pathological lesions

6.1 Endoscopic pituitary micro-adenoma and macro-adenoma surgery

6.1.1 The various approaches to the pituitary include

- Trans-septal, trans-sphenoidal
- Trans-nasal
- Transcolumellar approach(Fig 35)
- Via an external ethmoidectomy approach
- Through the upper buccal sulcus of the mouth and then trans-septal, trans-sphenoidal
- Via a craniotomy eg an anterolateral or a frontal approach

Fig. 35. A picture of transcolumella approach as an access route to the pituitary

6.1.2 Indications

Pituitary tumors occur in 9 in 10,000 pupulation and comprise 10% of intracranial tumors. The commonest pituitary tumors in patients under 35 years secrete prolactin and adrenocorticotropin whereas after 35 to 50 years they generally secrete growth hormone. In the latter, non-secreting tumors are more common. Symptoms can be caused by pressure on the anterior pituitary and hypo-pituitarism or by extra-sellar growth that can produce headaches, pressure on the optic chiasma or brain (Fig 36). Surgery is usually the treatment of choice. Surgery is the first-line treatment in acromegaly, where up to 90% of micro-adenomas are cured but the outcome is not as good as in large tumors.

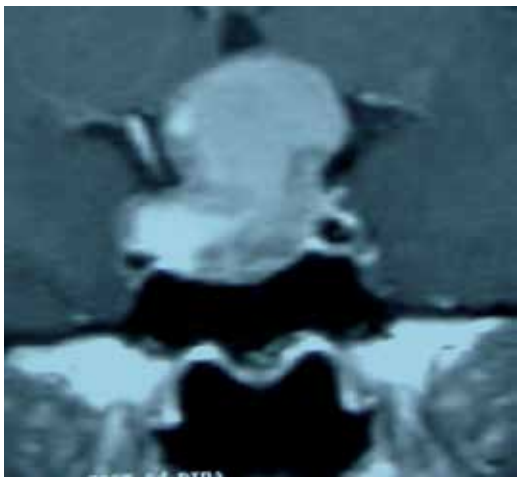

Fig. 36. A coronal MRI of the paranasal sinuses showing a suprasellar extension of a pituitary adenoma presenting with headaches and visual symptoms

Surgery for pituitary disease must be based on an assessment of the patient by a multidisciplinary team (Gendeh, 2006). The medical management of many pituitary tumors has reduced the frequency of the need for surgery in many patients. Medical management is rarely indicated in tumors that extend into the supra-sellar region and extending above the diaphragma sellae.

The endoscope gives excellent visibility within the sphenoid sinus and with a 45 degree endoscope it is possible to see more detail within the pituitary fossa than with the microscope. The advantages of the trans-nasal, trans-septal or lower buccal approach is that it avoids an external scar and by removing the posterior part of the septum, vomer and anterior wall of sphenoid, this approach allows wide access. In the endoscopic trans-nasal technique, mucosal preservation is an added advantage and allows the surgeon to work bimanually if necessary. The advantage of the two nostril technique is when there is moderate or severe bleeding, it can be controlled more readily. An external ethmoidectomy approach produces a scar and has the potential to cause stenosis of the frontal recess. Pituitary surgery has been routinely been performed with endoscopic endonasal approach at our referral center since 1990. (Gendeh, 2010)

6.1.3 Surgical anatomy

The vomer consistently joins the sphenoid in the mid-line and this is a very reliable landmark. The sphenoid inter-sinus septum is often asymmetric(more than 75%) and its essential to review the CT scans pre-operatively. The degree of pneumatization of the sphenoid sinus also varies greatly (Lang, 1989). A chonchal sinus is small and confined to the anterior aspect of the sphenoid in 5% of cases. A pre-sellar sinus extends to the coronal plane level with the anterior wall of the sphenoid in 28% of cases. In 67% of cases it is sellar type(Fig 37). Agenesis of the sphenoid sinus occurs in 0.7% of patients. The carotid artery bulges into its lateral wall and it can be dehiscent in up to 30% of patients. Axillary imaging cuts complement coronal sections and sagittal reconstruction helps. The natural sphenoid sinus is relatively high in the posterior wall of the sphenoid and is often placed at the level of the superior turbinate which may be readily visible after gentle lateralization of the middle turbinate. The bony anterior wall of the sphenoid sinus is often thin or deficient 1 to 1.5 cm above the posterior choana. The lateral wall of the sphenoid sinus has indentations from various structures (Fig 38):

- The optic nerve can indent its surface in the upper third
- The maxillary nerve can form an almost horizontal semicircular intrusion that may be mistaken for optic nerve in its medial third
- The degree of pneumatization of the sinus varies and influences how prominent structures are in its lateral wall. Pneumatization can extend to the clivus, the lesser wing and the root of the pterygoid process).
- The vidian nerve can bulge into its floor

1. Choncal (5%)
   - Common in children below 12 years
   - Area below sella is complete block of bone
2. Presellar (28%)
   - Posterior limit of air cavity is perpendicular to sella
3. Sellar (67%)
   - Commonest,
   - Air cavity extended into body of sphenoid below sella and may extend as posterior as clivus

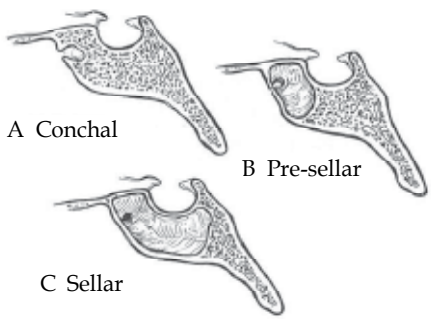

Fig. 37. Types of sphenoid sinus pneumatization

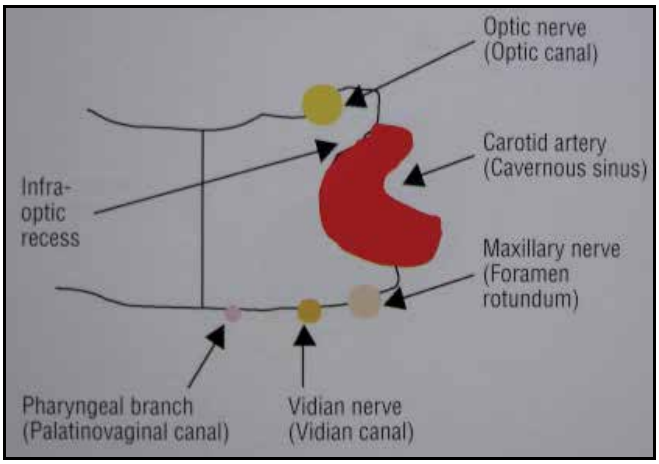

Fig. 38. A diagrammatic coronal section of the sphenoid sinus showing the anatomical indentaions of vital structures in its roof, lateral wall and floor.

6.1.4 Useful instruments

- Hajek-Koffler punch (Stortz, Germany) to remove thick bone. The rotating sleeve allows its jaws to be pointed in any direction and for the handle to be in a comfortable position for the operator
- A Kerrison punch (Stortz, Germany) allows fine controlled removal of small segments of bone and the slight reversed angle of its jaws help to remove the back of the vomer
- A long-shanked drill with a coarse diamond (Metronic Xomed) to remove any bone in the roof of the sphenoid bone in a controlled way
- A computer guided systems

6.1.5 Surgical technique

The trans-nasal endoscopic approach commences by making a sphenoidotomy on the side of the tumor or when it is in the midline opening, the side where the sinus is larger. The sphenoidotomy is opened up to the level of the skull base using a sphenoid punch. Suction diathermy will be needed to stop the bleeding from the posterior branch of spheno-palatine artery when opening the sphenoidotomy inferiorly. Any vomerine spur should be removed. After careful CT examination and endoscopically inspecting the sphenoid sinus to check on the proximity of the lateral structures, the lateral aspect of the anterior wall can be removed if necessary. A Kerrison antrum punch (Stortz, Germany) is useful for performing this as its small diameter means that the bone can be removed in small pieces with good visibility. If more space is required across the midline, the vomer can be fractured across or it can be incised 1cm in front of the sphenoid and removed. The vomer can be very thick where it joins the sphenoid but it rarely needs drilling (Fig 39). The pituitary often bulges into the roof of the sphenoid and the bone may be very thin (Fig 40). If the bone is thick, a course diamond burr (Metronic Xomed) should be used to thin it. A diathermy point is useful to open the dura by making a cross-shaped incision through it. A 45 degree endoscope gives

excellent visibility and helps to avoid going through the diaphragm sellae. A Hajek punch (Stortz, Germany) helps to remove the bone over the pituitary. The tumor is often grey in colour, but occasional it can be vascular and ooze moderately. The pituitary fossa can be closed at the end of the procedure with raised naso-septal flap placed onto the bony defect. If there is a CSF leak, in addition an underlay duragen(collagen matrix graft) is placed before a naso-septal flap is placed as overlay flap and secured in position by Tisseel and gel-foam over it.

Fig. 39. Intraoperative endoscopic view showing a transseptal transsphenoidal approach to pituitary adenoma exposing the sphenoid rostrum

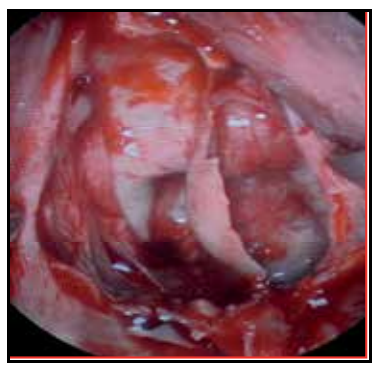

Fig. 40. A 45 degree endoscopic view of exposed sphenoid sinus showing a intersinus septum and an enlarged sella

It is possible to approach the pituitary via a limited sphenoidotomy, although it reduces access and visibility. It may be useful to trim the middle turbinate on one side for better access and visibility utilizing a four hand technique.

7. Endoscopic repair of skull base CSF fistula

CSF leak results from a breach in the dura, which may be spontaneous, secondary to a fracture, related to a surgical trauma or associated with pathology of the skull base and/or secondary to a high-pressure system (Fig 41).

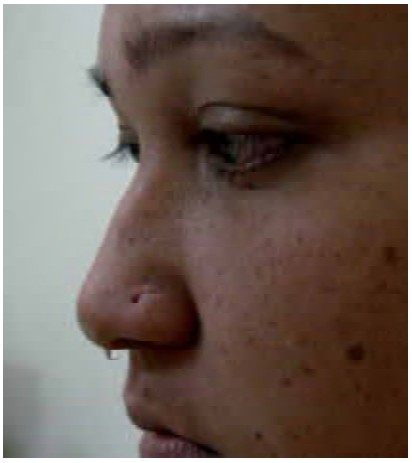

Fig. 41. Picture of an adult obese female presenting with unilateral clear watery spontaneous CSF rhinorrhoea on exertion

7.1 Indications

The main indications for repairing a CSF leak is its association with a 10% risk per year of developing meningitis (Gendeh et al, 1998). Those who have a leak from a fracture of the anterior skull base repaired still have a slightly increased risk of developing meningitis in the future but this is less than those whose leak stops spontaneously. Therefore, active leaks should probably be repaired at any stage.

7.2 Surgical anatomy

The skull base is made up anteriorly of the posterior wall of the frontal sinus, which is a thick frontal bone that extends posteriorly to form roof of ethmoid sinuses(fovea ethmoidalis) on either side of the cribriform plate. The cribriform plate joins the fovea through the lateral lamella and can be almost non-existent when the cribriform plate and fovea ethmoidalis are on the same plane or it can form the thin vertical bone connecting them, depending on how far the cribriform plate dips into the nose (Fig 42). Posteriorly, the sphenoid sinus and posterior ethmoidal air cells form the inferior relationship of the skull base.

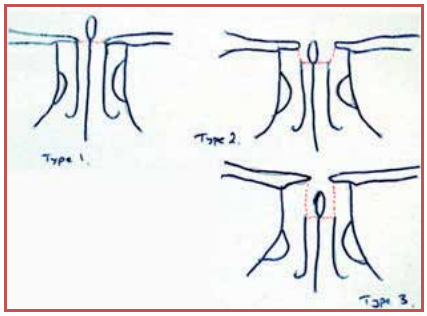

Fig. 42. Keros classification of the anatomy of the cribriform plate which may lie at different level in relation to the anterior skull base

The commonest site of a spontaneous CSF leak is the area of the cribriform plate where dura around the olfactory nerves appears to have extended through the cribriform plate and ruptured (Fig 43). The next most commonest leak is from a very well-pneumatized sphenoid sinus (Fig 44). A high-pressure system may be a contributing factor in these cases and a shunt or venrticulostomy may be required.

Fig. 43. Intraoperative endoscopic view showing arachnoid granulations arising from the left cribriform area in an obese female presenting with spontaneous cerebro-spina fluid rhinorrhea

Fig. 44. A coronal CT scan showing a well pneumatized sphenoid sinus

Iatrogenic CSF leaks are often found around the lamina lateralis (the vertical thin bone joining the cribriform plate to the fovea ethmoidalis) near the anterior ethmoidal artery. Post neurosurgical procedure leaks most commonly follow pituitary surgery, come from the posterior wall of frontal sinus when it has not been cranialized and more likely if a peri-cranial flap has not been used to repair any dural defect.

7.3 Diagnosis

- It is vital to localize the site of a leak (Marshall et al, 2001)
- Fluid collected should be tested for immune-fixation of beta-2-transferrin
- Rule out any high- pressure system leak
- Successful closure depends on localizing the exact site of the fistula

It is essential to confirm the diagnosis with immune-fixation of beta-2-transferrin which is extremely specific and sensitive test (Eljamel, 1993). Unilateral autonomic rhinitis is unusual but can mimic CSF rhinorrhea.

Site of any defect should be defined using high-resolution coronal CT (Lloyd et al, 1994). If CT fails to define the site of the defect, T2-weighted MRI may help which has superseded CT cisternography (Stafford et al, 1996). In a few post-trauma patients the site of leak is uncertain or it could be that there is more than one leak. In dural defects less than 15mm, the 'bath plug' technique is encouraged which consists of introducing a fat plug with vicryl suture into the intra-dural space (Wormald & McDonough, 1997) It is believed that this technique would prevent high pressure from pushing the graft away from the defect (Gendeh et al, 2002). The fat pug can be harvested from the ear lobule. A 4 0 vicryl suture is knotted through one end of the fat plug and the suture is passed down the length of the fat plug. A free mucosal graft about 3 x 3 cm is harvested anterior to the middle turbinate from the contralateral lateral nasal wall. The fat plug is placed below the defect and the malleable frontal sinus probe (Metronic Xomed, Jacksonville, Florida, USA) is used gently to introduce the fat plug through the defect (Wormald and McDonough, 1997). Once the fat plug has been safely introduced through the defect, the plug is stabilized with the probe and the vicryl suture is gently pulled. The seal is tested by placing the patient head down and asking the anaesthetist to perform a forced-inspiration maneuver. No Fluorescein-stained CSF should be seen. The patient is placed head-up (15 degrees) and the free mucosal graft is slid up the vicryl suture until it covers the defect (Fig 45). Ensure that the graft is correctly orientated with the mucosal surface facing the nasal cavity. Fibrin glue is applied and the vicryl suture cut. Gelfoam is placed over the free mucosal graft and fibrin glue is reapplied. No other nasal packing is used.

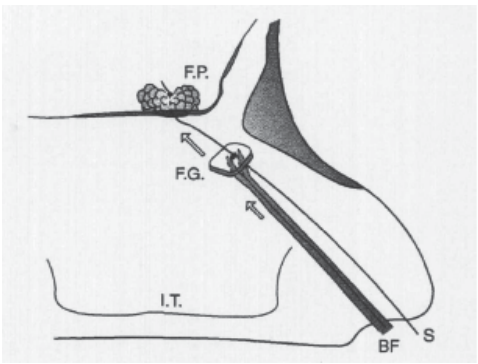

Fig. 45. A diagrammatic sagittal section of the nose showing the a free mucosal graft being slid up the vicry suture to cover the protruding fat plug and skull base defect. Adapted with permission from Wormald and McDonough. Americal J Rhinol 2003; 17:299-305

A diagnostic or pre-operative sodium fluorescein lumbar puncture will help define the source of leak(Fig 46 a). It is vital to ensure that there is a free flow of CSF before proceeding to inject any sodium fluorescein. The patient was skin tested with 2% sodium flourescein eye drops one day before surgery. A lumbar drain was inserted on the day of surgery and intrathecal sodium fluorescein 10%(0.1% of sodium flourescein is diluted with 10ml of withdrawn CSF) was given in a slow bolus over 10 minutes to identify site of fistula (Gendeh et al, 2005). The ideal time for the sodium fluorescein to be injected is one hour beforehand. It is a great help to place the patient in a 10 degree head-down position. The

fluid will appear bright yellow, unless a blue filter is used when it appears fluorescent green (Fig 46 b). The systemic clearance of fluorescein is essentially complete by 48 to 72 hours from the patient's body.

(a) (b)

Fig. 46. A 30 degrees endoscopic view showing a spontaneous CSF leak from the anterior cribriform plate using intrathecal sodium fluorescein(a) and highlighted using blue blue filter(b) in the same patient

The adverse reactions of intrathecal fluorescein administration are nausea, vomiting, gastrointestinal distress, headache, syncome and hypotention. Cardiac arrest, basilar artery ischaemia, severe shock, convultions, thrombophlebitis at the injection site and rare cases of death have been reported.

7.4 Surgical technique

Initially the repair of CSF fistula involved the use of multi-layered barrier comprised of free tissue grafts harvested from the nasal perichondrium or temporalis fascia. On top of the on lay graft, an abdominal fat graft was used as a bolster and a biological dressing. A fibrin sealant was applied to help fixate the fat graft. Sponge packing (Merocel tampons) were placed intra-nasally to support the fat graft and provide some compression.

We adopted the use of collagen matrix graft (duragen, Intra Life Sciences, USA), which was easy to maneuver, is soft and pliable, thus decreasing the risk of injuring any critical structures as we tuck the graft to overlap the surrounding dural edges of the defect. Duragen is an absorbable and sutureless collagen onlay indicated as dura substitute for the repair of dura mater. We eliminated the routine use of lumbar drains and reserved them for high-risk situations or secondary repairs.

The latest intervention to decrease CSF leaks employs vascularized mucosal flaps which hastens the healing process, especially in patients with prior radiation therapy and make patients more suitable for early postoperative radiation therapy. Hadad and Bassagasteguy from Argentina developed the nasoseptal flap, supplied by the posterior nasoseptal arteries

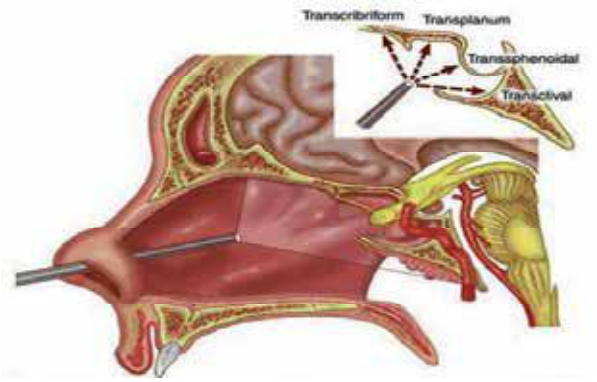
which are branches of the posterior nasal artery. A mucoperichondrial/mucoperiosteal flap pedicle on the posterior nasal arteries provides a long flap that has a wide arc of rotation and a potential for area of coverage that is superior to any other flap previously described(Fig 47). The flap may be harvested to cover the entire anterior skull base from the frontal sinus to the sella or cover a clival defect from the sella to second cervical vertebra (C2). Use of this flap has to be anticipated in advance, since a posterior septectomy and a wide large slphenoidotomy removes the vascular pedicle. This flap is very reliable and is typically positioned over a fascial graft or fat graft and held in place with fibrin glue and a balloon catheter. We have not observed any significant donor site morbidity with the use of this flap and the septum becomes remucosalized within several months of surgery

Fig. 47. Endoscopic view of a healed nasoseptal flap repair at 3 months post surgery for a pituitary macroadenoma with evidence of CSF fistula

8. Recent advances in technology and its application to anterior and ventral skull base lesions

There is an ongoing revolution in multiple surgical specialties with the introduction of minimally invasive techniques. A natural extension of ESS has been the application of endoscopic techniques for the surgical treatment of pathologic conditions of the cranial base. This has been driven by the ongoing development of endoscopic technology increasing consumer demand. Furthermore, as the limits of ESS is tested, the possibilities for cranial base surgery are expanded. Truly, it is a maximally invasive endoscopic surgery than minimally invasive surgery.

The Expanded Endo-nasal Approach(EEA) to the ventral skull base provides endoscopic access from the frontal sinus to C2 in the sagittal plane and from the midline to the jugular foramen, internal acoustic canal(IAC) and lateral mass of C2 in the coronal plane (Fig 48). Potential advantages of the EEA not only include improved cosmesis but more importantly, the potential for much less neurovascular manipulation in well selected cases. In pediatric patients, preservation of facial skeleton avoids disruption of growth centers and development of facial asymmetry with further growth. In contrast to an intracranial approach, an endo-nasal approach avoids the need for any brain retraction and may result in less damage to brain tissue. Improved visualization and better access to difficult sites may result in improved oncological outcomes.



Slide Courtesy of the Pittsburgh Otolaryngologists & Neurosurgical team

Fig. 48. Expanded endonasal approaches to base of skull

Advances in cranial base surgery over the last two decades have only been possible with the collaboration of multiple surgical specialities (Kassam et al, 2007). This is more obvious with endoscopic skull base surgery. Rather than working sequentially as is often done with open approaches, surgeons from different speciality work together simultaneously as a team: one person maintaining a view with the endoscope and the other working bimanually to dissect the tissues. The benefits of the two team surgery include improved visualization, increased efficiency and the ability to deal with a crisis such as vascular injury. There is added value of having a 'co-pilot' for problem solving, avoiding complications and modulating enthusiasm.

The primary advantage of the endoscope compared to other methods is improved visualization which accounts for an increased access to difficult to reach areas and may facilitate complete tumor resection and avoidance of complications due to poor visualization. Other potential benefits of endoscopic surgery include improved cosmesis and decreased morbidity from tissue trauma and manipulation of vessels and nerves. The consequences of decreased morbidity are a faster recovery, shortened hospitalization and decreased cost of medical care (Gendeh, 2009).

Familiarity with endoscopic anatomy, proper instrumentation, an experienced surgical team and adherence to endoscopic surgical principles are essential ingrediants for avoiding severe complications. The basic principle of endoscopic cranial base surgery is internal debulking of tumor to allow extra-capsular dissection of tumor margin with early identification of neural and vascular structures. This principle is the same for open neurosurgical procedures and sharp dissection of tumor margins is performed without pulling on tumor. Adherence to these fundamental principles minimizes the risk of neural or vascular injury.

In the late 1970s and early 1980s, the combined effort between the Otolaryngologist and neurosurgeons worldwide, made significant strides in the surgical removal of tumors at the base of the skull and brain. These procedures were however disfiguring and painful for the patient. Furthermore, patients encountered long recovery periods and significant risk of complications because the procedures involved large incisions in the face and scalp and removal of parts of the skull to reach the abnormality at the cranial base.

In 1998, a group of Otolaryngologist and neurosurgeons at UPMC in Pittsburgh, USA initiated the first systemic approach to using the nose as a minimally invasive passageway to the brain. They began the extensive process of mapping anatomy and in collaboration with the medical device manufacturers, designed new instruments to make this idea a reality.

By 2000, the Pittsburgh team of doctors had developed the necessary tools and techniques to access tumors located inside the skull by the way of the nose known as EEA. In EEA, the surgeons use endoscopes with light source as well as other instruments especially designed, to treat various types of brain and spinal abnormality. Hence, today surgeons can take out baseball-sized growths without pulling on the brain or touching the normal tissue. This continued refinement of EEA now allows access to an expanded region of the brain, skull base and spine. The classification of endoscopic approaches to cranial base are listed in Table 3.

SAGGITAL PLANE

- Transfrontal
- Transcribriform
- Transplanum (Suprasellar/Subchiasmatic
- Transsphenoidal (Sellar/Medial transcavernous)
- Transclival
    - Posterior clinoid
    - Mid-clivus
    - Foramen magnum
- Transodontoid

CORONAL PLANE

- Transorbital
- Petrous apex (Medial transpetrous)
- Lateral transcavernous
- Transpterygoid
- Transpetrous
    - Superior
    - Inferior
- Transcondylar
- Parapharyngeal space

Snyderman CH.2007. Acquisation of surgical skills for endonasal skull base surgery: a training program. Laryngoscope 117(4): 699-705

Table 3. Classification of endoscopic approaches to cranial base

The collaborative effort has put the Otolaryngologist and the neurosurgeon to work closely via the nose using the two-nostril and four hand technique was first advocated by Prof. Dr Heinz Stammberger from Graz, Austria for endoscopic cranial base surgery.

Standardization of training and the adoption of modular, incremental training program are expected to facilitate the gradual training of endo-nasal surgeons in Otolaryngology and Neurosurgical disciplines. Stages of training are established for both surgical speciality based on level of technical difficulty, potential risk of vascular and neural injury and unfamiliar endoscopic anatomy. Mastery of each level is recommended before attempting procedures at higher level. Adherence to such a program during the growth phase of endoscopic skull base surgery may decrease the risk of complications as the surgeon's knowledge and surgical expertise develop (Snyderman et al, 2007).

Complications of EEA are the same as open approaches: neural and vascular injury, infection and CSF leak. Literature report of neural and vascular injury are fortunately rare accounting for 1% incidence. These can be avoided with attention to anatomical landmarks and proper dissection techniques. An experienced team can effectively control venous bleeding from the cavernous sinus or basilar plexus. Peri-operative antibiotic prophylaxis, multilayered repair of dural defects and aggressive management of postoperative CSF leaks are contributing factors. One of the biggest remaining challenges is repair of large dural defects and prevention of post-operative leaks. With the advent of the septal mucosal flap, the Pittsburgh group suggest an incidence of 6% of CSF leak. Developments that have decreased the incidence of postoperative CSF leaks include a multilayered closure, direct suturing of grafts to dural edges, use of biological glues, coverage with vascularized septal mucosal flap and supporting the reconstruction with an intranasal balloon catheter.

Edited by Shimon Rumelt

This book focuses on the different aspects of ophthalmology - the medical science of diagnosis and treatment of eye disorders. Ophthalmology is divided into various clinical subspecialties, such as cornea, cataract, glaucoma, uveitis, retina, neuro-ophthalmology, pediatric ophthalmology, oncology, pathology, and oculoplastics. This book incorporates new developments as well as future perspectives in ophthalmology and is a balanced product between covering a wide range of diseases and expedited publication. It is intended to be the appetizer for other books to follow. Ophthalmologists, researchers, specialists, trainees, and general practitioners with an interest in ophthalmology will find this book interesting and useful.
