
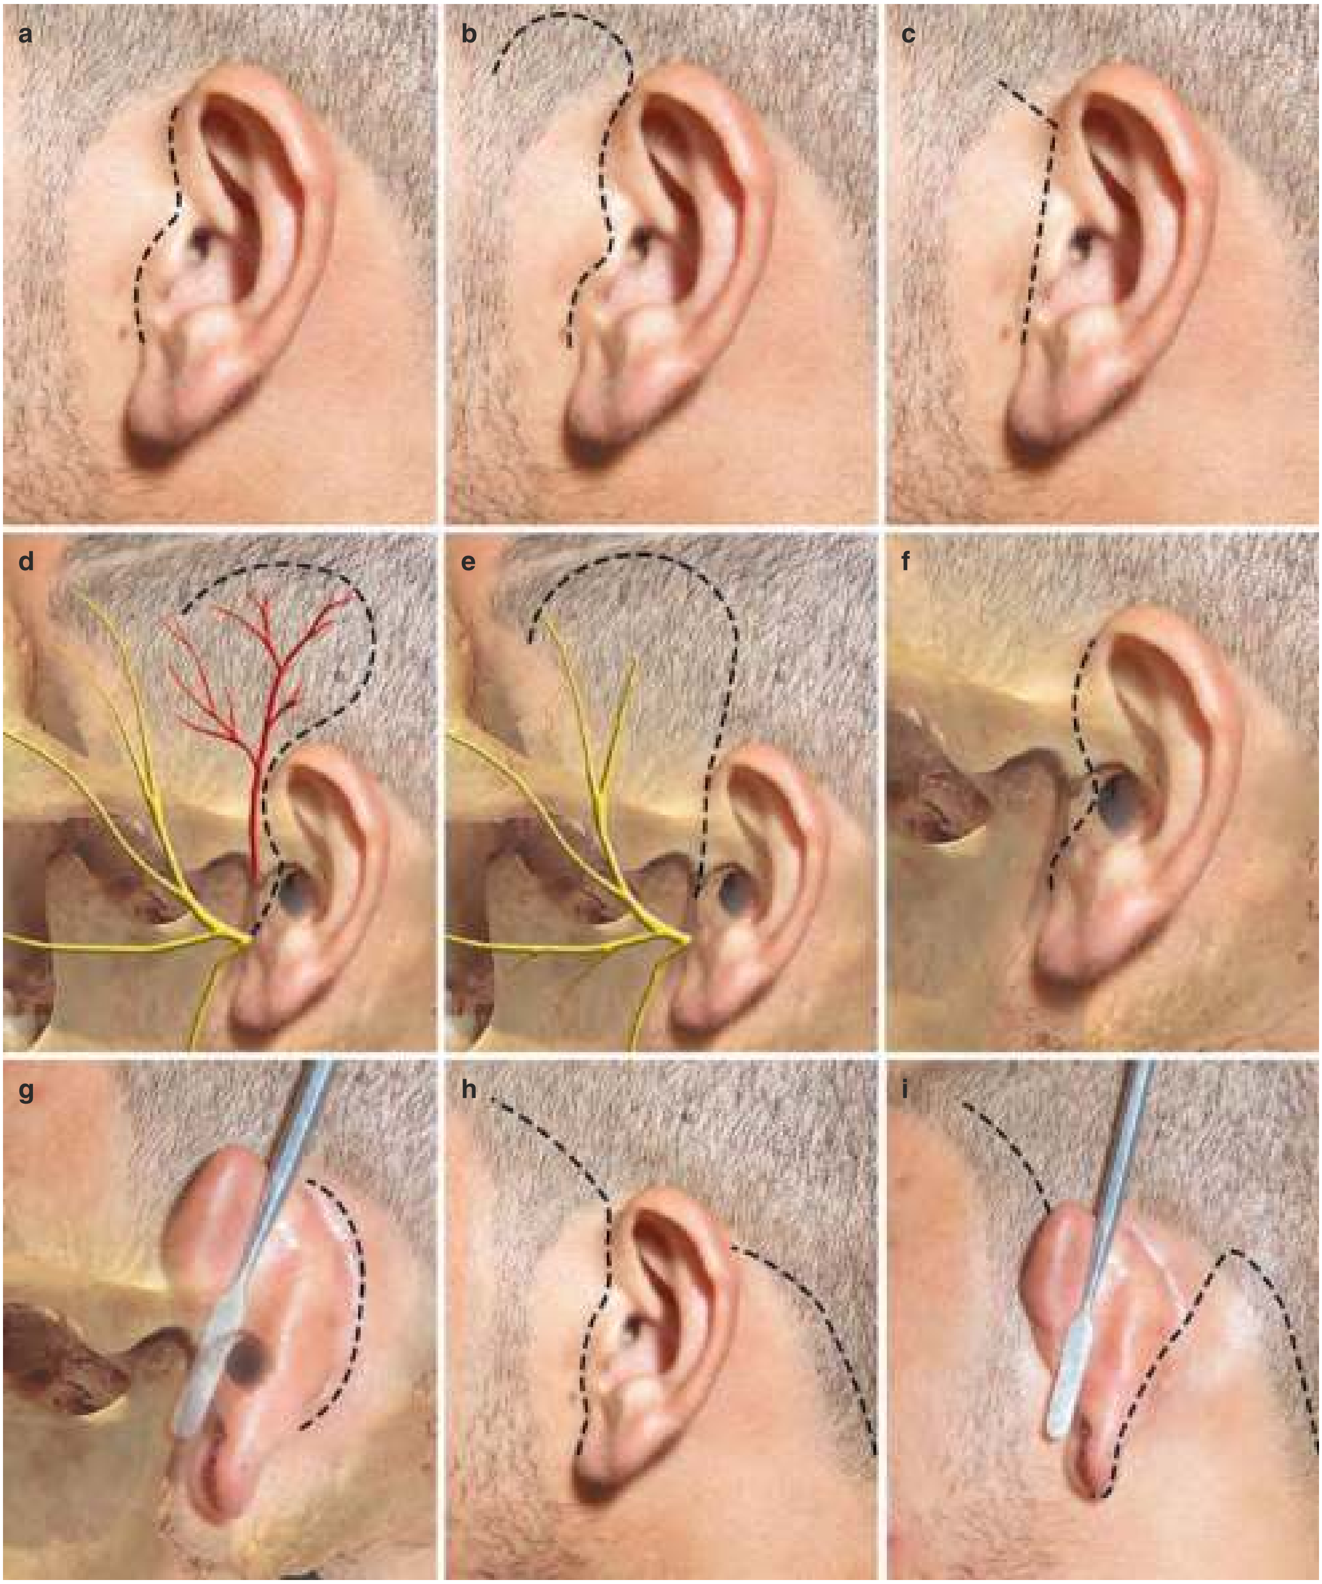

Fig. 65.6 (**a**) Dingman, (**b**) Blair's inverted hockey stick, (**c**) Thoma's, (**d**) Al-Kayat and Bramley. (**e**) Popowich's modification, (**f**) endaural, (**g**) postauricular, (**h**) rhytidectomy, (**i**) retro-auricular limb of rhytidectomy incision

like a hockey stick. The disadvantages include an unsightly scar and possible damage to the frontal branch of the facial nerve.

65.5.3.3 Thoma (1945)

The vertical limb is in the preauricular fold but angulated at 45° in the hairline near the bifurcation of the superficial temporal vessels.

65.5.3.4 Al-Kayat and Bramley (1979) (refer video on Al Kayat Bramley approach in Chap. 53)

This reverse question mark cosmetically acceptable incision gives excellent access to the TMJ without causing any damage to important anatomical structures. It starts superiorly through the scalp in the temporal region and extends to the inferior tragus. The superficial layer of the temporalis fascia is identified and incised at the root of the arch at 45° anterosuperiorly to avoid branches of the facial nerve. A vertical incision may be used if the temporalis fascia or muscle is to be used.

65.5.3.5 Popowich's Modification of Al-Kayat and Bramley [5]

This approach to the zygomatic arch and joint gives excellent visibility with safety. It is longer and wider than the conventional and question mark shaped and begins about a pinna's length away from the ear, anteroposterior just within the hair line, curves backward and downward well posterior to the main branches of the temporal vessels, till it meets the upper attachment of the ear.

65.5.3.6 Endaural [10]

This was first described by Rongetti in 1954, with the incision carried in the external ear. The advantages are good aesthetics and excellent access to the TMJ. However, the disadvantages include perichondritis, infection, paresthesia of the pinna, and deformity of the ear.

65.5.3.7 Coronal Extension of Preauricular Incision

The anterosuperior extension over the scalp of the preauricular incision gives a more aesthetic scar.

65.5.3.8 Rhytidectomy [10]

The endaural incision is extended in a curvilinear fashion around the mastoid tip, with an S-shaped extension ending in a submandibular incision. This allows access to the entire posterior border of the mandible and allows for identification of the main trunk of the facial nerve.

65.5.3.9 Postauricular

First described by Alexander [15] in 1975, its biggest advantage is that it avoids facial nerve injury and salivary fistula. However, possible complications include stenosis of external auditory canal, infection, and paresthesia of the pinna.

65.6 Treatment Protocol

Kaban [2] and colleagues described an approach for the treatment of TMJ ankylosis to minimize the incidence of re-ankylosis and produce satisfactory movement of the joint. Their study in 1990 became a landmark management protocol for the management of TMJ ankylosis (Table 65.2).

Yet again in 2009, Kaban [16] considered the potential effect of time and growth (i.e., the fourth dimension) on the outcome of TMJ ankylosis in children and presented another protocol (Table 65.2).

65.6.1 Surgical Options for Ankylosis Release (Fig. 65.7a–c)

History Ankylosis release surgeries, i.e., various ways of separation of the ramus from the skull have undergone great evolution during the nineteenth century. Esmarch [17] osteotomized the angle to release TMJ ankylosis in 1851. The first interpositional material was the pterygomasseteric sling, also developed by Esmarch. Condylectomy was first advocated by Humphrey in 1854. Abbe performed the first gap arthroplasty in 1880. But it was Topazian in the 1960s [18, 19] who signified the importance of interpositional grafts for reducing re-ankylosis.

65.6.1.1 Gap Arthroplasty

The conventional surgical treatment of TMJ ankylosis by gap arthroplasty includes complete resection of the ankylotic

Table 65.2 Kaban's protocols for TMJ ankylosis

1. Kaban's protocol for management of temporomandibular joint ankylosis (1990) [2]
(a) Aggressive resection of the ankylotic segment (b) Ipsilateral coronoidectomy (c) Contralateral coronoidectomy when necessary (d) Lining the joint with temporalis fascia or cartilage (e) Reconstruction of the ramus with a costochondral graft (f) Rigid fixation of the graft (g) Early mobilization and aggressive physiotherapy
2. Kaban's modified protocol for management of TMJ ankylosis in children (2009) [16]
(a) Aggressive excision of fibrous and/or bony mass (b) Coronoidectomy on affected side (c) Coronoidectomy on opposite side if steps 1 and 2 do not result in MIO of 35 mm or to point of dislocation of opposite side (d) Lining of joint with temporalis fascia or the native disk, if it can be salvaged (e) Reconstruction of RCU with either DO or CCG and rigid fixation (f) Early mobilization of jaw; if DO used to reconstruct RCU, mobilize day of surgery; if CCG used, early mobilization with minimal intermaxillary fixation (not > 10 days) (g) Aggressive physiotherapy

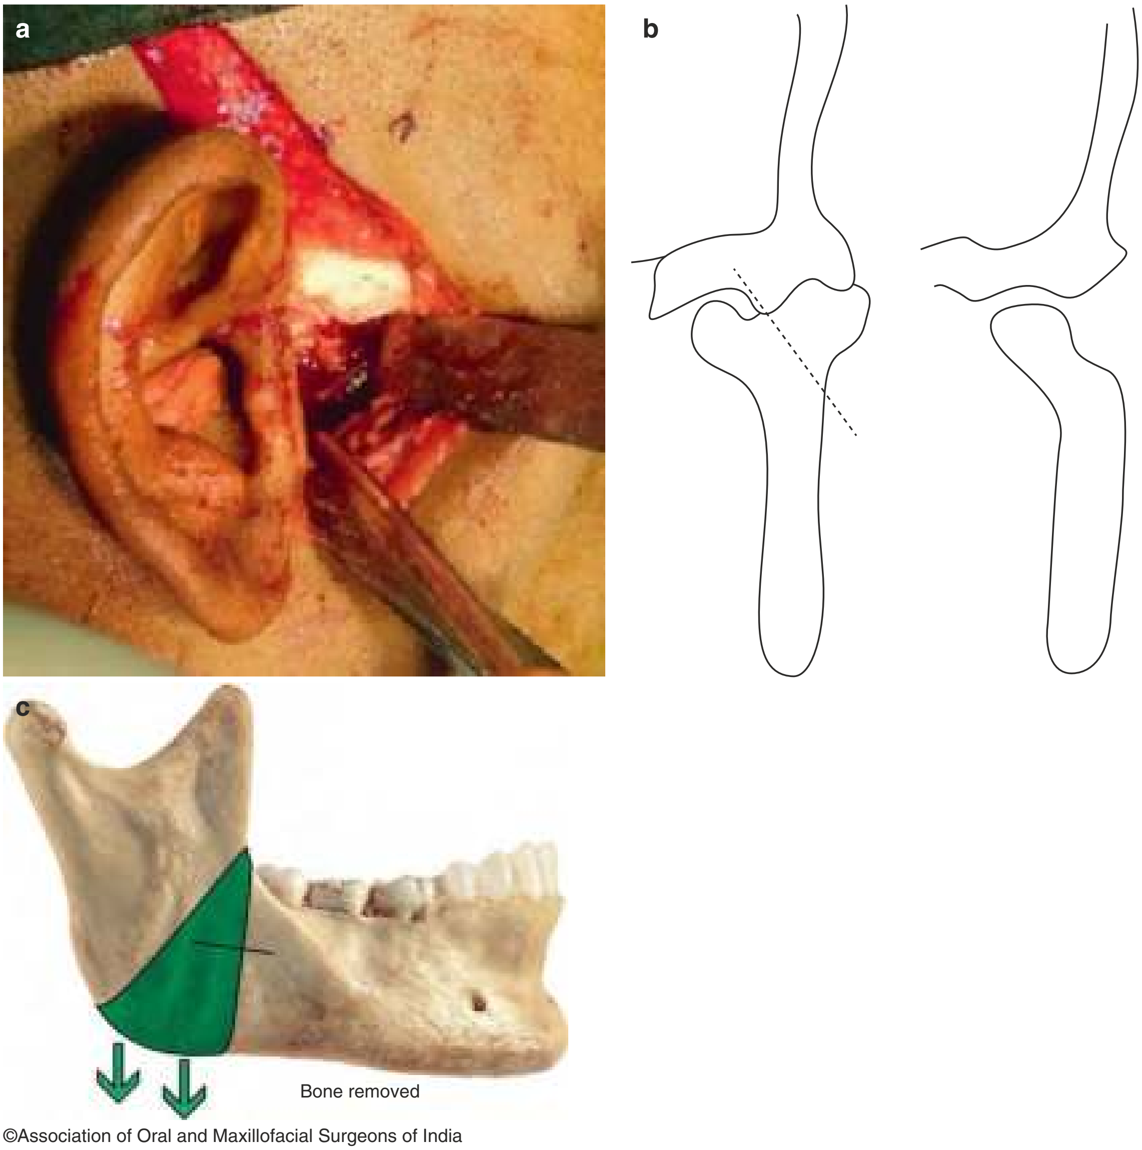

Fig. 65.7 (**a**) Gap arthroplasty, (**b**) Lateral arthroplasty (LAP), (**c**) Esmarch's procedure

mass with no soft tissue as an interposition between two cut ends. When a soft tissue is placed between the cut ends, it is known as interpositional arthroplasty. Gap arthroplasty is a relatively simple procedure requiring less operative time; however, it may cause ramal shortening, malocclusion, OSA, and, most distressingly, re-ankylosis. But it may still be used in certain adult patients, where the removal of a small ankylotic mass would not decrease the ramal height significantly.

Patients are operated under general anesthesia using a preauricular approach. After the ankylotic mass is exposed, the upper cut is marked, and the lower cut is placed 1.5 cm below it. In cases where normal architecture of the joint is maintained, the lower osteotomy cut is placed from the anterior to the posterior border of ramus just below the sigmoid notch. In cases where normal architecture is not clear, a cut is placed 1.5 cm below the lower border of zygomatic arch. Then the upper cut is completed, and the ankylotic mass is removed. The osteotomy is directed at 45° to prevent fracture of middle cranial fossa. The venous plexus if encountered medially needs only be packed to control bleeding.

A condylar retractor is kept below the ankylotic mass to prevent injury to the internal maxillary artery. Bone is cut initially using a bur/saw/piezoelectric unit through two thirds of its thickness. The remaining one thirds may be removed with an osteotome. A Piezoelectric unit if used, may cut bone till its very end. In case of a larger mass, it may also be removed in pieces. The ipsilateral coronoid process is always resected. Care is always taken to stop the application of Heister's mouth gag intraoperatively just before the opposite condyle dislocates.

In some patients with longstanding ankylosis, the coronoid process of the opposite site becomes hyperplastic. There may also occur fibrosis of the masseter, which would restrict jaw movements further. Thus, not only would the contralateral coronoidectomy be required, but the masseter attachment would also need to be completely dissected off the zygomatic arch. A coronoidotomy may not be adequate, as it may re form and attach again to the temporalis and subsequently cause decrease in mouth opening. An intact disc may not require another soft tissue interpositional graft but may itself be mobilized and repositioned into the new glenoid fossa.

R. F. Elgazzar [20] reviewed 101 patients (109 joints) and, on follow-up, reported that in comparison with other techniques of ankylosis release, gap arthroplasty had the least amount of mouth opening. Interpositional arthroplasty with temporalis gives better results in comparison.

Surgical navigation systems are useful in TMJ ankylosis surgery as they improve both the safety and accuracy of the surgery. The distance from the top of the glenoid fossa to the middle cranial fossa and that from the posterior margin of the fossa to the anterior border of the bony external auditory canal can be monitored via the navigation system. A safety distance of at least 3 mm from the middle cranial fossa and bony external auditory canal should be maintained to avoid injury. It reduces the risks of bleeding and CSF leak [21].

65.6.1.2 Esmarch's Procedure

This is of historical significance only. Esmarch [22] made a small incision posterior to the angle of the mandible and dissected the masseter and medial pterygoid muscles off the bone. A 2.5 cm wide wedge of bone, at the angle of the mandible with apex at upper border and base at the posteroinferior border, was removed. The muscles were then sutured back.

The disadvantage is that since the osteotomy is in the ramus, no ramal osteotomy or distraction can be done for correction of facial deformity. Hence, it is no longer used for ankylosis release.

65.6.1.3 Lateral Arthroplasty (LAP)

Nitzan hypothesized that in Sawhney's [3] Type II TMJ ankylosis or He's Type A2 [23], if the integrity and location of the displaced condyle and disc can be determined (despite morphological and positional alterations), both could be preserved to fulfill their roles in mandibular growth and function. Only the lateral part of the ankylosed mass was resected. Eight young patients were kept under observation for a period ranging from 6 to 60 months after surgery. She found significant improvement in facial symmetry and thereby concluded that the residual condyle retained its own growth potential and helped maintain normal mandibular movement function and occlusion [24].

Yang and Dongmei He evaluated long-term results after LAP in nine growing children and concluded that the residual condyle continues to grow after LAP. This then decreases the amount of further facial asymmetry [25].

65.6.2 Arthroplasty with Ramus-Condyle Unit (RCU) Reconstruction *(Details Covered Under "Hard Tissue Interposition")*

Interpositional arthroplasty with RCU reconstruction is the procedure of choice in recent times. The procedure consists of:

(i) Removal of the ankylotic mass.
(ii) Reconstruction of the RCU may be considered from amongst any of the following in costochondral graft, coronoid process graft, distraction osteogenesis (DO), total alloplastic joint replacement.

Early postoperative exercises and appropriate physiotherapy are essential to prevent re-ankylosis, adhesions, and soft tissue contracture and to regain normal function of the muscles. Dynamic mouth opening exercise initiated in the immediate postop period by achieving pain control using local infiltration of bupivacaine. Dynamic mouth exercises would have to be continued for at least 6 months after surgery.

65.7 Soft Tissue Interpositional Materials (Video 65.1)

65.7.1 Temporalis Myofascial Flap (Fig. 65.8d, e)

Historically, it has been the most commonly used material for interpositional arthroplasty as it is simple in technique and in the vicinity of the original area of surgery. An inferiorly based pedicled composite (fascia and muscle), temporalis myofascial flap is raised supraperiosteally which is finger shaped and about 5 × 2 cm. The flap is taken either over/under the zygomatic arch and sutured medially and posteriorly. However, its potential disadvantages include an extended incision, temporal hollowing, increased chances of facial nerve injury, inability to be used again in cases of re-ankylosis, and myofascial pain secondary to muscle flap compression.

Albert and Merril described the use of a posterior temporalis myofascial flap to prevent a visible anterior flap hollowing [26]. Pogrel and Kaban used an axial patterned temporalis myofascial flap, based on a branch of the middle temporal artery [27].

65.7.2 Dermal Fat Graft (Fig. 65.8a, b, c)

The abdominal dermal fat graft is harvested from the suprapubic area used an elliptical incision of around 7 × 3 cm. The fat is then de-epithelized to procure a volume of 6–20 ml. About 20–30% excess is taken than the actual requirement. The graft is folded onto itself with the dermis surfaces apposed.

It can be procured quickly and easily with a hidden scar. It is easy to sculpt into the gap after ankylosis release. Minimal heterotopic calcification is the advantage of dermal fat graft. However, since this is a non-vascularized graft, it may be prone to resorption.

Dimitroulis presented his study on dermal fat grafts. After a mean follow-up of 41.5 months, only 1 out of the 13 joints reported recurrence of ankylosis [28]. Thangavelu presented a review of eight ankylosed joints treated using full-thickness skin subcutaneous fat grafts and concluded that they were safe and effective [29].

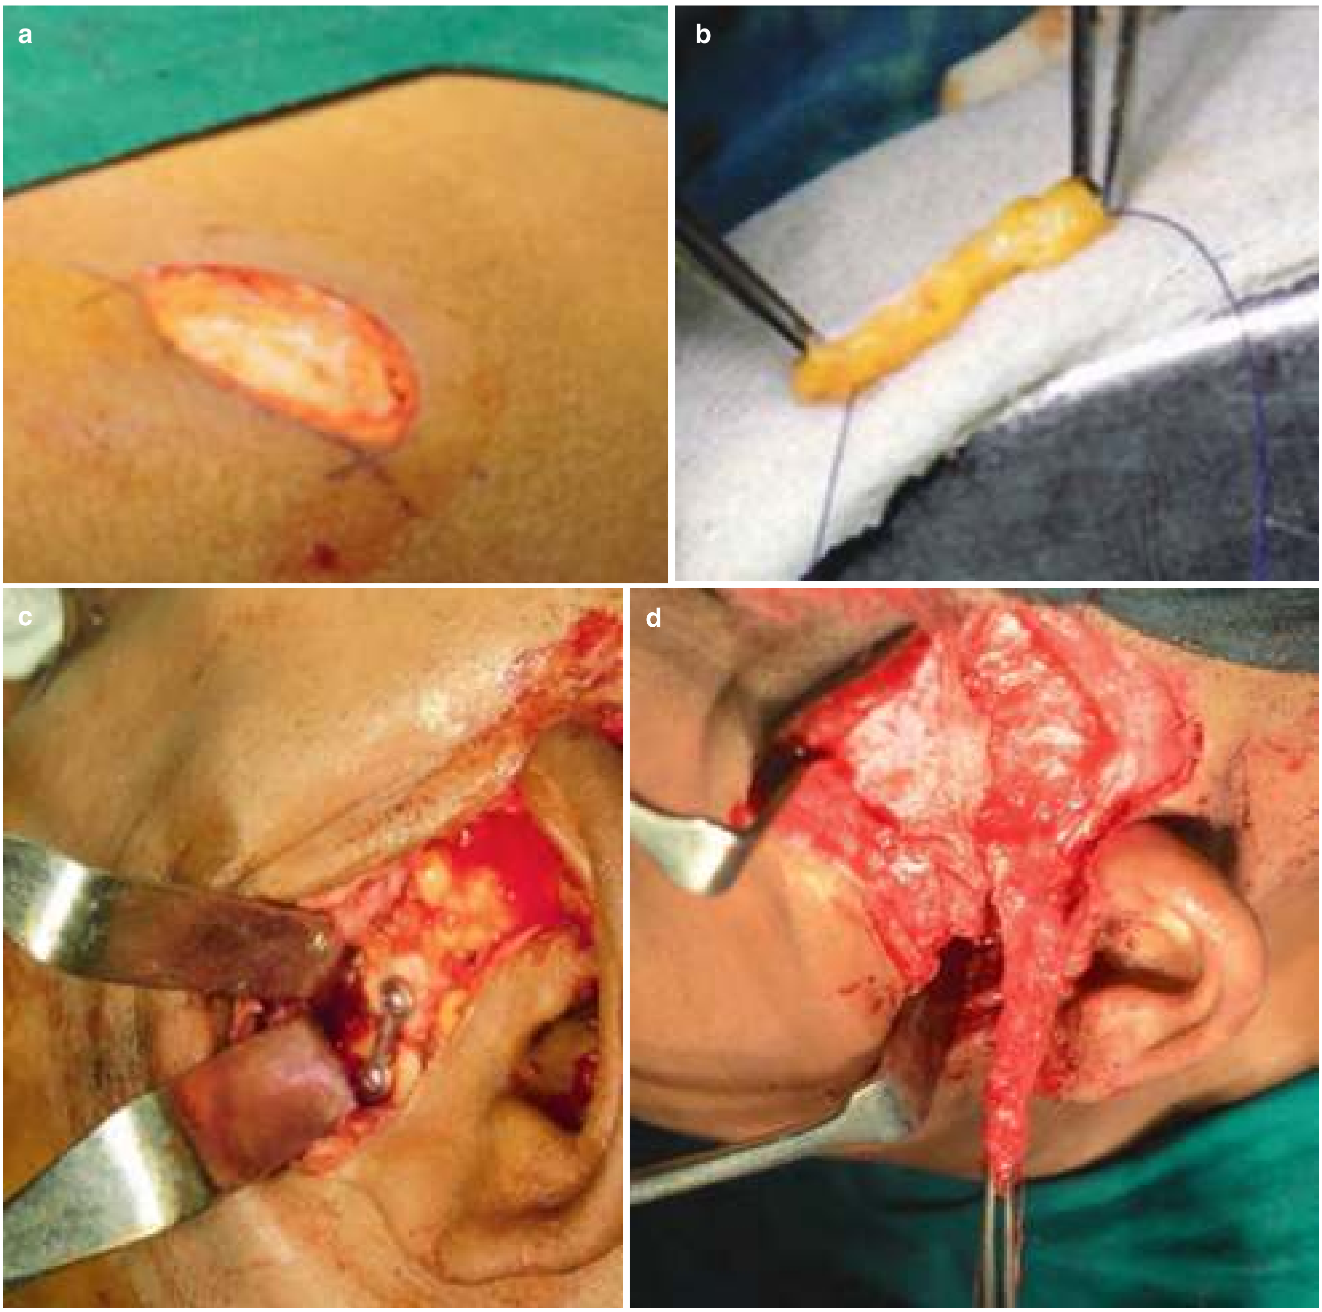

Fig. 65.8 (**a**) Abdominal fat graft donor site and (**b**) harvested graft, (**c**) abdominal fat graft in place, (**d**) harvested temporalis flap, (**e**) temporalis flap in place, (**f**) maneuver for harvesting buccal fat pad, (**g**) harvested buccal fat pad

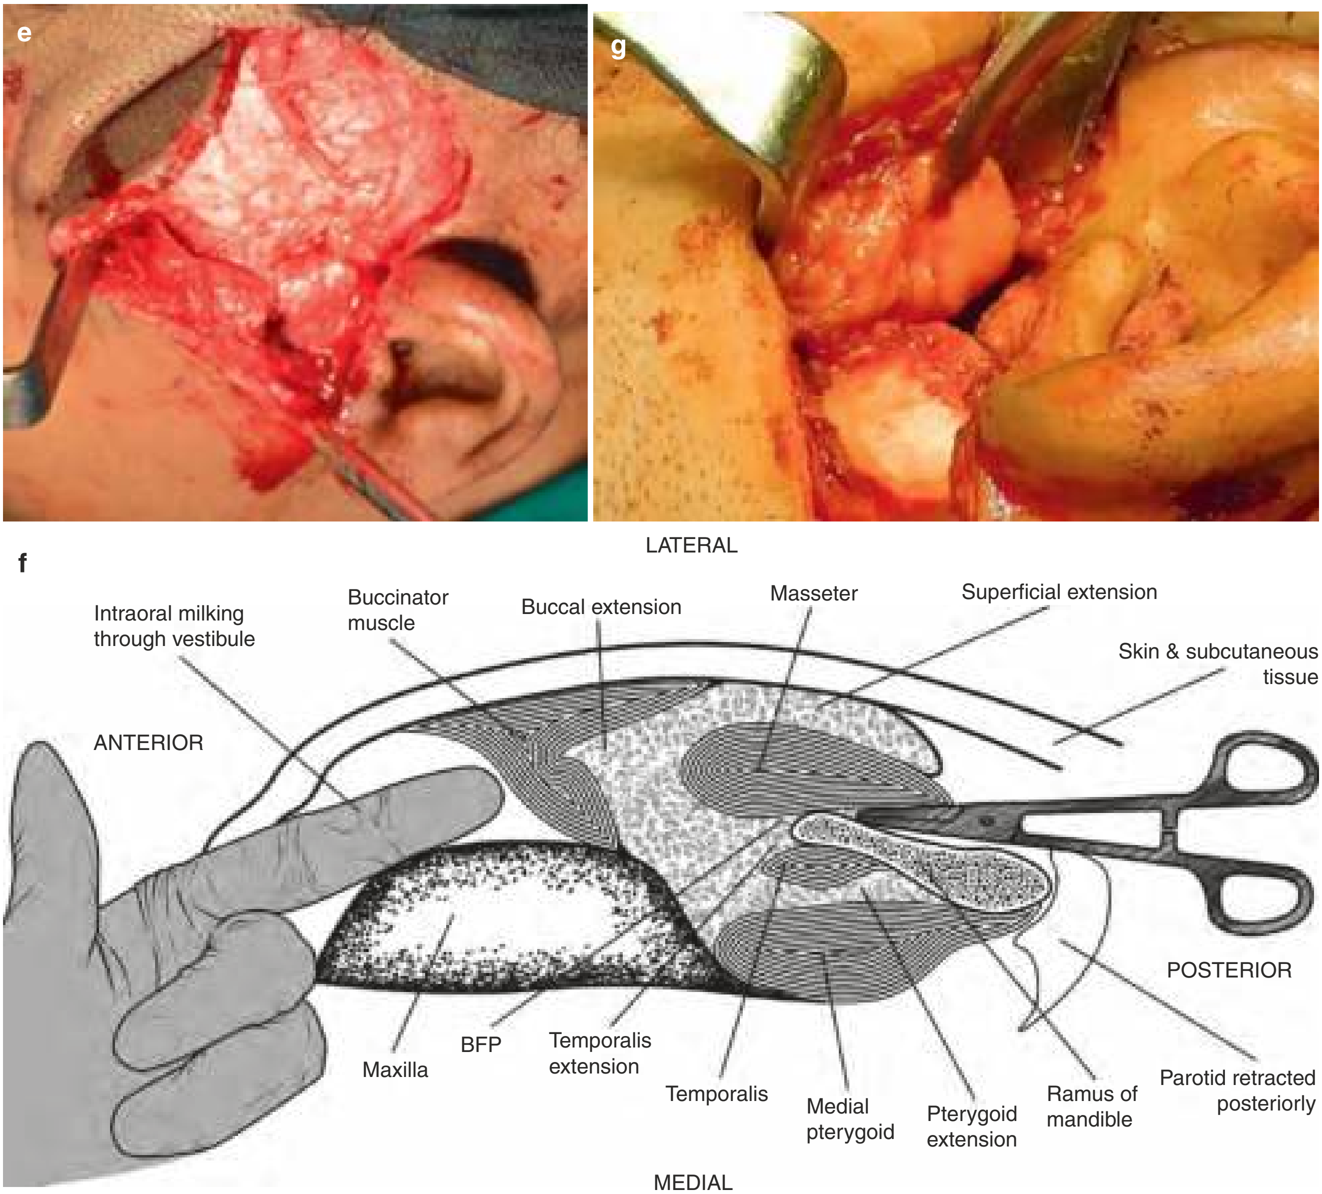

Fig. 65.8 (continued)

65.7.3 Buccal Fat Pad Graft (BFP) (Fig. 65.8f, g)

After the coronoid process is removed, dissection maybe performed along the anterior border of ramus. The main part and temporal extension of buccal fat pad are in close approximation to the coronoid process and tendon of the temporalis. Thus, incising through the periosteum and fascial envelope of BFP at the anterior most edge of the coronoid stump/superior most stump of anterior border of ramus exposes the yellowish buccal pad of fat.

Further blunt dissection is performed to herniate the BFP into the defect with a little teasing and simultaneous milking of maxillary buccal sulcus intraorally near second and third molar region. The main advantage is that its vascularity would maintain the volume of fat for a longer duration with minimal resorption.

Gaba et al. prospectively assessed the fate of BFP following interpositional arthroplasty in 23 joints. In 18 cases, BFP was viable even after 1 year [30]. Refer Chap. 24 for detailed anatomy of the Buccal fat pad.

65.7.4 Amniotic Membrane

The amniotic membrane, being a natural biologic entity, prevents inflammation, reduces scarring, and promotes healing and re-epithelialization. It also has pluripotent, non-antigenic properties. Akhter M. et al. used gamma radiation sterilized and freeze-dried amniotic membranes in 13 patients of TMJ ankylosis and showed that it prevented recurrence of ankylosis [31].

65.7.5 Auricular Cartilage

Parko in 1973 first published the use of aural cartilage to replace the meniscus. The biggest advantage of auricular cartilage graft is that it can be harvested from the same surgical field, remains viable and inert and takes the shape of the glenoid fossa.

However, there are studies that have reported adhesions between the auricular cartilage graft and the condyle, leading to re-ankylosis.

65.8 Hard Tissue Interpositional Materials (RCU Reconstruction)

65.8.1 Rationale for RCU Reconstruction

The goal of RCU reconstruction in TMJ ankylosis includes restoration of ramal height. This not only avoids occlusal discrepancies and deviation on mouth opening in unilateral cases but also anterior open bite in bilateral ankylosis. It also provides enough bone stock for future jaw corrective surgeries. The RCU may not contribute as much to facial aesthetics but impacts function greatly. In cases where RCU has not been reconstructed, the jaw deviates laterally when opening the mouth. When closing the mouth, tangential rather than vertical striking occurs on the occlusal surfaces, making mastication difficult.

Most importantly, in bilateral TMJ ankylosis after gap arthroplasty without RCU reconstruction, there are increased chances of OSA because the ramus falls back due to lack of posterosuperior stop. Also, it may be possible that restoring normal jaw movement and a symmetric mandible will allow future soft and hard tissue development. This would probably lead to decrease in facial asymmetry by giving as near normal anatomy as possible by restoration of growth spurts (Moss's functional matrix theory).

65.8.2 Options, Techniques, Advantages, and Disadvantages

65.8.2.1 Ankylotic Mass (Fig. 65.9a)

The ankylotic mass is recontoured and utilized to reconstruct the RCU and thereby restore the mandibular ramal height. All neocondyles after RCU reconstruction are fixed into position with miniplates/screws in the new glenoid fossa just 2 mm short of the soft tissue interpositional material after placing the patient into intermaxillary fixation (IMF).

R. Gunaseelan excised the ankylotic mass, recontoured and reimplanted it, and used it successfully for three cases of condylar reconstruction [32]. However, only if the ankylotic mass is resected as a whole (which poses greater risk to middle meningeal artery) can it be recontoured in an adequate size to reconstruct the RCU, hence the difficulty in routine use.

65.8.2.2 Coronoid Process Graft (Fig. 65.9b)

Khadka and Hu first reconstructed RCU using the coronoid process [33]. Reshaped, the coronoid process provides good bone of adequate quality and quantity to reconstruct the RCU. Its membranous origin leads to lesser resorption. Also, a secondary donor site is not utilized. However, as the coronoid is a nonvascular graft, there does exist a very real possibility of its resorption.

Gagan Mehta and Shadab Mohammad conducted a study on 20 cases and reported that there did occur resorption of the coronoid in most of the cases. However, that did not change mandibular function and occlusion [34].

Another method of using the coronoid process is to use it as RCU with its attachment to the temporalis kept intact. Most of the attachment may be stripped of, and only the anterior part of temporalis may be kept attached to the tip of the coronoid. It may cause less resorption as it would be a pedicled graft. Yiming Liu studied 48 patients and compared free vs. pedicled coronoid process grafts and proved that pedicled grafts showed less resorption on prolonged follow-up [35].

65.8.2.3 Costochondral Graft (CCG) (Fig. 65.9c)

Poswillo popularized the procedure for using CCG for TMJ ankylosis in 1987. In unilateral cases, CCG may be taken from the fifth rib using a submammary incision. If required on both the sides, alternate ribs, i.e., fifth and seventh, are used [36].

CCG has various benefits including its growth potential, its biological compatibility and the fact that it can remodel to form a new condyle. However, donor site morbidity, resorption or excessive growth on the treated side, and inability to catch up with the speed of growth on the normal side are its potential demerits. Perrott and Kaban [16] described two types of overgrowth—(a) linear overgrowth causing an

Box 65.1 Technical Tip

To maximize the chances of survival rate of CCG, the following techniques may be followed: meticulous dissection of periosteum and perichondrium, harvesting alternate ribs to prevent pain and pleural tear, retaining intact periosteum and perichondrium at costochondral junction, sectioning the chondral before the osseous part to reduce fracture at the costochondral junction, and only 2–3 mm chondral portion to prevent overgrowth.

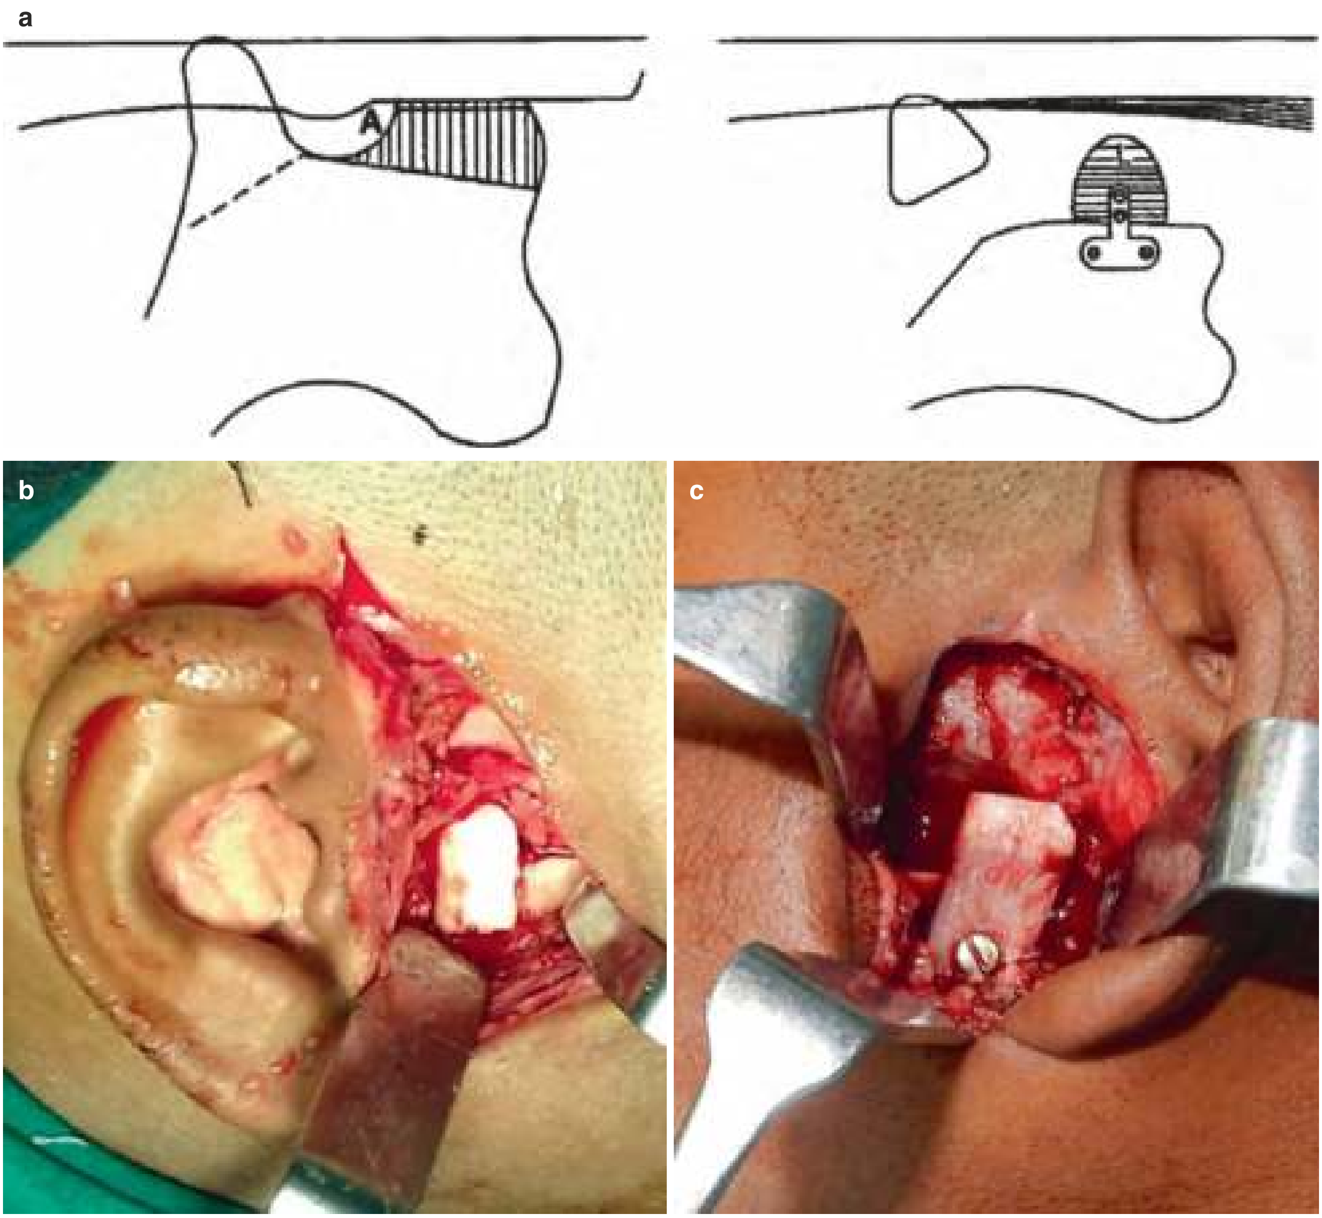

Fig. 65.9 (**a**) Ankylotic mass, (**b**) coronoid graft, (**c**) costocondral graft

asymmetric or bilateral prognathism and (b) tumor-like overgrowth causing re-ankylosis.

There are various controversies regarding which ribs and how much cartilaginous cap should be taken, how to fix, whether post-op IMF is required or not, and resorption vs. hypertrophy of the graft. Jean Salash reported that out of 72 cases, excessive growth occurred in 54% and equal growth occurred in 38% [37].

Hence, CCG may be used for RCU reconstruction in children less than 8 years of age with facial asymmetry. The justification is that it may help in growth. However, if it overgrows, the overgrowth may be treated like condylar hypertrophy, and the superior 2–3 mm may be cut off.

Children less than 8 years but without facial asymmetry would probably not need a growth impetus, in which cases, a coronoid graft would be sufficient. In children more than 8 years of age, vertical ramus osteotomies may be used to recreate the RCU.

65.8.2.4 Ramus Osteotomy Pedicled Grafts (Fig. 65.10a, b)

Y. Liu [38] used the method of total (Vertical ramus osteotomy—VRO) and partial (L- ramus osteotomy—LRO) sliding osteotomy on the posterior border of the ramus for reconstructing the mandibular condyle in TMJ ankylosis.

The chances of bony resorption and graft failure of the newly reconstructed RCU are greatly reduced as this segment is a pedicled graft with attachment to the medial pterygoid muscle and periosteum and is not a free graft. Hence the height of the ramus is maintained. This also leads to adequate bone stock for further corrective surgeries if and when so required.

For the VRO, the cut is made in a vertical direction starting from the sigmoid notch to the inferior border of the mandible just lateral to the lingula and parallel to the posterior border of the ramus. While retaining an adequate amount of medial pterygoid, the proximal segment is pushed upward to recreate the RCU and plated in the new position. A small triangular chunk of bone just anterior to the osteotomy cut is resected to reshape the lower border and mandibular angle.

For the LRO, an L-shaped cut is made from sigmoid notch parallel to the posterior border of the mandibular ramus, just lateral to the lingula, till 10 mm above the angle of the mandible. The osteotomized segment is shifted upward and fixed with a mini plate creating a gap between the osteotomized segment and remaining mandibular angle. The coronoid process on the affected side is resected, recontoured, and fixed in that gap with another mini plate. The upper part of the ramus is then reshaped like a condyle.

LRO and VRO differ in the residual height of the ramus left after ramal osteotomy. In LRO it is retained, and in VRO it decreases due to the removal of the step at the inferior bor-

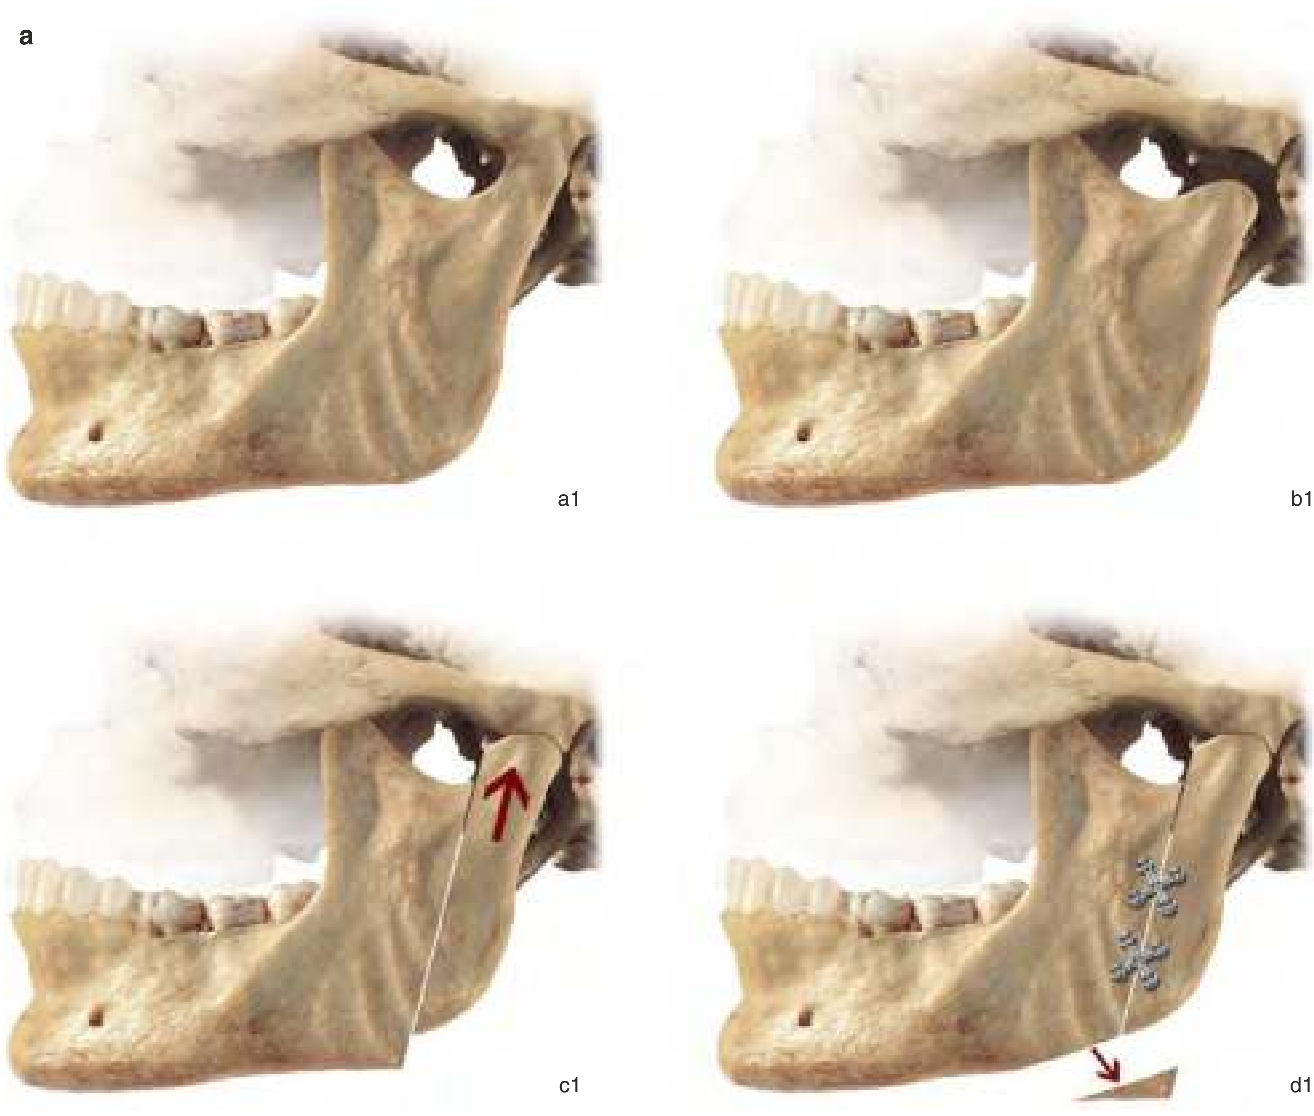

Fig. 65.10 (**a**) V Ramus osteotomy, (**b**) L Ramus osteotomy [38]

Fig. 65.10 (continued)

der. Thus, VRO may be performed in cases where a pronounced antegonial notch is present.

However, these osteotomies cannot be performed in patients less than 8 years because as observed on CBCT, the amount of bone behind the lingula is generally not enough to osteotomize the posterior border of the ramus.

65.8.2.5 Transport Distraction Osteogenesis (Fig. 65.11a, b) (Refer Chap. 87)

In multiple operated patients, scar tissue forms with each surgery, which may affect angiogenesis due to limited diffusion. Thus, free autogenous tissue grafts, such as costochondral and coronoid grafts often fail in such cases. Hence, transport distraction osteogenesis is considered as an option for RCU reconstruction, especially in re-ankylosis cases in children. The same L osteotomy cut may be used to fix the distractor.

When RCU reconstruction is performed by transport distraction, it forms a fibrous/pseudo-disc by compressing the connective tissue between the transport segment and the glenoid fossa. This disk decreases the chances of re-ankylosis [39]. Sharma et al. in 2019 carried out neocondyle distraction in five patients and reported adequate mouth opening and functional movements in all patients. None of them reported re-ankylosis [40]. But a long-term follow-up study found that the height of these condyles was unstable. Also, these mandibles exhibited some degree of asymmetry [41].

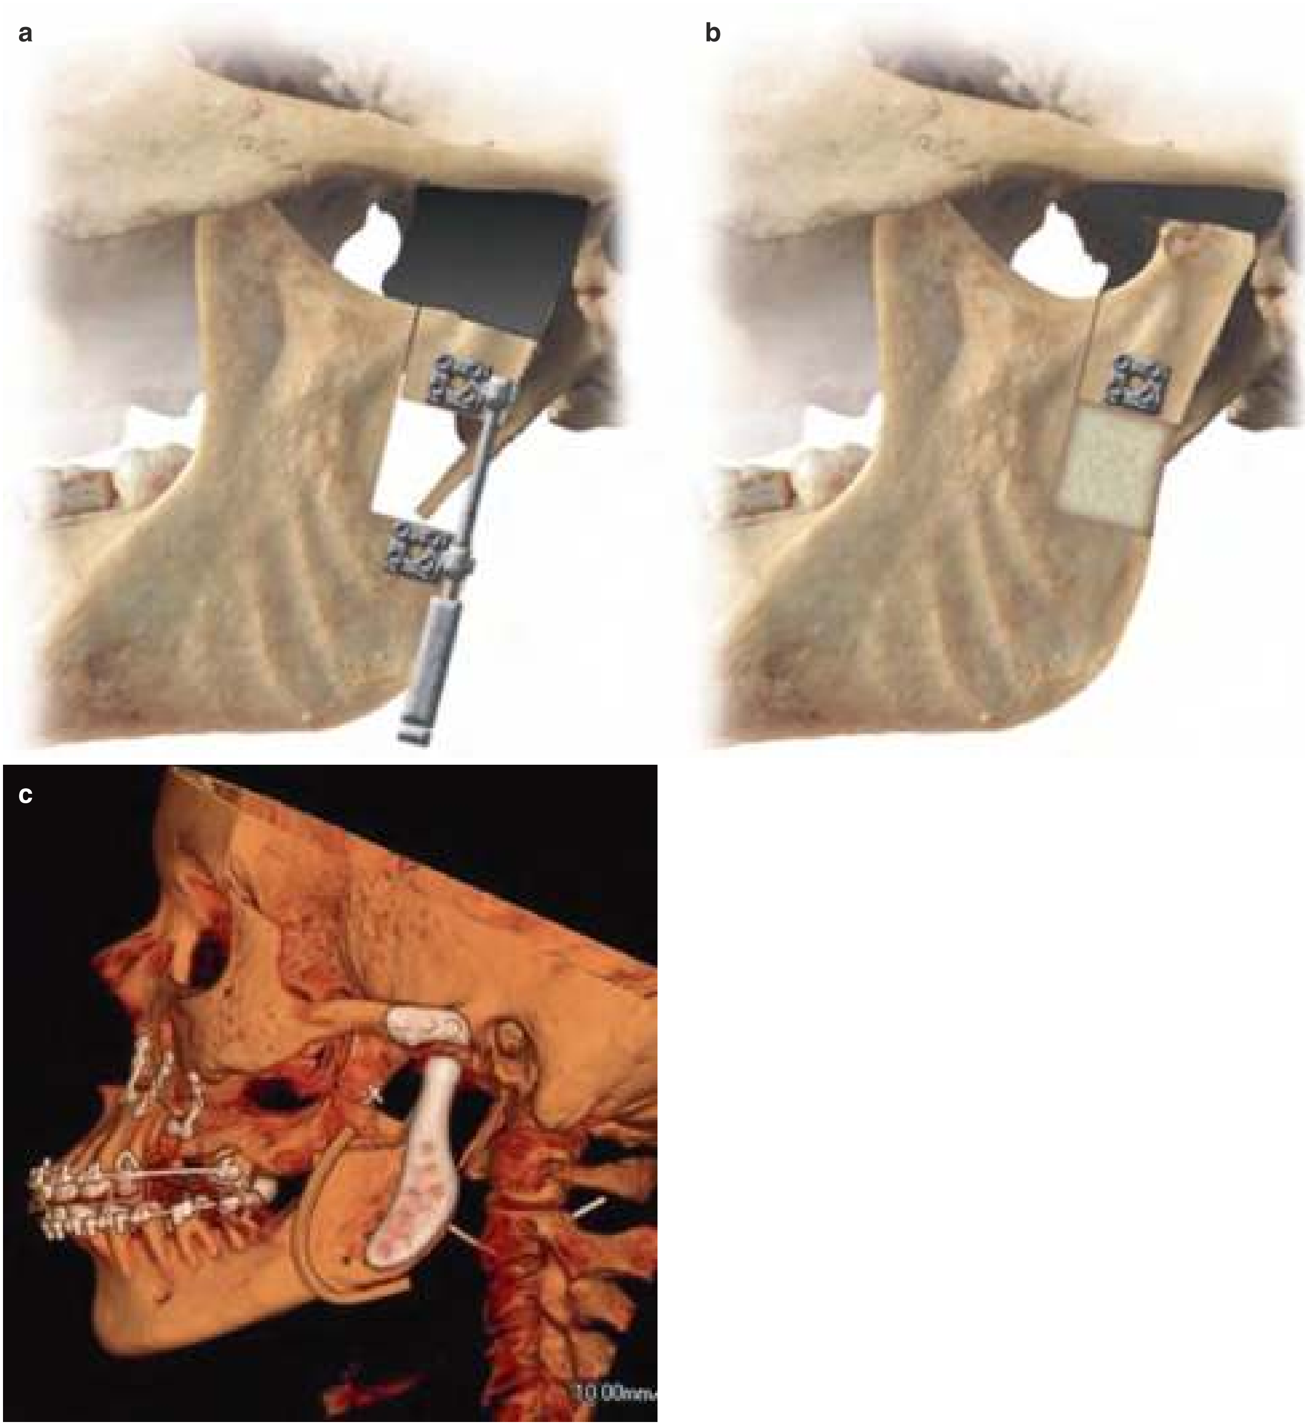

Fig. 65.11 (**a**) Transport distraction osteogenesis, (**b**) shows woven bone formation in place of callus in distracted gap, (**c**) alloplastic TMJ replacement with simultaneous release and OGS

65.8.2.6 Alloplastic Total TMJ Replacement (TJR) (Fig. 65.11c)

The alloplastic joint consists of a fossa component and a ramal component, as a stock or a custom-made prosthesis. Re-ankylotic scar tissue in an adult is best treated by total alloplastic TM joint replacement. Dongmei He and Yi Hui Hu reported that alloplastic TMJ prosthesis is a reliable method to treat recurrent TMJ ankylosis. It may be accompanied by bimaxillary osteotomies for simultaneous correction of secondary ankylotic deformity as well. Its distinct disadvantage is the fact that if used in children, it would need to be replaced [42].

Mercuri et al. [43] specified the indications of TJR (Box 65.2).

Based on all the above RCU reconstruction options, guidelines are proposed for technique of RCU reconstruction in various clinical situations (Table 65.3).

Box 65.2

1. Recurrent fibrous or bony ankylosis not responsive to the modalities of treatment which have been hitherto applied
2. Failed (bone and soft) tissue grafts
3. Loss of vertical mandibular height and occlusal relationship due to bone resorption, trauma, developmental abnormalities, or pathological lesions
4. Severe inflammation of TMJ involving damage to its structures and lack of response to other treatment methods.

Table 65.3 Guidelines for technique of RCU reconstruction in various clinical situations

	Situations		Technique	Justification
1.	<8 years	(a) With facial asymmetry	Costochondral Graft ± eventual high condylectomy	• Potential for growth • Treat overgrowth like condylar hypertrophy
		(b) Without facial asymmetry	Coronoid graft	• Potential for growth not required • Cannot do ramus osteotomy because of inadequate ramal width
2.	>8 years	(a) With prominent antegonial notch	Vertical ramus osteotomy	• Reduces antegonial notch
		(b) Without prominent antegonial notch	L-shaped ramus osteotomy	• Maintains height of ramus • Adequate ramal size
3.	Re-ankylosis	(a) Child	Ramal distraction	• Free graft will not take in scar tissue • Alloplastic joint will not grow
		(b) Adult	Total alloplastic TMJ replacement	• Best option for scarred tissue

Table 65.4 Treatment guidelines for different types of ankylotic deformities

Type I (presence of occlusal cant): treatment planning for both maxilla and mandible
1. Involved side is normal and other side is excess (**<6 mm deficiency**)
(a) Differential maxillary impaction (b) Mandibular ramus osteotomy (i) Sagittal split osteotomy (ii) Inverted L ramus osteotomy (c) ± Genioplasty
2. Involved side is deficient and other side is normal (**<6 mm deficiency**)
(a) Differential down fracture and bone grafting of maxilla (b) Mandibular ramus osteotomy (i) Sagittal split osteotomy (ii) Inverted L ramus osteotomy (c) ± Genioplasty
3. 6–8 mm discrepancy in maxilla **(6–8 mm in mandible)**
(a) Simultaneous maxillomandibular distraction
4. 6–8 mm discrepancy in maxilla (**>8 mm discrepancy in mandible)**
(a) Cant correction in maxilla (b) Mandibular distraction as per type II-4, 5, 6 (c) Simultaneous OGS with TJR
Type II: (with minimal occlusal cant) treatment planning for mandible alone
1. Mandibular ramus osteotomy 2. Genioplasty 3. Orthomorphic osteotomy 4. Orthomorphic distraction 5. Unidirectional distraction 6. Bidirectional distraction 7. Simultaneous OGS with TJR

65.9 Facial Deformity Secondary to TMJ Ankylosis

TMJ ankylosis leads to mandibular deformity of varying magnitude and morphology in the form of decreased ramus and/or body length, deviation of chin, retrognathic/microgenia, bird face deformity, and narrow PAS leading to OSA (refer Fig. 68.18). Hence, establishing a single set treatment protocol for all clinical situations is not possible. Table 65.4 is an attempt to classify and thereby establish treatment guidelines for different types of ankylotic deformities.

Surgical Techniques and Indications:

65.9.1 Osteotomies (Fig. 65.12a–c)

They are indicated for movements of about 6–8 mm. For maxilla, Le Fort osteotomies and, for mandible, sagittal split osteotomy or inverted L ramus osteotomy may be performed.

65.9.1.1 Le Fort I Osteotomy (Refer Chap. 69)

It allows correction in three dimensions including roll, pitch, and yaw. For vertical maxillary excess, differential maxillary

Fig. 65.12 (**a**) Le Fort I osteotomy, (**b**) sagittal split osteotomy (SSO), (**c**) inverted L ramus osteotomy (ILRO)

impaction may be performed, while for vertical maxillary deficiency, maxillary down fracture may be done along with bone grafting. Posterior maxillary height adjustments may also be required.

65.9.1.2 Sagittal Split Osteotomy (SSO) (Refer Chap. 68)

SSO is useful to differentially settle the occlusion according to the movement of the maxilla, as well as bring the retrognathic mandible forward. The procedure involves three corticotomies—the lingual horizontal, the buccal vertical, and the intermediate cuts. This osteotomy is generally done on the normal side in case of unilateral ankylosis. On the affected side, ramal contour and condylar anatomy distortions, reduced height of the ramus and steep mandibular plane angle make SSO difficult to perform.

65.9.1.3 Inverted L Ramus Osteotomy (ILRO) (Fig. 68.6)

ILRO can be better utilized for increasing the ramal height. This technique is advocated in cases which require significant counterclockwise movement to increase projection of the lower third of the face when the ramal anatomy is altered.

The cuts are placed using a submandibular and/or an intraoral approach, posterior and superior to the inferior alveolar canal. A horizontal cut is made above and behind the lingula and then joined to the vertical cut from the inferior border of the mandible.

65.9.1.4 Genioplasty (Figs. 68.29, 68.32 and 68.34)

Patients indicated for genioplasty have normal ramal height, functional occlusion, deficient or normal pharyngeal airway space, and chin deviation or retrusion up to a maximum of 10 mm, hence minimally deformed cases.

An extended genioplasty is performed with the osteotomy cuts extending up to the first molar on both sides. Advancement and translational movements in coronal and sagittal planes are carried out. Interpositional or onlay bone grafting may be done so as to achieve further symmetry wherever required.

Alloplastic chin implants made of PTFE, silicon, PEEK, or customized titanium are alternatives to the traditional genioplasty.

65.9.1.5 Orthomorphic Osteotomy

As opposed to conventional orthognathic surgery, an osteotomy used to restore morphology is termed “orthomorphic correction.”

Patients who may undergo orthomorphic osteotomies are the ones having normal ramal height, functional occlusion, deficient or normal posterior airway space, and chin deviation or retrusion up to a maximum of 10 mm, but this can be done only in cases of unilateral ankylosis. Most importantly, the primary indication for this surgery is the presence of soft tissue depression over the mandibular ramus on the unaffected side resulting in a contour defect. The osteotomy cuts are placed on the unaffected side.

Paul Salins [44] designed the osteotomy as an eccentric genioplasty extending from the body to the buccal cortex of the mandible. The cut changes from full thickness from the body to the sagittal buccal cortical cut in the ramus. The segment is then repositioned in such a way that it corrects the midline, the anteroposterior deficit, as well as the lateral morphological contour defects Fig. 65.13a.

65.9.2 Distraction Osteogenesis (DO)

Traditional bone grafting and orthognathic surgery have disadvantages—bony resorption, necrosis, donor site morbidity, limited advancement, relapse, etc.

Advancement of the mandible using SSO generally is restricted to a maximum of 10–12 mm. In ankylotic patients, the mandible requires much greater movements. Kohn et al. have reported high relapse after SSO [45], especially when used for advancement of mandible. Patients with ankylosis may report higher relapse rate than others. All the above issues may be dealt with DO.

Mandible lengthening with distraction leads to increase in bone stock of the mandible as well as proportionate and harmonious growth of the surrounding soft tissues. This bony regeneration is principally dependent on intramembranous ossification. Also healing and mineralization need adequate vascularity. Therefore, the incision to perform the surgery may be kept as limited as possible.

Early distraction may have beneficial effects, on the facial harmony as well as on the TMJ. If the anatomy and thereby function of the soft and hard tissues of craniofacial skeleton is established early in life, it may be possible to regain as near normal growth of the face.

Distraction in TMJ ankylosis patients with obstructive sleep apnea has led to decrease in snoring, daytime somnolence, Apnoea Hypopnoea Index (AHI), and oxygen desaturation episodes. The disadvantage however is that the device may be costly and needs to remain in situ for several months.

65.9.2.1 Simultaneous Maxillomandibular DO

This technique was first described by Molina and Monasterio in 1997 [46]. The first stage of surgery comprises of a Le Fort I osteotomy and a unilateral mandibular osteotomy. The distraction device is fixed to the mandible on the affected site. Under IMF, as the mandible moves forward, the maxilla comes downward, thereby correcting the cant and, simultaneously, the anteroposterior deficiency of the mandible. As this whole procedure is done under IMF, occlusion is maintained. The second stage comprises of removal distraction device and an additional genioplasty if required.

This is indicated when the occlusal cant is such that there is vertical maxillary deficiency but with presence of functional occlusion. If the mandible alone is distracted, it may lead to occlusal disasters, hence the need to keep the patient under IMF while the distraction is being performed.

65.9.2.2 Orthomorphic DO (Figs. 65.13a–d, 78.23, 78.24 and 78.25)

As laid down by Manikandan et al. [47] , the concept of orthomorphic distraction of the mandible is a modification of Paul Salin's morphometric osteotomy. It involves the distraction of mandibular basal bone to correct the asymmetry in all dimensions, despite a deficient soft tissue capsule. It also provides more movement than that attainable via osteotomy.

The osteotomy design is similar to the one used in conventional orthomorphic surgery. Once the osteotomized segment is mobilized, an internal/external distractor may be placed. Maintenance of the periosteal attachment at the pterygomassetric sling region brings about a pivotal movement at the gonion facilitating the lateralization and advancement of the osteotomized segment. The mechanics of the mandibular asymmetry correction is based on the law of parallelogram of vectors.

65.9.2.3 Genial Distraction

Distraction of the chin may be performed either in isolation or simultaneously with ankylosis release. A case report on the latter has been published by Gunaseelan et al. [48] in 2007 wherein an extended genioplasty osteotomy was performed and external distractors placed and activated. They suggested that simultaneous genial distraction and arthroplasty may be performed in adults, as the mandible is no longer growing.

This is advocated in adults because they have functional stable occlusion. Therefore, distraction of the basal bone of the mandible without distracting the occlusion bearing segment will only correct the mandibular deformity and the OSAS, but not interfere with the occlusion. However, in children, dental relationships due to mandibular hypoplasia may be very severe and therefore this may not be the treatment of choice. Also, the eruption of the permanent teeth may interfere in osteotomy used in this technique.

Genial distraction is an option to gain larger advancements, although may be limited by an unsightly labiomental fold as advancement increases.

65.9.2.4 Unidirectional DO (Fig. 65.14a–i)

This procedure is indicated in patients with near normal ramal height but deficient corpus length, chin retrusion and deviation greater than 10 mm, and presence of mild to moderate OSA.

For deficient corpus length, osteotomy cut is placed in the body region, generally between second premolar and first molar or between first and second molars. If the patient has not undergone presurgical orthodontics or if distraction is being performed pre-ankylosis release, the cut depends on the distance between the roots of the teeth and presence of impacted teeth. Maria B. Papageorge [49] advised that the cut should be placed in such a manner that the integrity of mandibular angle is maintained as it forms a very important aesthetic component of the face.

According to Samchukov, the vector of distraction should always be parallel to the occlusal plane, regardless of the direction of the osteotomy, to prevent anterior open bite deformity. Kunz et al. [50] has stated it to be a well-known complication of mandibular distraction. Unidirectional distraction is contraindicated in patients exhibiting vertical growth pattern. This is because unidirectional distraction in patients with a steep mandibular plane angle and substantially deficient ramal height may again lead to anterior open bite.

Internal distraction has a definite edge over external distraction in terms of aesthetics and patient compliance. However, chances of postoperative infection are greater with internal distractors. Also, they have limitations in terms of the amount of distraction possible.

Unidirectional distractors may be placed through either intraoral or extraoral approach. Surgical splints may be prepared on 3D-printed models preoperatively. Upon exposure of the bone, these premarked splints are positioned. Using them as guides, corticotomy sites and sites for distractor pins/screws are marked. Buccal corticotomy and lower border full-thickness cuts are placed. Distractor is fixed and the osteotomy cuts are completed. In case impacted teeth are in the way of the osteotomy cuts, they may be removed intraoperatively itself.

The distractors are activated to check completeness of the cuts and then brought back. Latency period is of 5–7 days, depending on the patient's age. Larger movements require larger periods of consolidation to prevent relapse.

After distracting for around 8–10 days, shape of the regenerate may be changed (callus molding) during the distraction process. Complications may include infection, tooth fracture, change of vector, loosening of pin, anterior open bite, and parotid fistula, but all can be managed conservatively. Callous molding can take care of occlusal discrepancies to a large extent, except that if there is absolutely no overjet. However, with some amount of overjet present, differential distraction may be done on the superior and inferior borders of the mandible. Herein, with the help of callous molding using IMF screws/eyelets and elastics, the inferior border may be distracted more than the superior border.

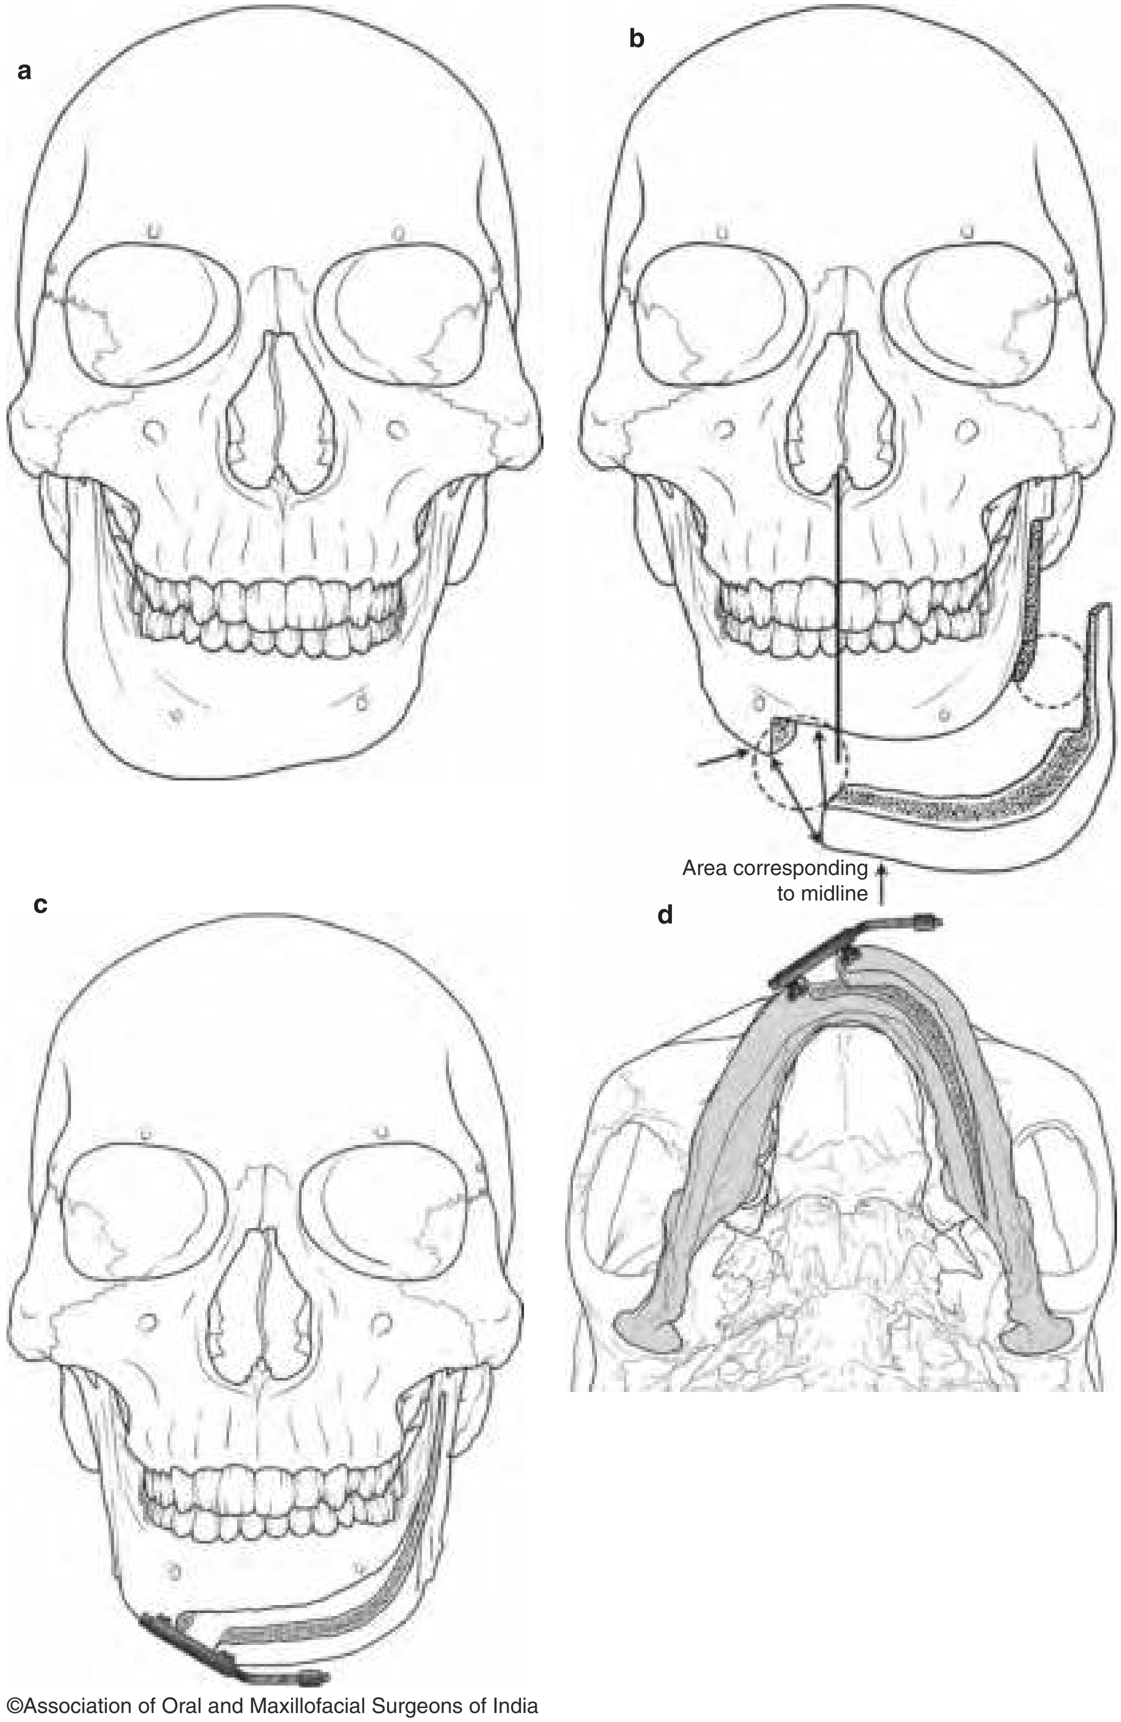

Fig. 65.13 (**a, b**) Orthomorphic osteotomy, (**c, d**) orthomorphic distraction

Fig. 65.14 (**a**) Uniplanar distractor fixed on the 3D stereolithographic model with osteotomy cut marked, (**b**) preoperative lateral cephalogram, (**c**) post-distraction lateral cephalogram, (**d**) preoperative frontal view, (**e**) post-distraction, frontal view (**f**) preoperative lateral view, (**g**) post-distraction lateral view, (**h**) six-month follow-up lateral, (**i**) six month follow-up frontal

Sometimes there may be occlusal locking thereby preventing the distracted regenerate from moving in the direction that is required. A composite block may be prepared on the tooth to first disocclude it and thereby get distraction in the favorable direction. Later occlusion may be regained by callous molding. The molding of the regenerate substantially reduces the time required for post operative orthodontics.

65.9.2.5 Bidirectional DO (Fig. 65.15a–g)

Bidirectional distractors are indicated for patients with severely shortened ramal height as well as corpal (body) length, requiring vertical as well as horizontal components of distraction. They are also indicated in cases with increased mandibular plane angle as well as for patients with moderate to severe OSA.

Surgical splints are prepared on 3D-printed models. Upon exposure of bone through a submandibular incision, two osteotomy cuts are placed on either side. One osteotomy cut is placed on the ramus and the other in the body region on either side of the angle, keeping the intermediate segment between 2.5 and 3 cm to avoid avascular necrosis. The device is secured to the mandible with six percutaneous pins (Schantz' pins)—one pair each at the ramus, angle, and corpus. The same procedure may be used for internal distractors as well.

The osteotomy site depends on position of teeth, lingula, mental foramen, and size of the intermediate segment. Vector of horizontal distraction should be parallel to occlusal plane, and vector of vertical distraction should be parallel to posterior border of ramus. In bilateral cases, horizontal and vertical components of either side should be parallel to each other. A 2–3 mm overcorrection is generally advisable. Callous molding may be used for occlusal adjustments. A single osteotomy cut may however be used for 3D or multivector distractors, thereby considerably reducing the surgical difficulty as well as the intraoperative time. Their main drawback is their prohibitive cost.

65.9.2.6 Impact of Mandibular DO on OSA

The ankylotic retruded mandible has an inefficient genial muscular apparatus as well, thereby causing retroglossal airway obstruction, therefore, OSAS. Mandibular advancement

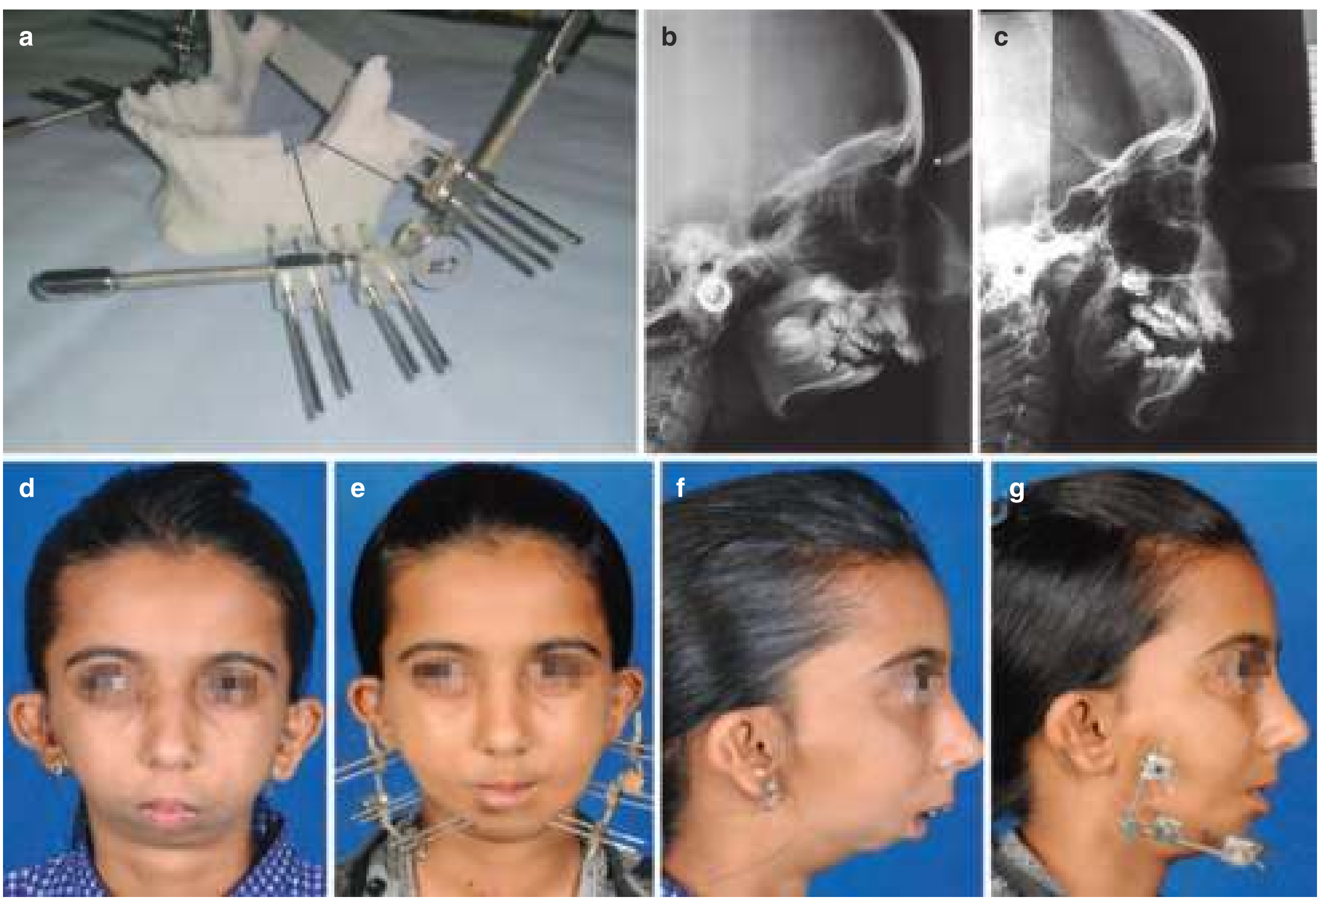

Fig. 65.15 (**a**) Biplanar distractor fixed on the 3D stereolithographic model with osteotomy cuts marked, (**b**) preoperative lateral cephalogram, (**c**) post-distraction lateral cephalogram (marked increase in PAS can be appreciated) (**d**) preoperative frontal view, (**e**) post-distraction frontal view, (**f**) preoperative lateral view, (**g**) post-distraction lateral view

in such cases has shown 97% success in pediatric and 100% success in adult patients. Decrease in OSAS may be evaluated by an AHI less than 50% decrease in the AHI with a near normal peripheral oxygen saturation.

65.10 Sequence of Release and Deformity Correction

OSA, in terms of AHI and PAS, is the principal factor that determines the sequence of release and deformity correction, i.e., whether to release first or distract first (refer Chap. 71 on OSAS and Figs. 71.8, 71.9, 71.10, 71.11, 71.12, 71.13 and 71.14).

Single-Stage vs. Multistage Procedure:

Treatment protocols can generally be categorized into single-stage or multistage treatments. Single-stage treatments institute ankylosis release and correction of secondary deformities (in the form of maxillary and mandibular osteotomies or distraction) all together. In the multistage protocol, ankylosis is released, and deformities are corrected in different stages.

65.10.1 Multistage Surgical Treatment

Severe secondary deformities are candidates for multistage procedures as a single-stage surgery may cause severe malocclusion. Correction of the same would require unrealistic amount of tooth movement.

Advantages: The multistage protocol is generally better for patients with significant medical comorbidity. This is so because a single-stage procedure obviously demands greater surgical time, thereby increasing the intraoperative risks. Multistage procedures facilitate early postoperative physiotherapy and, thus, a more stable postsurgical outcome. Also, the relapse monitoring is easier.

Disadvantages: Multiple surgeries, increased cost, and patient compliance issues

65.10.1.1 Multistage with Ankylosis Release First

According to López et al. [51], mandibular distraction should be performed after ankylosis release, as only then would be complete growth potential of the mandible be known. Releasing the ankylosis first would ensure adequate food intake, preparing the patients for subsequent, more complex surgeries. Also, surgeons could then formulate customized treatment plans based on individual clinical requirements and thereby provide more accurate correction of the deformity.

65.10.1.2 Multistage with Distraction First

Some surgeons recommend that distraction may be first used to restore the length and projection of the mandible. Later arthroplasty may be followed by orthognathic surgery to obtain mouth opening and settle the occlusion.
Advantages: The mandibular bone deficiency and the airway volume are both increased simultaneously. The subsequent intubation is much safer. Secondly, for patients with OSA, this treatment sequence reduces the incidence of postoperative airway issues—if ankylosis is released first, as the mandible falls back specially in bilateral cases, the already reduced airway space then gets further reduced, requiring reintubation or emergency tracheostomy. This incident can be avoided if distraction proceeds release.

65.10.2 Single-Stage Surgical Treatment

Patients with mild to moderate dental and skeletal deformities are ideal candidates for single-stage procedures. The minimal malocclusion may be treated by orthodontics alone. In these such cases, ankylosis release along with facial aesthetic surgeries which do not involve the occlusion may be performed, e.g., genioplasty, mandibular recontouring, and alloplastic implants.

Advantages: This corrects the restricted mouth opening as well as the secondary deformity simultaneously and avoids further surgeries. It provides low cost, immediate satisfaction, particularly in patients with psychological issues, and mild OSA.

Disadvantages: Maxillomandibular fixation often required after orthognathic surgery interferes with postoperative mouth opening exercises and therefore increases the chances of re-ankylosis. In case of internal distraction devices, there still arises the need for a second surgery to remove it. Also, the effect of distraction may be unsatisfactory because of the unstable condyle—if the osteotomy is placed in the ramus, the proximal segment may go up into the gap created after ankylotic mass removal, cause loss of vector and thereby re-ankylosis. Thus, to prevent this complication, while performing concomitant release and distraction, osteotomy cut may be placed only anterior to the angle, in the body region.

Another potential complication is the interference between physical exercises and distraction. A pseudo-joint may be formed in the callus area when the patient exercises, with the mouth opening force being directed toward the callus instead of the newly released joint. To prevent this complication, intensive active mouth opening exercise with wooden sticks/heisters may be started from postoperative day 1 itself. Mouth opening exercise from day 7 onward, i.e., once distraction is started, should exclude the use of the above.

65.10.2.1 Single-Stage Release with Orthognathic Surgery (OGS)

As mentioned earlier, in patients that exhibit mild dental and skeletal deformities, aesthetic surgeries not involving the tooth-bearing segments may be performed.

For the patients with moderate skeletal deformities, SSO along with ILRO and bone grafts may be used to lengthen the affected ramus. If necessary, Le Fort I osteotomy may be used to correct the occlusal cant in unilateral cases or bring the posterior maxilla down in bilateral cases.

Songsong Zhu [52] performed a study on 27 adult patients who underwent simultaneous ankylosis release and correction of secondary deformity as a single surgery. No relapse occurred.

Yi Hui Hu [42] studied 11 patients where CAD/CAM technique was utilized as a guide to determine level of removal of ankylotic mass and placement of TMJ prosthesis. Simultaneous Le Fort I osteotomy was performed in two patients guided by digital templates. Results showed that alloplastic TMJ prosthesis is a reliable treatment for recurrent ankylosis. The CAD/CAM technique produces accurate therefore stable results.

Many cases would require a custom-made prosthesis, typically fabricated with a stereolithographic model. Ryu et al. in 2016 reported a case where bilateral TM joints were replaced with a custom-made TMJ prosthesis. Virtual surgical planning (VSP) and STL model simulation helped in placing the mandible in a new improved occlusal and aesthetic profile [53]. This has become a routine procedure now in adult patients, i.e., custom-made joints based on VSP along with simultaneous OGS.

65.10.2.2 Single-Stage Release with DO

Simultaneous interpositional arthroplasty with DO for TMJ ankylosis, apart from increasing the length of the mandible, leads to the correction of gross facial asymmetry and midline shift and provides space for eruption of hitherto unerupted teeth. It helps reduce treatment time and need for an additional surgery and also alleviates the need for second tracheostomy, if the fiberoptic intubation is not possible.

Only unidirectional distraction in the mandibular body (in patients with AHI 15–30) may be performed along with release. If bidirectional distraction is performed, after placing the arthroplasty cuts, if two more cuts are placed in the body and the ramus, there are increased chances of avascular necrosis of the segments. Thus, bidirectional distraction may not be performed along with release; it may be performed either pre- or post-release, unless a 3D distractor is being used.

Krishna Rao et al. [54] performed a study on six patients and concluded that simultaneous release with DO should be used to correct ankylosis with facial asymmetry and reported satisfactory cosmetic correction of deformities**.** Girish B Giraddi et al. [55] performed a similar study with nine cases and concluded that it not only corrects the facial deformity but also saves the trauma of a second difficult intubation**.**

Lopez and Dogliotti [51] in 2004 asked a pertinent question—“Is it reasonable to perform ankylosis release and mandibular distraction simultaneously without knowing which patients will be able to experience growth with time? In that case it would be necessary to predict growth to apply the exact amount of mandibular distraction for obtaining stable results.” This question can now be answered—in children, the only indications for simultaneous release with distraction would be moderate to severe OSA, with AHI 15–30 (however with normal ramal height) and extreme facial deformity causing issues with the child’s psyche.

65.10.2.3 Single-Stage Release with Genioplasty

Most literature till date has either been looking at ankylosis in isolation from facial asymmetry and has been dealing with only ankylosis release or facial deformity as staged events or has been looking at correcting one of the biggest facial deformities, all at one go. There is no middle path mentioned in literature wherein ankylosis and a substantial part of its related deformities can be corrected without the following problems—a supra-major surgery under general anesthesia, extremely expensive 3D-printed splints and alloplastic joint replacements, expensive and protracted orthodontics requiring multiple hospital visits from the underprivileged, undernourished patients living in far-flung areas, and long-term patient noncompliance for distraction. Also, if osteotomies are performed before the TMJ attains stability, surgical outcome may be less than satisfactory as related to aesthetics and occlusion.

A suggested solution for the above problem in adults with mild to moderate OSA is a single-stage surgery—ankylosis release by interpositional arthroplasty simultaneously with genioplasty. It would provide a one-step solution to restoration of function and reasonable aesthetics within a reasonable amount of general anesthesia time, no occlusal discrepancies, no compliance for distraction, and no need for orthodontics. Most importantly, it would not interfere with any other secondary corrective procedure later, if the patient so desires.

The author has conducted a study on 43 ankylosed joints & set forth single-staged treatment guidelines—ankylosis release, RCU reconstruction, and extended advancement centering genioplasty for increase in mouth opening, restoration of ramal height, and improvement in facial asymmetry as well as OSA. Average mouth opening at maximum follow-up of 20 months was 34.36 mm with no reported recurrence. Average increase in N perpendicular to Pog was 7.16 mm, average decrease in neck-chin angle and labiomental angle was 31.6° and 35.4°; respectively, average increase in PAS was 2.92 mm. Average 50% improvement of AHI was seen in all 18 patients who had OSA [56].

65.11 Guidelines for sequencing of release and deformity correction

65.11.1 In Ankylosed Patients: To Decide Regarding Distraction Pre-/Post-/Simultaneously with Release (Table 65.5)

- AHI >30: Children and adults—distract first
- AHI <15
  - Children
    - Release first
    - Simultaneous release and unidirectional distraction
  - Adult
    - Release first
    - Simultaneous release with/without joint replacement and osteotomies
    - Simultaneous release and unidirectional distraction
- AHI 15–30
  - Short ramus (requiring bidirectional distraction)
    Children and adults: distract first
  - Normal ramus (requiring unidirectional distraction)
    - Children: simultaneous release and distraction
    - Adults
      - Joint replacement with osteotomies
      - Simultaneous release with distraction

Table 65.5 Relation of Apnea-hypoapnea index with PAS

PAS (mm)	AHI	Rating
>8	<5	Normal
8	5–10	Mild sleep apnea
5–7	15–30	Moderate sleep apnea
<4	>30	Severe sleep apnea

65.11.2 In Released Patients: To Decide Regarding Type of DO

- Only body deficiency with normal Mandibular Plane Angle (MPA)—unidirectional distraction
- Body and ramus deficiency with steep MPA—bidirectional distraction
- AHI >30—bidirectional distraction
- Asymmetry of mandibular angles—one side unidirectional, one side bidirectional distraction
- Dysmorphic asymmetry: orthomorphic distraction
- Functional occlusion in adults with normal ramus: genial distraction

65.12 Unfavorable Results in TMJ Ankylosis Surgery (Table 65.6)

Table 65.6

1. Issues in primary surgery
(a) ***Incomplete appreciation of the extent of the deformity***   (i) Unilateral or bilateral   (ii) Length of the coronoid process
(b) ***Anaesthesia-related issues***   (i) Excessive bleeding during fibreoptic intubation   (ii) Emergency tracheostomy
(c) ***Intra- and immediate postoperative issues***
(i) Surgical mishaps   1. Nerve traction   2. Inadequate exposure of the bony block   3. Bleeding from pterygoid venous plexus   4. Injury to the internal maxillary artery
(ii) Failure to achieve adequate mouth opening
1. Ipsilateral joint release → ipsilateral coronoidectomy → contralateral intraoral coronoidotomy
(iii) Severe bradycardia on mouth opening
(iv) Postoperatively open bite after bilateral arthroplasty/coronoidectomy
(d) ***Intermediate and long-term issues following primary surgery***
(i) Re-ankylosis—reasons
1. Incomplete or inadequate primary release
2. Inadequate mouth opening exercises
(ii) Growth alterations of costochondral graft
2. Issues related to secondary surgery of deformities
(a) No control of movement of proximal segment
(b) Careful calculation of the vector

65.13 Conclusion

- Traditionally, TMJ ankylosis and its associated micrognathia have been treated in multiple stages. Rehabilitation of mandibular function, prevention of re-ankylosis, and promotion of mandibular growth have been the main aims of treatment. The treatment has now advanced from only ankylosis release to total joint replacement as well as facial deformity correction, all simultaneously as far as possible.

- The patient at the time of presentation itself is looked at holistically. A more nuanced decision tree for treatment planning is formulated, be it for release, new joint reconstruction, distraction, osteotomies, or the sequencing of release vs. facial deformity correction. The most critical deciding factor in the treatment planning is obstructive sleep apnea, and the key for successful treatment is appropriate planning at each stage.
- Therefore, just because in the past, we were releasing all ankylosis first and doing corrective surgeries later, we cannot continue doing the same; albeit neither can we distract all patients first because that is the latest fad. An extensive review of literature as well as the vast experience of the author has helped lay down guidelines for most clinical scenarios of varying magnitude of deformities in TMJ ankylosis.
- In a few patients, some degree of facial imbalance may continue to persist even after surgical interventions. Additional aesthetic surgery, such as malarplasty reshaping of the chin, angle and lower border of the mandible, may be required to achieve the best results [57].
- Since TMJ ankylosis is generally a disease of the underprivileged and socioeconomically backward strata of society, it should be noted that the deformity cannot be the only criteria to select the surgical procedure. Patient's preference, the treatment cost, and compliance also need to be taken into consideration. Some patients are more concerned about their mouth opening and aesthetics rather than their occlusal disharmony.

Acknowledgment I wish to convey my deepest thanks and sincerest gratitude to my resident Dr. Hrushikesh Gosai, without whose observations, comments, and technical expertise this manuscript would have not been possible. A mere word of thanks is not sufficient to express the unflinching support and inestimable aid of my staff Dr. Jigar, Dr. Utsav, and Dr. Bipin and my residents Dr. Hiral, Dr. Philip and Dr. Nisha during the preparation of this chapter. I would be failing in my duty if I did not recognize the contribution of my biggest teacher in TMJ ankylosis, my Ex-Hod Dr. Babu Parmar.

Disclosure Authors have no financial conflicts to disclose

65.14 Case Scenarios

Case 1 (Fig. 65.16a–h)

A 23-year-old male patient presented with unilateral right-sided bony ankylosis with retruded and deviated chin with body and ramal length near normal. So, the patient was planned for advancement centering genioplasty and onlay bone graft along with TMJ ankylosis release.

Case 2 (Fig. 65.17a–f)

A 14-year-old male patient presented with facial asymmetry secondary to TMJ ankylosis with moderate OSA. Cephalometric analysis revealed deficiencies in the length of the mandibular ramus and corpus of the right side and the corpus alone on the left side. So, he was planned for biplanar distraction on right side and uniplanar distraction on left side.

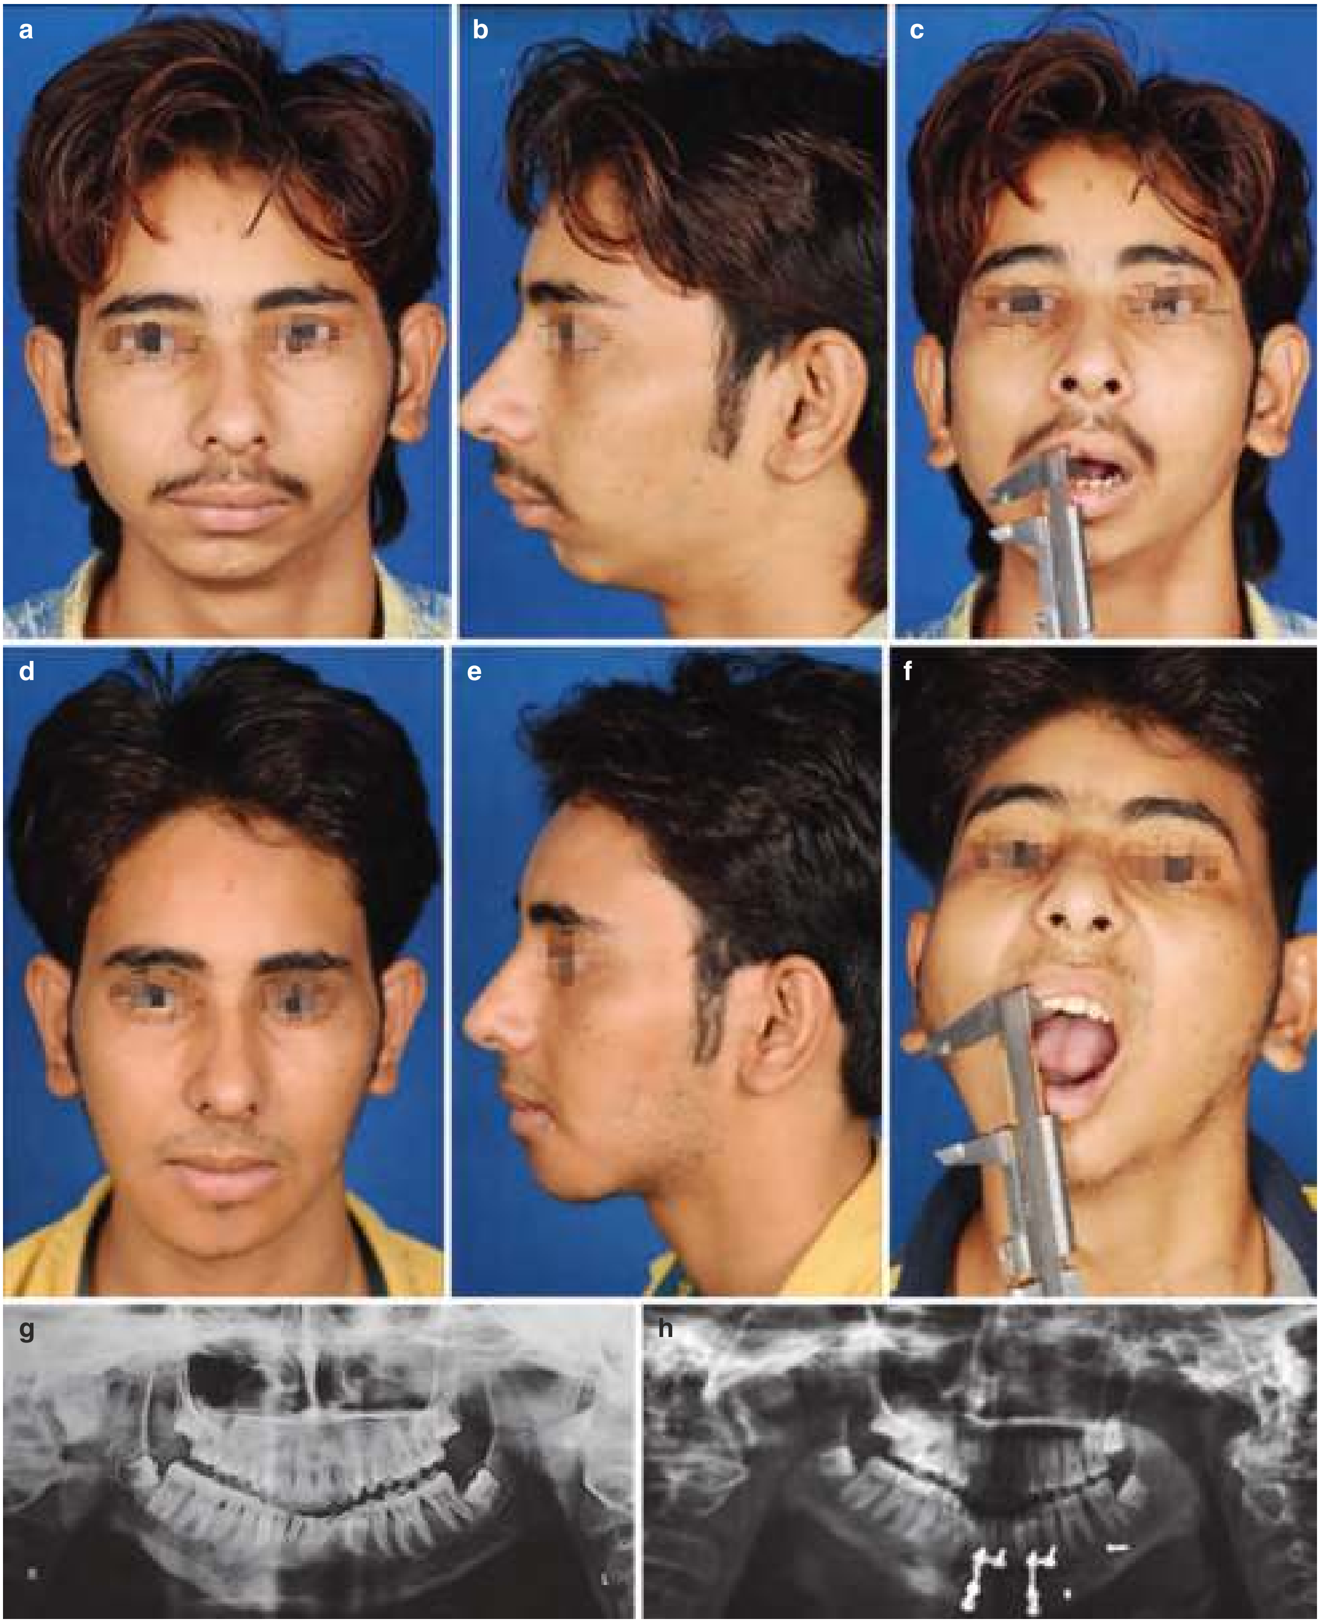

Fig. 65.16 (a–h) Case 1 Right side TMJ ankylosis (**a**) Preoperative frontal view, (**b**) preoperative lateral view, (**c**) preoperative mouth opening, (**d**) postoperative frontal view, (**e**) postoperative lateral view, (**f**) postoperative mouth opening, (**g**) preoperative orthopantomogram, (**h**) postoperative orthopantomogram (note the genioplasty and onlay bone graft fixations)

Orthognathic Surgery

66 Diagnosis and Planning in Orthognathic Surgery

Johan P. Reyneke and Carlo Ferretti

66.1 Introduction

Over the last four decades, the scientific foundations for the art of changing facial appearance and improving orofacial function through orthognathic surgery were laid, and the value of treatment to improve lives is undisputed. The main treatment objective is currently not limited to achieving short-term improved occlusal function but also enhanced facial aesthetics and an open airway. Orthognathic surgery requires the combined skills of the specialities of orthodontics and oral and maxillofacial surgery; however, there remain major limitations relating to the uneven geographical distribution of experienced dedicated clinicians and financial barriers to the correction of dentofacial deformities. The treatment of some malocclusions combined with mild skeletal disharmony is possible by orthodontic compensation of the dentition with compromised facial aesthetics. Borderline cases therefore require meticulous assessment before finally deciding on orthodontic treatment alone or a combination of orthodontics and surgery as treatment approach.

Most compromised treatments lead to suboptimal results such as:

- Dental instability
- Skeletal instability
- Poor facial aesthetics
- Airway problems
- Periodontal problems

Which treatment plan to adopt should be discussed with the patient (and perhaps the parents or spouse) and all the advantages and disadvantages of each approach explained. The decision may also be influenced by factors such as the orthodontist's experience, financial insurance cover, available surgical expertise, and the patient's attitude and preferences [1].

Patients with dentofacial deformities are treated with four prime goals in mind:

1. *Function.* Apart from establishing normal masticatory function, the clinicians should also consider other problems caused by an abnormal jaw relationship such as speech defects, sleep apnea, attrition of the teeth, periodontal problems, and temporomandibular joint problems.
2. *Stability of results*. Definitive orthognathic treatment is a change for life, and it is important to achieve dental and skeletal stability following treatment.
3. *Aesthetics.* Facial appearance is often the patient's main concern, but patients are often reticent to voice these concerns. However, the surgeon should resist the temptation to determine unilaterally what a patient's aesthetic concerns are but should encourage the patient to express these.
4. *Airway.* The impact of jaw malalignment (and its correction) on the patency of the upper airways is a relatively recent addition to the treatment considerations in patients with dentoskeletal malocclusion. The support of the retropharyngeal soft tissues is determined to a large degree by the position of the anterior osseous attachments. Inadequate support for

these soft tissues will contribute greatly to the development of sleep apnea especially as soft tissue laxity develops with aging. This consideration may influence treatment decisions particularly in Class III malocclusion. For example, we may be loath to unduly setback a mandible in a young adult due the future potential for sleep apnea development. Thus, in double jaw surgery, a treatment plan that favors greater maxillary advancement or in a single jaw surgery case a maxillary advancement may be preferable to a mandibular setback. These considerations add a further layer of complexity to the treatment algorithm as airway considerations may mean a compromise of aesthetics and vice versa [2, 3].

66.2 Systematic Aesthetic Facial Evaluation

The clinical assessment of the face is the most valuable of all diagnostic procedures and should be performed in a systematic fashion. The facial examination should start at the first instant a clinician meets the patient and continues during the initial informal discussion. During this period the patient is not self-aware, and facial function and features will be at their most natural. The focused facial examination follows and should be done while the patient is seated comfortably in natural head posture, the teeth in centric occlusion and the lips relaxed. The goal of the facial examination is to determine what components of the face are detracting from facial harmony and what functional problems may accompany the malocclusion and to make a tentative diagnosis.

It is helpful to structure the facial examination into frontal and profile views [4].

66.2.1 Frontal View

Facial appearance when viewed from the front is, not surprisingly, what a patient will value most.

A helpful first step is to assess the facial form.

- Facial form (Fig. 66.1a–h)—The relationship between the facial width and height has a strong influence on facial harmony. The ratio of facial width to facial height is more important than absolute values in establishing the overall facial type. Attractive faces tend to have proportions that fall within normative values. When evaluating facial form, the overall body build of the individual (corporo-facial relationship) should be considered (i.e., short and stocky versus long and thin). The height-to-width proportion (trichion to menton: bizygomatic width) is 1.3:1 for females and 1.35:1 for males. The bigonial width should be approximately 30% less than the bizygomatic dimension, and the width and shape of the chin should form a harmonious part of the overall facial contour. Leptoprosopic faces (long and narrow) are often associated with vertical maxillary excess, a narrow nose, mandibular anteroposterior deficiency, narrow gonial angles, microgenia, a high palatal vault, and an anterior open bite (Fig. 66.1a–c), while dolichoprosopic faces (short and square) are often associated with vertical maxillary deficiency, masseter hyperplasia, wide gonial angles, macrogenia, and Class III deep bite malocclusions (Fig. 66.1d, e). Individuals from Asia often have round oval faces (Fig. 66.1f). Patients with mandibular deficiency often have a tapered facial lower facial third and microgenia (Fig. 66.1g, h).
- Transverse facial dimensions (Fig. 66.2)—In general terms the *rule of fifths* is a convenient method used to evaluate the transverse proportions of the face. The face is sagittally divided into five equal parts, each the approximate width of the eye, from helix of the outer ears.
  - *Outer fifths:* Is measured from the lateral helix of the ear to the lateral canthus and is an indication of the width of the ears. Bat ears can be camouflaged by an appropriate hairstyle; however, otoplastic surgical procedures are relatively atraumatic and can improve the facial appearance dramatically. Otoplasty can be performed at the same time as orthognathic procedures.
  - *Medial fifths:* Are measured from the outer to the inner canthus of the eyes. The outer border should coincide with the gonial angles of the mandible. In patients with long and narrow faces, the gonial angles will fall medial to this line, while in patients with broad and square faces, the gonial angles will fall lateral to these lines. Within these fifths it should be noted that the distance between the inner margins of the irides of the eyes should be equal to the width of the mouth. Abnormal interpupillary and intercanthal distance are often observed in syndromic patients and can only be altered by means of craniofacial surgery.
  - *Middle fifth:* Is demarcated by the lines through the inner canthus of the eyes. In patients with hypertelorism, this fifth would be relatively larger than the others. The ala of the nose (alar base width) should coincide with these lines, while the nasal dorsum

Fig. 66.1 The relationship between the facial height and width influences facial harmony. The variations of facial form: (**a**) narrow, (**b**) long, (**c**) tapered, (**d**) square, (**e**) round, (**f**) oval, (**g**) sharp, and (**h**) pointed, are demonstrated

should be approximately half of the intercanthal distance. For patients in whom maxillary advancement and/or superior repositioning is planned, this measurement should be considered and surgical control of the alar base may be indicated.

- Vertical evaluation (Fig. 66.3)—By convention the face is divided into three parts by horizontal lines adjacent to the hairline (trichion) to the soft tissue glabella, the nasal base (subnasale), and the lower border of the chin (menton). An aesthetically pleasing face should have approximate equivalence of the three parts.
  - *Upper third:* Deformities in this third can fortunately often be masked by an appropriate hairstyle; however, it is important to record deformities in this area as they may indicate craniofacial syndromes.
  - *Middle third:* Generally, no sclera is seen above and below the iris in a relaxed eyelid position. Individuals with midface deficiency tend to show sclera under the iris of the eye and will tend to have a long narrow nose. The cheekbone-nasal base-upper lip-lower lip contour line is a convenient indicator of the harmony of the structures of the midface (zygoma, maxilla, and nasal base) with the paranasal area and upper lip. This imaginary line starts just anterior to the ear, extends anteriorly across the cheekbone, and then curves antero-inferior over the maxilla adjacent to the alar

base of the nose, ending lateral and slightly below the commissure of the mouth. The line should form a smooth, continuous curve (Fig. 66.4a, c). A skeletal deformity will cause an interruption of the curve, and the area of interruption in the line is often an indication of a specific underlying deformity (Fig. 66.4b).

– *Lower third:* (Fig. 66.3) The middle to lower third vertical height of the face should have a 5:6 ratio. In the well-balanced lower third of the face, the upper lip makes up one third, while the lower lip and chin composes the lower two thirds. Normal upper lip length is 20 ± 2 mm for females and 22 ± 2 mm for males and measured from subnasale to upper lip sto-

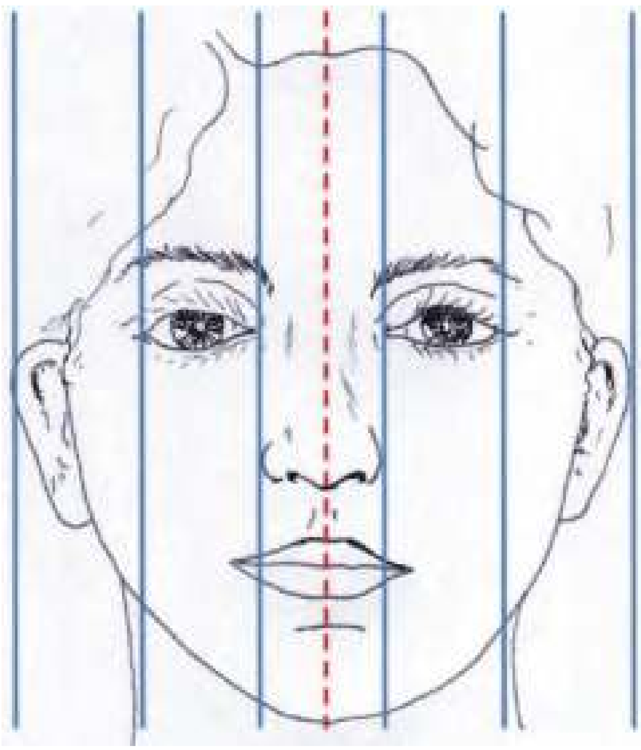

Fig. 66.2 Transverse facial proportions

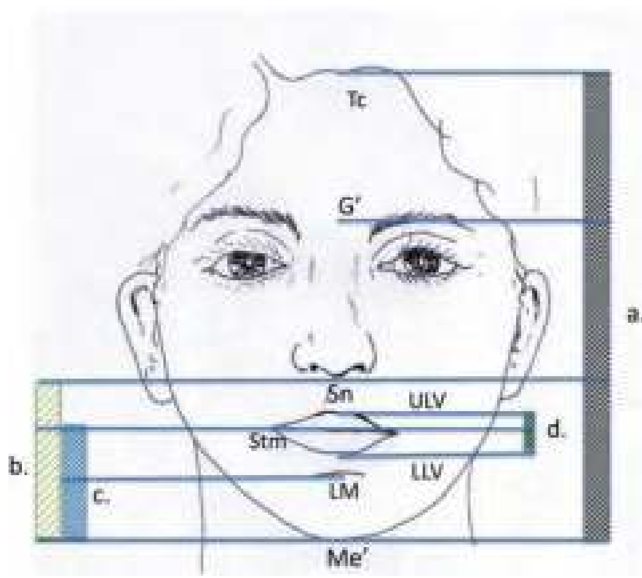

Fig. 66.3 Vertical facial proportions

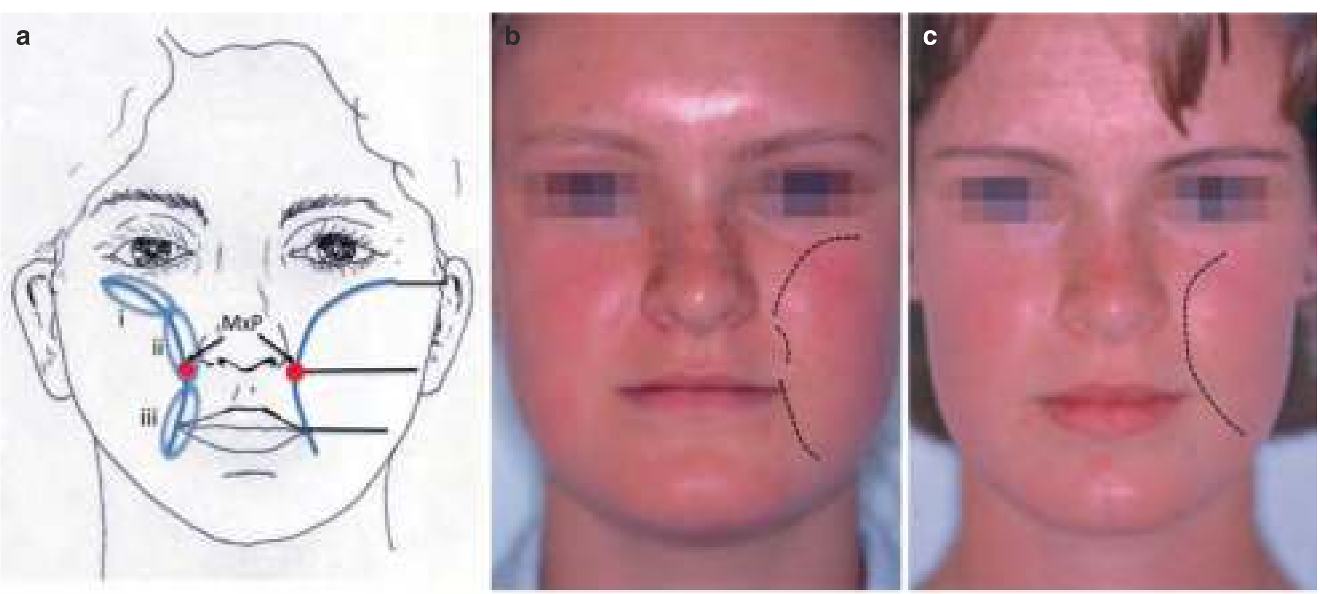

Fig. 66.4 (**a**) Cheekbone-nasal base-lip contour. (**b**) The interruption of the curve at MxP (maxillary plane) indicates maxillary anteroposterior deficiency. (**c**) Correction of the malocclusion establishes a smooth contour line

mion (stomion superius). When the upper lip is relatively short, there will be a tendency to an increased interlabial gap and excessive upper incisor exposure with normal facial height. This should not be confused with the same observations in patients with vertical maxillary excess (Fig. 66.8). Normal lower lip length is 40 ± 2 mm for females and 44 ± 2 mm for males. The lower lip may give the false impression of being short due to a deep bite. It is mandatory that the interlabial gap and tooth exposure be evaluated with the teeth in occlusion and the lips in repose (Fig. 66.8b). A gummy smile is not a definite indication of vertical maxillary excess as some patients may have a normal maxillary height but hyperactive upper lip when smiling. An increased interlabial gap (more than 3 mm), excessive upper incisor exposure (more than 4mm), and a gummy smile are typical characteristics of vertical maxillary excess (Fig. 66.9). For patients in whom the upper incisors are not visible under the upper lip, the tooth lip relationship should be evaluated with the mandible rotated open until the lips just separate (Fig. 66.8a). Lack of upper incisor exposure is indicative of vertical maxillary deficiency and usually occurs in combination with decreased lower facial height. The height of the lower face can also be influenced by the height of the mandible, and the height of the chin should be noted in any discrepancy in vertical facial height.

The arbitrary subdivision of the face into vertical thirds has a critical flaw. The effects of a deformity of one jaw and the correction thereof may stretch across two conventional facial thirds.

It is for this reason that the authors believe a more pragmatic approach to facial aesthetic assessment is to divide the face into zones of influence, i.e., zones which can be modified by orthodontics and orthognathic surgery.

The *Ferretti-Reyneke analysis* (Fig. 66.5) divides the face into five zones of influence, i.e., zones of soft tissue facial integument that are under the influence of the corresponding underlying skeleton:

- *The fore-head zone* (i). Extending from trichion (hairline) to a line connecting the eyebrows across glabella.
- *The oculonasal zone* (ii). Extending inferiorly from the eyebrow line to a line extending from the lower border of the zygomatic arch curving upward to the infraorbital foramen onto the nose above the supra tip break and continuing to the opposite side.

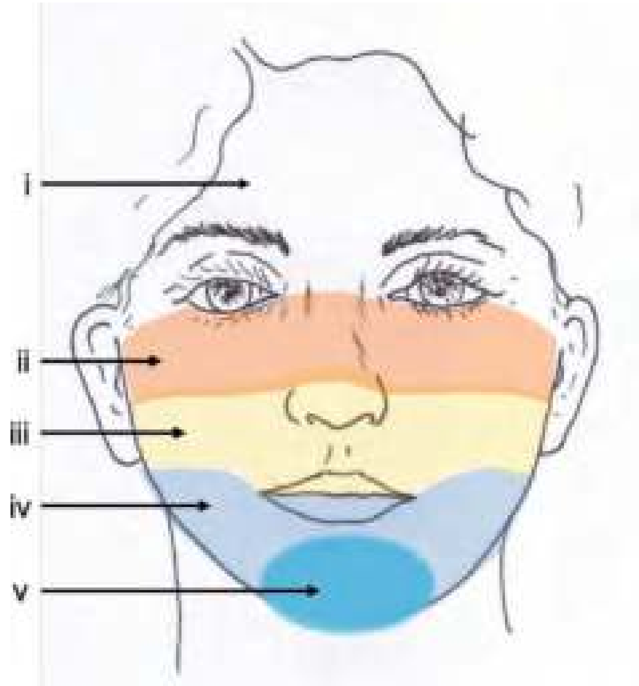

Fig. 66.5 The *Ferretti-Reyneke* analysis

- *The gnathic complex.* This subunit is subdivided into an upper *maxillary component* (iii) which extends from the lower aspect of the oculonasal complex to a curved line extending along the lower margin of the upper lip (or the incisal edge of exposed maxillary teeth) to the angle of the mouth and proceeding in a curvilinear fashion to the lower attachment of the auricle and a lower *mandibular component* (iv) which extends to the lower border of the mandible and contains in its anterior aspect the oval *mental subunit* (v) which delimits the soft tissue chin.

It is critical to remember that facial evaluation is not the search for deviation from the norm of a single subunit but the search for proportion. For example, a facial form diagnosed as vertically excessive means it is excessive in relation to its transverse dimension, *not* that it is longer than the norm. By increasing only the transverse or only the vertical dimension, facial harmony will be lost; however, harmony is re-established by increasing both the transverse and vertical dimensions.

Facial Symmetry

The facial midline is the reference line to evaluate the forehead (glabella), nasal dorsum, nasal tip, maxillary dental midline, columella of the nose, philtrum of the upper lip, mandibular dental midline, lower lip, and the chin (Figs. 66.2 and 66.6). In the initial overall assessment of facial asymmetry, we should establish whether the asymmetry involves the chin, the mandible or the maxilla, or a combination of the structures. Careful assessment of an occlusal cant of the maxilla is mandatory as it will play an important role in the correction of the asymmetry. Soft tissue asymmetry, either primary or secondary to skeletal asymmetry, should be noted. Finally, symmetry of the nose, orbits, and forehead should be evaluated (Figs. 66.2 and 66.6).

The face is a three-dimensional structure, and the symmetry of the face will be influenced by deformities in the vertical, anteroposterior, and transverse planes. Clinical frontal assessment of the face is however the most critical, and discrepancies should be correlated with posterior facial asymmetry by noting any transverse, anteroposterior, and/or sagittal cants in the occlusal plane. The occlusal plane should be parallel to the interpupillary line, provided there is no orbital dystopia. Surgical correction of an occlusal plane cant often corrects facial asymmetry, and the severity of the cant should correlate with the dental and facial asymmetry. During treatment planning the clinicians should assess if orthodontic or surgical correction of dental midlines is required. With skeletal asymmetry the dental midline should not be orthodontically coordinated but rather aligned in the center of each jaw to allow surgical correction of the skeletal asymmetry. Keep in mind that no face is perfectly symmetric.

Lips

The lips play an extremely important role in the overall facial aesthetics, and careful assessment is required. Lip symmetry should be evaluated in the rest position as well as when the patient is smiling. Lip symmetry may be influenced by facial nerve dysfunction, underlying dentoskeletal deformities, scarring due to previous trauma, congenital clefting, microstomia, macrostomia, or hyperplasia. The lower lip generally exhibits 25% more vermillion than the upper lip. With the presence of an accentuated Cupid's bow, only the upper incisor may be visible under the upper lip and very little or even no lateral incisor (Fig. 66.7). An interlabial gap of 0 to 4mm and 1 to 4mm of upper incisor tooth exposure under the upper lip with the lips in repose are considered pleasing while the full crown of the incisor exposed when smiling.

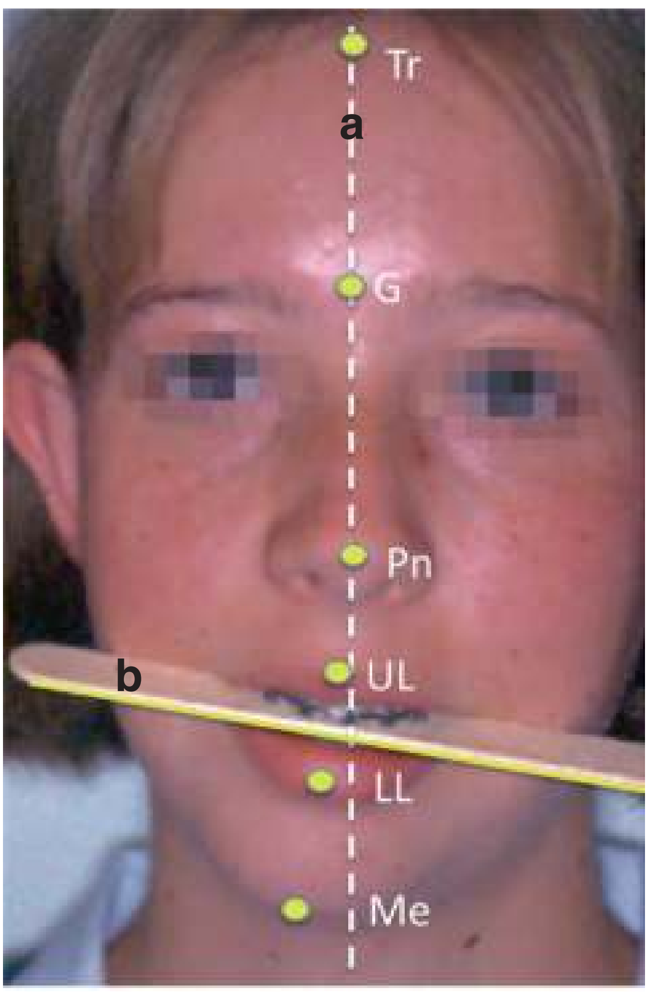

Fig. 66.6 The facial midline (**a**), and occlusal cant (**b**)

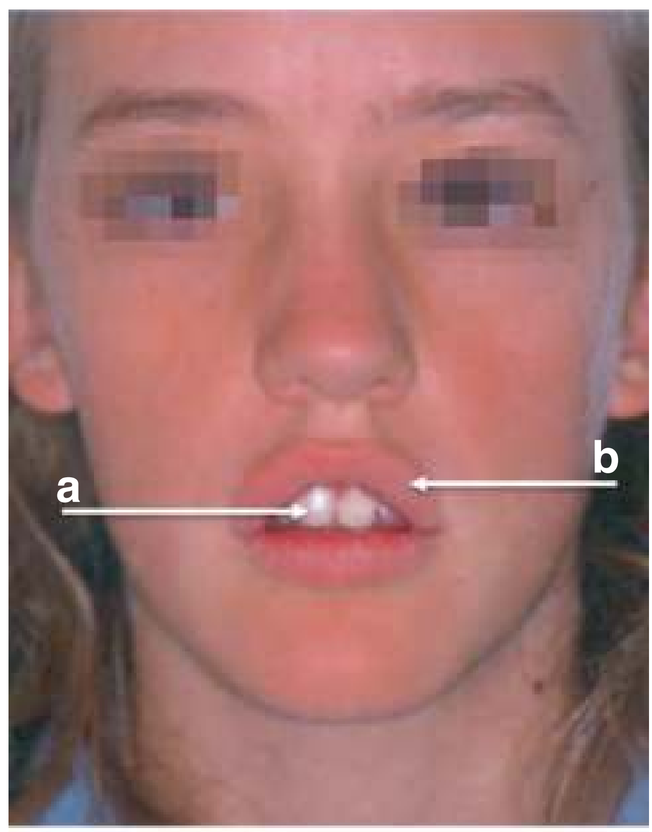

Fig. 66.7 An increased interlabial gap with excessive amount of upper incisor exposure under the upper lip (**a**). A poorly shaped upper lip (distorted Cupid's bow) and excessive amount of vermillion excessive exposure (**b**)

Note any asymmetry of the lips when smiling (Fig. 66.10). When vertical skeletal or dental corrections are contemplated, the vertical relationship of all four incisors to the upper lip should be clinically considered. Only the upper central incisors are visible on a lateral cephalometric radiograph and should not be used to plan vertical maxillary changes (c in Fig. 66.13).

66.2.2 Profile View

Although it is emphasized that the clinical assessment of the face is mandatory, the cephalometric analysis of the lateral cephalometric radiograph has been the predominant method of profile evaluation. Many orthodontists are accustomed to using the quantitative data obtained from the lateral cephalometric analysis as the main diagnostic tool. The contemporary orthodontist and facial surgeon rely on facial proportionality and more subjective aesthetic evaluation criteria than linear and angular measurements. Treatment decisions should rather be made by what is most aesthetically appealing rather than by what the cephalometric norms indicate. The plethora of cephalometric values available can lead to confusion and unnecessary complexity. The undermentioned cephalometric measurements are the most useful indicators to confirm a clinical diagnosis.

Nasolabial Angle (a in Fig. 66.11)

The angle is measured between the columella of the nose and the upper lip and should be between 85° and 105°. It is influenced by the position and angle of the upper incisor teeth and the anatomy of the nasal columella. Excessive orthodontic retraction of the upper incisor teeth (i.e., com-

Fig. 66.8 No upper incisor exposure under the upper lip leads to a "toothless" look (**a**). An increased interlabial gap with excessive upper incisor exposure suggests vertical maxillary excess (**b**). The assessment should always be done with the lips in repose

Fig. 66.9 A patient with vertical maxillary excess. Note the increased interlabial gap with the lips in repose (**a**) and gummy smile (**b**)

promised treatment for a Class II occlusion) will lead to poor upper lip support and an increased nasolabial angle. This will often lead to early wrinkling and an aging appearance of the lip. An over-closed bite will cause an acute angle, while a hanging columella of the nose will increase the angle.

Labiomental Angle (b in Fig. 66.11)

This angle is formed by the intersection of the lower lip and chin measured at the soft tissue of the chin. The angle is a gentle curve and should be 120° ± 10°. The lower lip, the depth of the labiomental fold, and chin button should form a smooth and harmonious S-shaped curve with the labiomental fold dividing the chin into an upper third and lower two thirds. The angle is acute in patients with Class II dentoskeletal deformities due to the everted lower lip or patients with macrogenia. Individuals with Class III dentoskeletal deformities and the lower incisors retroclined (compensated) or patients with microgenia will exhibit an obtuse labiomental angle.

Lip-Chin-Throat Angle ((i) in Fig. 66.12)

The angle is formed between the lower border of the chin and a line connecting the lower lip and soft tissue pogonion. The chin and submental area are considered attractive with an angle between 100° and 120°.

Fig. 66.10 An asymmetric smile

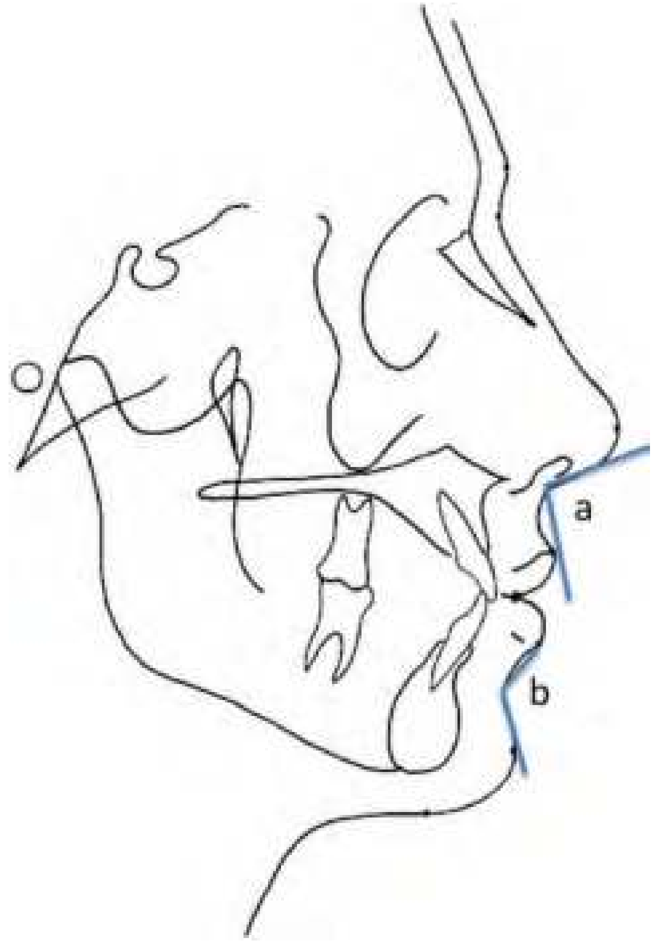

Fig. 66.11 (a) The nasolabial angle, measured between the inclination of the columella of the nose and the upper lip, should be 85°–105°. (b) Labiomental fold. The lower lip-chin angle should be 130°. However the general shape of the chin should be considered

Chin-Throat Length ((ii) in Fig. 66.12)

It is measured from the angle of the throat to the soft tissue menton. It is only meaningful when this angle is measured with the patient's head in natural posture. A length of between 38 and 48mm is considered to be normal and is significant when assessing mandibular length. This measurement is helpful for differentiating between mandibular anteroposterior excess and maxillary anteroposterior deficiency. For a patient with a Class III malocclusion and normal chin-throat length, maxillary deficiency should be suspected.

Upper Lip Length (b in Fig. 66.13)

The length of the upper lip is measured from subnasale to the lower border of the upper lip (stomion superius) and should be 18–22 mm in females and 20–24 mm in males. This measurement should be performed with the lips in repose. During the planning of tooth-lip relationship, it should be kept in mind that the upper lip will increase in length with age.

Interlabial gap (d in Fig. 66.13)

The interlabial gap should be assessed with the lips in repose and the teeth in occlusion. It is measured between stomion superius and stomion inferius (0–4 mm). If the lips touch when the teeth are in occlusion, the upper incisor-lip relationship should be evaluated with the lower jaw rotated open until the lips are slightly apart.

Facial Contour Angle (e in Fig. 66.13)

This measurement will give the clinician an indication of facial convexity or concavity and is influenced by the antero-posterior relationship between glabella, subnasale, and menton. The angle is formed between the upper facial plane (glabella-subnasale) and lower facial plane (subnasale-pogonion). The angle is recorded above subnasale and expressed as negative when the angle is ahead of the upper facial plane (in convex profiles) and as positive when the angle is behind the upper facial plane (usually in concave profiles). A pleasing facial profile for females will have a facial contour angle of $-13° \pm 4°$ and for males $-11° \pm 4°$. This measurement will also be influenced by the height of the maxilla. The mandible will rotate counterclockwise (upward and forward) with vertical maxillary deficiency leading to a more concave profile, while it will rotate clockwise (downward and backward) with vertical maxillary excess leading to a more convex profile.

Nose (Fig. 66.14)

This important anatomic structure is situated in the middle of the face, and its important influence on facial aesthetics has often been neglected by orthodontists and maxillofacial surgeons in the past. More focus is placed on the aesthetic evaluation of the nose by the fact that the relative nasal aesthetics can be influenced by orthodontic treatment and certainly by orthognathic surgery. The fact that rhinoplasty is now considered to be part of the field of treatment for many orthognathic surgeons has certainly made the careful aesthetic evaluation of the nose an important consideration. In many cases nasal reconstruction will form part of the orthognathic treatment plan, and in some cases, reconstruction can be performed concurrently with orthognathic surgery. The authors prefer to defer most nasal reconstructions to 6 months after orthognathic surgery due to the substantial relative effects orthognathic surgery has on nasal aesthetic.

The amount of nostril show in profile view may be affected by either a hanging columella or retracted alae (Fig. 66.14a). The shape of the dorsum should be noted as normal, convex, or concave. It is important to distinguish between a large dorsum and a turned-down nasal tip as the treatment would be entirely different. The relationship between the lengths of the nasal dorsum and the projection

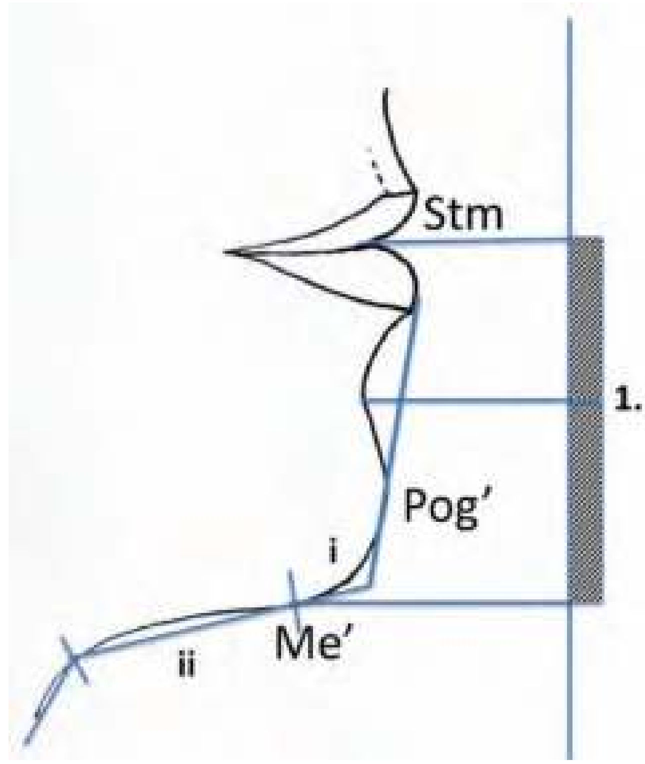

Fig. 66.12 The lip-chin-throat angle (i). Chin-throat length (ii)

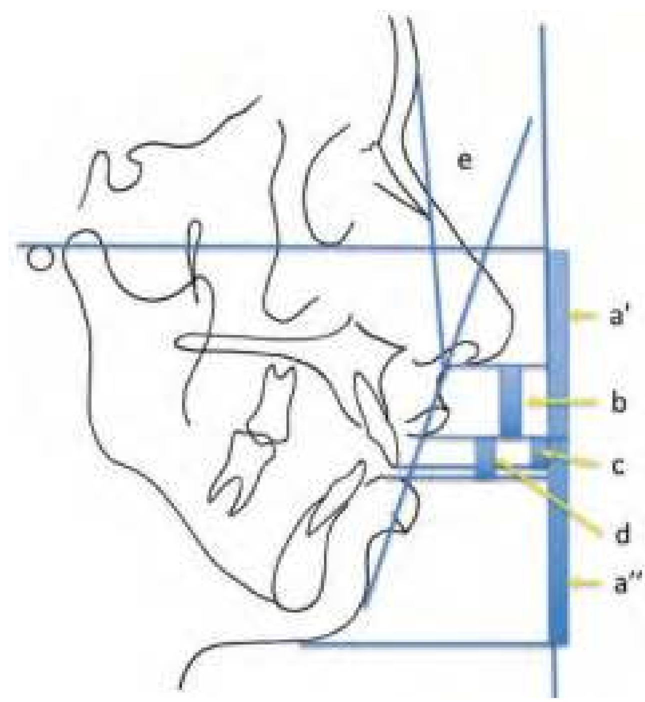

Fig. 66.13 Midface height (a'), lower facial height (a''), upper lip length (b), upper lip vermillion (c), interlabial gap (d), and facial contour angle (e)

of the nose can be evaluated by the method of Goode. According to Goode the length of the nose should be about 55–60% greater than the projection of the nose (Fig. 66.14b). From nasal base to the tip, the ratio of projection should be 1–2 (Fig. 66.14c). The nostrils and columella should be assessed from a "worm's eye" view (Fig. 66.14d). The nasal bridge should project about 5–8 mm in front of the globes of the eyes. The nasal tip should be noted as narrow, bulbous, asymmetric, or normal. The width of the nasal base, the acuteness of the supra tip break, the visibility of the nostrils,

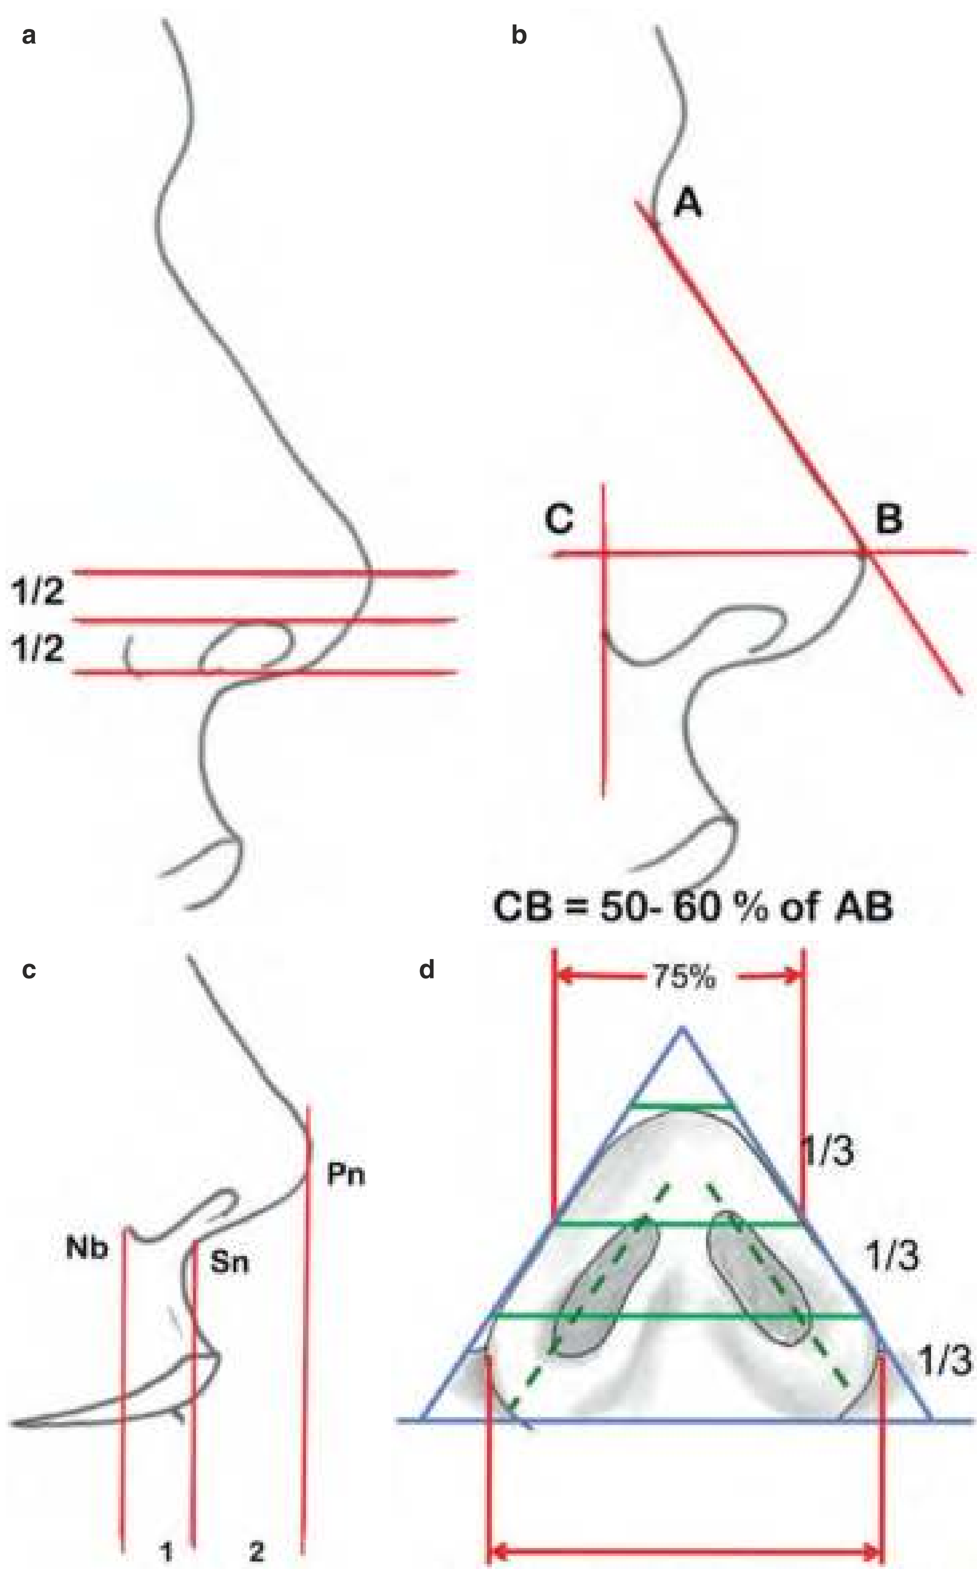

Fig. 66.14 Assessment of nostril show (**a**). Nasal projection (CB) to nasal length (AB), according to Goode's ratio: CB:AB = 0.55:0.6 is normal (**b**). Horizontal assessment of nasal projection: from nasal base (Nb), the Pn-Sn to Sn-Nb should be 2:1 (**c**). Nasal base ("worm's eye") view assessment of the nose. The general shape of the alar base should resemble an isosceles triangle (**d**)

and symmetry of the columella are important factors to consider when maxillary surgery (especially superior repositioning or advancement) is contemplated. Fortunately, adverse aesthetic effects as a result of maxillary surgery can be controlled during surgery [4].

Cheeks (Fig. 66.15)

As in the frontal evaluation, the *cheekbone-nasal base-upper lip-lower lip curve* contour line is also very helpful in the profile analysis. The line starts just in front of the ear, extending forward over the cheekbone, downward over the maxilla adjacent the ala of the nose, and ending lateral to the commissure of the mouth. The line should form a smooth continuous curve, and any interruption may indicate an underlying skeletal deformity (Fig. 66.15). The variations in interruptions in the curve and the possible underlying skeletal deformities responsible for the soft tissue deformities are demonstrated in Fig. 66.15b, c [5].

Orbit

The globes of the eye generally project 0–2 mm ahead of the infraorbital rims, while the lateral orbital rims lie 8–12 mm behind the most anterior projection of the globes. The bridge of the nose should be about 7 mm ahead of the globes although there is a significant ethnic difference in this measurement (Fig. 66.14) [6].

Paranasal Area

The flatness or fullness of the paranasal areas is an important indicator to distinguish between middle third deficiency and mandibular anteroposterior excess. Another useful indicator of midface deficiency is the ratio of the linear distance from the nasal tip to subnasale and from subnasale to the alar base crease. The ratio should be 2:1 (Fig. 66.14). A ratio closer to 1:1 will indicate maxillary anteroposterior deficiency, while an increased ratio will indicate decreased nasal projection.

Lips

The lips play an important part in the overall aesthetics of the face and should be carefully assessed before treatment. The effects of treatment as well as the aesthetic changes that may take place during the aging process should be considered. The upper lip usually projects slightly anterior to the lower lip, and the E-line and S-line are helpful guides to assess the projection of the lips (Fig. 66.16) [7].

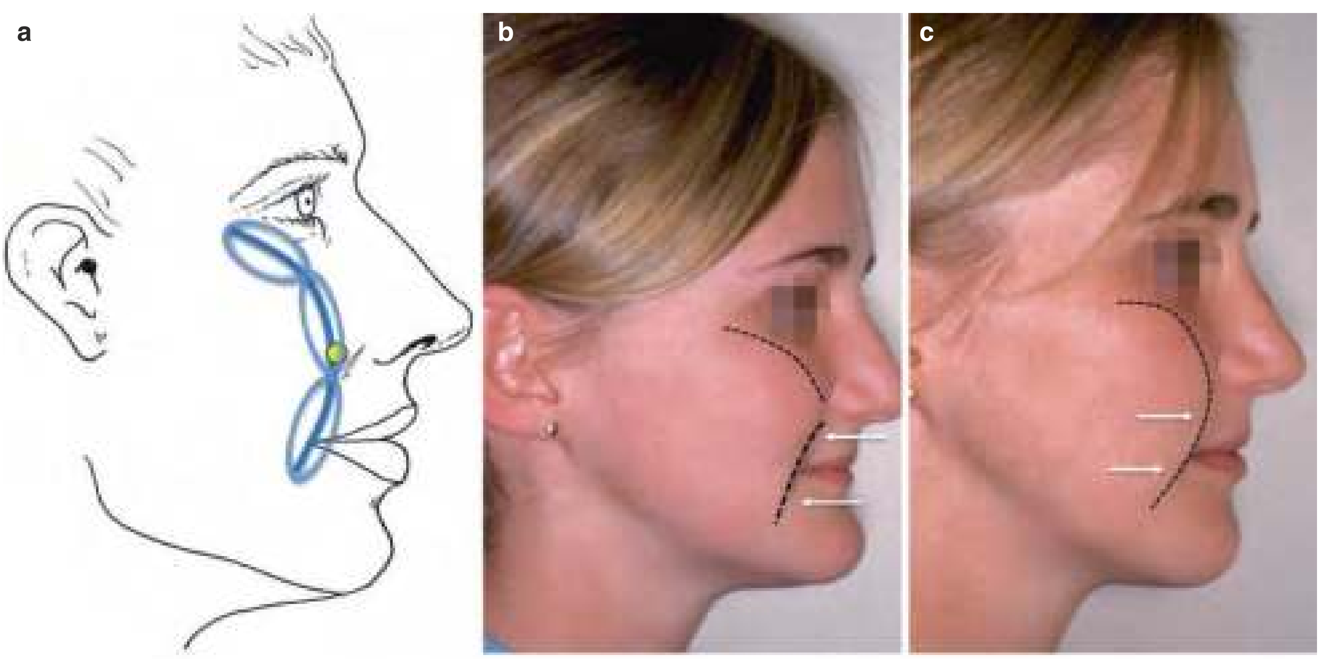

Fig. 66.15 (**a**) The cheekbone-nasal base-lip curve contour. The curve should be unerupted and smooth in an individual with good facial proportions. (**b**) The cheekbone-nasal base-lip curve contour. The interruption of the curve (arrows) indicates maxillary as well as mandibulae anteroposterior deficiency. (**c**) The cheekbone-nasal base-lip curve contour. Following maxillary and mandibular advancement, the curve is uninterrupted and smooth (arrows)

Chin

The chin is one of the most noticeable structures in the face and demands special evaluation. The shape of the chin is more important than the position of pogonion. Chin surgery should not be considered for patients requiring mandibular surgery. Performing an advancement genioplasty for a patient as compromise treatment for mandibular advancement may achieve correct chin projection; however, the balance and harmony of the chin will be poor. The authors use seven criteria for the aesthetic profile evaluation of the chin which also serve as a guide to surgical treatment planning (Figs. 66.11, 66.12, and 66.13) [8].

1. Height of the chin. The chin height is measured from lower lip stomion to soft tissue menton and should be equivalent to two thirds of the lower facial height. The linear height should be 40 ± 2 mm for females and 44 ± 2 mm for males. For individuals with deep bites, the measurement should be performed with the teeth apart and the lip separated (i in Fig. 66.12).
2. Vermillion exposure. The lower lip vermillion exposure should be 25% more than the upper lip. The lower lip will be everted with increased vermillion exposure when the lower incisors are proclined or in individuals with an increased overjet (Fig. 66.13).
3. The labiomental fold. The depth of the fold should divide the chin into an upper third and lower two thirds (Fig. 66.11).
4. Chin throat length. Patients with mandibular anteroposterior deficiency will have short chin-throat lengths and vice versa for individuals with mandibular anteroposterior excess. Normal length is considered to be 42 ± 6 mm. This measurement is important when considering setback or advancement of the chin (ii in Fig. 66.12).
5. Lower lip-chin-throat angle. The angle is considered pleasing at 110° ± 8° and tends to be acute in mandibular prognathism and obtuse in mandibular deficiency (Fig. 66.12).
6. S-shaped curvature. The profile of the chin should form a well-proportioned, harmonious and smooth curve (Fig. 66.12).
7. The lower lip position. A helpful guide to the lower lip position is the E-line (aesthetic line). The E-line is drawn from the nasal tip (pronasale) to pogonion. The lower lip should be 2 ± 2 mm behind the line. The measurement will be influenced by the projection of the nose and the anteroposterior position of the chin which should be kept in mind during this evaluation (Fig. 66.13).

Most of the aforementioned aesthetics parameters can also be assessed on a lateral cephalometric radiograph; however, there is no substitute for clinical evaluation of facial harmony. It is hoped that the short overview of the clinical assessment of facial aesthetics will increase the reader's acuity in the treatment of his/her patients. In most instances the orthodontist is the first professional to see patients with malocclusions. Some of these patients may require skeletal and/or soft tissue modification incorporated into the treatment plan, and the responsibility lies with the orthodontist to recognize the dental, skeletal, and soft tissue problems and then to appropriately inform the patient. The aesthetic outcome following orthodontic (and surgical) treatment should be a priority for the contemporary orthodontist.

66.3 Clinical Evaluation

The clinical assessment of the face is probably the most valuable of all diagnostic procedures. While an astute clinical diagnosis can be made at the chair side, photographs are essential for accurate assessment and record purposes. The face is systematically assessed from a frontal view, profile view, and three-quarter view. Figures 66.1, 66.2, 66.3, 66.4, 66.5, 66.6, 66.7, 66.8, 66.9, 66.10, 66.11, 66.12, and 66.13 illustrate some angular and linear parameters used during the clinical assessment of the face.

66.4 Special Investigations

Cephalometric and panoramic radiographs and dental casts are essential; however, temporomandibular joint investigations, Technetium bone scans, hand wrist radiographs, CT scans, etc. may be required. The lateral cephalometric radiograph taken in centric occlusion and the lips in repose allows the clinician to analyze and evaluate the soft tissue, skeletal, and dental relations of a dentofacial deformity.

66.5 Diagnosis and Problem List

A diagnosis is made following the clinical evaluation of the patient, a radiographic evaluation and cephalometric analysis, model analysis, and other indicated evaluations. The data base is used to compile a problem list.

66.6 Treatment Objectives

Clear orthodontic and surgical treatment objectives regarding soft tissue, skeletal, and dental structures should be identified and noted.

Development of a Visual Orthodontic and Surgical Cephalometric Treatment Objective The lateral cephalometric radiograph tracing is used to develop an orthodontic visual treatment objective to predict orthodontic tooth movements. This is followed by the development of a surgical visual treatment objective predicting the required jaw repositioning and expected soft tissue changes [10].

66.7 Treatment Plan

All the factors identified in the diagnosis and problem list as well as patient concerns and reasons for considering orthognathic surgery are considered to formulate a final treatment plan (Flowchart 1). The sequence of treatment and the treatment to be performed by all healthcare professionals concerned are outlined. When defining the treatment plan, a thorough knowledge of the many types of dentofacial deformities and the treatment modalities available to correct them is essential.

The flowchart (Fig. 66.17) summarizes the systematic gathering of data leading to diagnosis and, finally, the development of a treatment plan [9–11].

The basic treatment plan will consist of:

Presurgical Orthodontic Treatment

1. Alignment of both dental arches (with or without tooth extractions)
2. Levelling of both dental arches (in segments or one piece)
3. Deviation of tooth roots at planned interdental osteotomies areas
4. Decompensation of any dental compensations
5. Coordination of dental arches (or segments)

Surgery

The treatment of patients with dentofacial deformities can broadly be divided into four groups. The specific surgical procedure(s) will be indicated by the problem list as discussed:

1. Single jaw surgery—mandibular repositioning (advancement or setback)
2. Single jaw surgery—maxillary repositioning (advancement or setback or superior repositioning or downgraft and/or segmental surgery or a combination)
3. Double jaw surgery
4. Rotation of the maxillomandibular complex

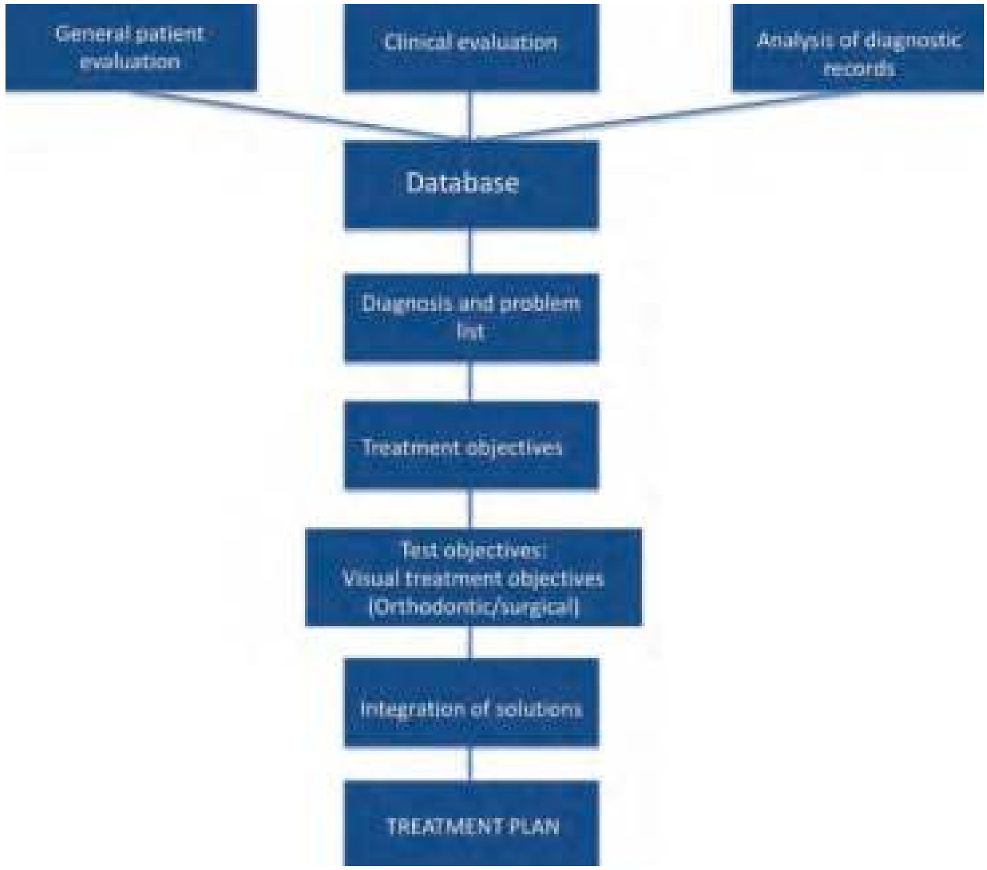

Fig. 66.17 Flowchart 1

For each of the above surgical treatment categories, the orthodontist and the surgeon will have specific responsibilities to make the treatment efforts occur smoothly and successfully. In most surgeries, conventional treatment planning using lateral cephalometric and PA cephalometric radiographs and cast model surgery with surgical splint fabrication is indicated. However the authors use 3D virtual treatment planning for more challenging surgeries such as facial asymmetries, rotation of the maxillomandibular complex, etc. [12, 13].

66.8 Treatment

Although the orthodontist and the oral and maxillofacial surgeon are the main role players, comprehensive correction of dentofacial deformities may involve several members of the healthcare team. The surgeon should understand the orthodontic decision-making process, while the orthodontist must understand the pre- and postsurgical orthodontic requirements. It is mandatory that the therapeutic management is carried out as planned and any problem or change in treatment plan should be communicated to the treatment team. Successful and knowledgeable practitioners always maintain good interprofessional communication and mutual respect to achieve the best treatment results.

66.9 Conclusion

Successful orthognathic surgery relies on understanding and interpreting a patient's desires, correlating these with the diagnosis, and finally developing a treatment plan and executing it accurately. While virtual 3D planning has provided another tool to aid in diagnosis and surgical planning, it behooves surgeons to continue to develop proficiency in traditional cephalometry-based treatment planning.

67 Surgery-First Orthognathic Approach

N. Viveka Vardhan Reddy and Abhinand Potturi

67.1 Introduction

Treatment philosophies for the management of dentofacial deformities are varied. Milder forms of dentofacial deformity not manifesting as a significant skeletal discrepancy can be corrected by orthodontic treatment alone called “orthodontic camouflage”, but those presenting with significant skeletal discrepancy need the skills of both the orthodontist and the maxillofacial surgeon. Hence, correction of dentofacial deformities has come to be a confederate work between both specialties. The dentition and maxillomandibular skeletal complex (MMSC) are intertwined, and changes to one will invariably affect the other, especially more so when the MMSC positional and spatial relationships change. Over the years many new concepts have evolved in orthognathic surgery, and the odyssey between the surgical and orthodontic teams is only getting more inseparable and interesting.

67.2 Background

Looking back to 1960s when techniques of mandibular and maxillary orthognathic surgeries were still evolving from the works of Obwegeser and Trauner, surgeons often performed the procedures either before orthodontic treatment or well after the completion of orthodontic treatment, and rarely any surgeon depended on an orthodontist to move the teeth into certain relationship before undertaking surgery [1]. With time it was realized that the natural dental compensations became a hindrance to the optimal movement of MMSC, thus compromising the results and final outcome.

Poulton et al. [1] in 1963 reported few cases of excessive mandibular growth (mandibular prognathism) which were treated surgically without any pre-surgical orthodontics. In the process, the authors observed that the overjet relationship between the upper and lower anterior teeth limited the amount of mandibular setback, thereby compromising the overall treatment outcome. They concluded that proper alignment of teeth in upper and lower arches is a prerequisite to get adequate mandibular setback. This proposal had almost paved the way for the “orthodontics-first” concept for correcting dentofacial deformities. Worms et al. [2] in the 1970s popularized the concept of “orthodontics first” for all orthognathic surgeries which led to the split of orthodontic treatment into two phases: the pre-surgical orthodontics phase and post-surgical orthodontics phase with an intervening surgical phase.

The pre-surgical orthodontics phase, which essentially antecedes the orthognathic surgical phase, brings out the accurate skeletal discordance by decompensating the natural compensations which have occurred, thereby helping the surgeon to perform a more precise spatial relocation of the MMSC during surgery [3]. However, the pre-surgical phase of orthodontic treatment, also called reverse orthodontics, is a long-drawn process lasting anywhere between 1 and 2 years depending on the complexity of the discrepancy [4]. To add to the woes, during this phase there is gradual deterioration of facial form and dental function [5–7]. Worsening of the facial profile has become a great deterrent for the patients seeking orthognathic surgery because the very reason for seeking the orthognathic surgery for improving facial aesthetics stands defeated and therefore fails to address the patients’ chief complaint. Also, the long preoperative preparatory phase can aggravate or initiate other dental problems like dental caries or periodontal problems. For all these reasons, the “orthodontics-first” concept can produce a negative influence on the patient’s compliance [8] (Table 67.1).

Table 67.1 Challenges associated with conventional “orthodontics-first” approach

1. Time-consuming
2. Deterioration of facial form
3. Difficulty to chew or masticate during pre-surgical phase
4. Psychosocial problems
5. Other complications like dental decay, gum recession and root resorption or root damage

67.3 Surgery-First Orthognathic Approach (SFOA)

In order to overcome the shortcoming of conventional orthognathic surgery, a new approach has been conceptualized called “surgery-first orthognathic approach (SFOA)”.

Even though some surgeons expressed the necessity to reposition the MMSC before performing any orthodontics in the past, it did not gain much popularity. With the advent of skeletal anchorage system in orthodontics and rigid fixation system in orthognathic surgery, the problem of skeletal relapse due to unstable bony segments during post-surgical orthodontics has been significantly reduced, paving the way for popularization of SFOA [8, 9].

Correction of various skeletal deformities like Class III [10] and Class II [11] and facial asymmetry [12] using SFOA technique has been reported in the past, and all of them claimed shortening of the total treatment time as a significant and greatest advantage over the conventional technique. William Bell, the “godfather” of orthognathic surgery, during one of his clinical rounds with his residents, highlighted the changing trends in orthognathic surgery by contending that the present orthognathic surgical procedures remain too complicated, too invasive, too time-consuming, too expensive, and too unpredictable, and he literally set the tone for discussing “paradigm shifts in orthognathic surgery” [13]. After the clinical applications of advanced three-dimensional imaging and office-based surgery, the 2011 symposium on SFOA created a broader interest in complete elimination of time-consuming pre-surgical reverse orthodontics and paved the way for worldwide acceptance of this paradigm shift in orthognathic surgery [14, 15].

SFOA technique is fundamentally a “face-first” approach wherein the patient’s chief complaint is taken care immediately by improving the facial soft tissue profile and thereby increasing the patient’s compliance to overall treatment (Fig. 67.1). In SFOA, greater part of the dentition remains at the same position with respect to their respective arches as there is no pre-surgical orthodontic phase involved. Following the orthognathic surgery, MMSC will be in a Class I relationship, yet the upper and lower dentition may not fit perfectly into occlusion. A *treatable malocclusion*, called *transitional occlusion*, is set at the end of surgery which can be corrected by the orthodontists. Hence, the orthodontist must actively participate in the treatment planning in SFOA so as to achieve a treatable transitional occlusion at the end of surgery. The orthodontist must be able to foresee the resulting occlusion even before the surgery, and this ability to plan and foresee the resultant transitional occlusion accurately is the linchpin of the entire SFOA technique. Therefore, in SFOA technique the orthodontic principles and guidelines must be established in advance so as to ensure that treatable malocclusions are attained.

Kim JH et al. [8] in their treatise called “Guidelines for “surgery first” orthodontic treatment” have emphasized caution when embarking on SFOA technique. The entire planning process (Fig. 67.2) is laborious since the skeletal changes should be preconceived and the casts should be mounted accordingly to determine the anticipated post-operative orthodontic teeth movements, and, even for the highly accomplished orthodontic and surgical team, it is

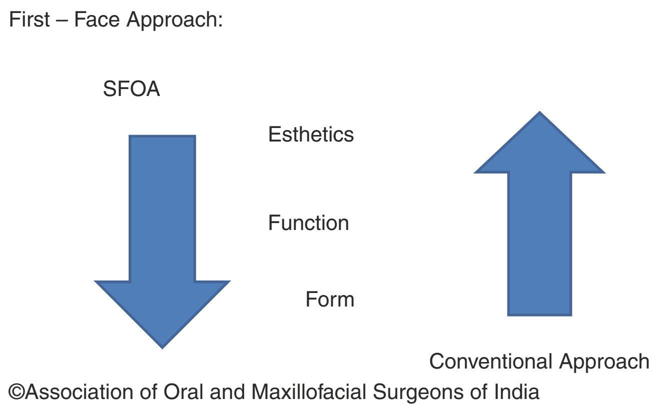

Fig. 67.1 The flow diagram demonstrating fundamental differences and the order of priority between the SFOA and conventional approach

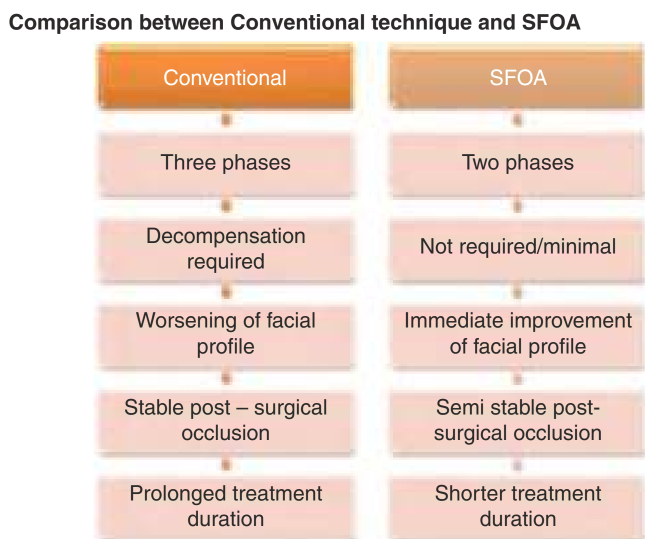

Fig. 67.2 The comparison chart demonstrating various steps for conventional technique and SFOA

challenging to pinpoint accurately the occlusal relationship that will balance ideal aesthetic and functional results. It should be remembered during planning that surgical movement should be adequate enough such that dental decompensation is possible after the surgery. Customarily, the dentition is bonded/banded and a passive arch wire is placed before surgery. Active orthodontic tooth movement begins within a relatively short period of time after the jaw(s) are repositioned to take advantage on the inherent phenomena called accelerated tooth movement [8].

67.4 Regional Accelerated Phenomena (RAP)

It is observed that the orthodontic tooth movement following orthognathic surgery is rapid and it is significantly rapid during initial 4–5 post-operative months. This rapid tooth movement post-surgery is attributed to RAP, and it is observed with all the three planes, sagittal, vertical and transverse.

It is an established fact that orthodontic tooth movement is a metabolic event of alveolar bone resorption in the areas of pressure and bone formation in the areas of tension [16, 17]. In order to analyse post-surgical changes in bone metabolism after orthognathic surgery and the corresponding response in the dento-alveolus, Liou et al. conducted a prospective clinical pilot study in 2011. All 22 adult patients who participated in their study underwent both maxillary LeFort I osteotomy and mandibular bilateral sagittal split osteotomy for repositioning of their jaws. Each of these patients was evaluated for serum alkaline phosphatase (ALP) and C-terminal telopeptide of type I collagen (ICTP) before and after surgery at sequential intervals for up to 4 months post-operatively [14].

ALP and ICTP are two bone markers which are indicative of bone turnover rate. ICTP is a bone resorption metabolite of type I collagen in bone and has been associated with the activities of osteoclasts [18]. ALP is an enzyme for bone formation and has been found to associate with osteoblasts function [19]. The results of Liou et al.'s study [14] showed transient increase in the levels of both ICTP and ALP in the immediate post-surgical period indicating burst in the activity of bone remodelling and turnover activity. It was observed from Liou et al.'s [14] study that the ICTP levels peaked from 1 week to 3 months and the ALP levels from 1 to 4 months post orthognathic surgery. This increase in bone turnover markers in the initial post-operative period is a clear indicator of high metabolic activity in the bone and therefore can be used to advantage in shortening the total treatment time in SFOA.

The RAP is not isolated to SFOA. Even in conventional, orthodontics-first approach, this phenomenon plays its role in post-surgical orthodontics. The only difference is that in conventional technique the surgery is done after the decompensation is achieved. The SFOA technique utilizes the golden opportunity of RAP by speeding up the decompensation process which occurs after the orthognathic surgery contrary to that in conventional technique. Therefore, in SFOA, the surgical procedure increases the bone metabolic rate of dento-alveolus in the first 4 post-operative months, which in turn accelerates the orthodontic tooth movement. Hence to make complete use of RAP in SFOA, the post-surgical orthodontic tooth movements have to be begun as early as 1st week and completed by the 4th month.

67.5 Indications

Though SFOA technique can be employed in any kind of maxillomandibular skeletal discrepancy, Liou et al. proposed the following indications in 2011 (Box 67.1) which could help in easy case selection and will act as a guide for the beginners.

67.6 Treatment Planning Considerations

67.6.1 General Guidelines

- The upper and lower dentition are bonded and banded before the surgery without placing any arch wire in order to keep the dentition undisturbed and solid during and after the surgery.
- When planning for SFOA, multiple treatment options must be taken into account. It is very important for the orthodontist to plan the resulting occlusion on the preoperative model set-up in order to achieve relatively stable occlusion on the table during surgery.
- The decompensation of the teeth to normal positions and angulations will be done after surgery, and hence transitional occlusion should allow any orthodontic teeth movement after the surgery. Since the incisors cannot be used as a guide to foresee the final form of occlusion in SFOA, the molar relationship can be utilized as a starting point to come up with a temporary occlusion.

Box 67.1 Proposed indications for SFOA technique

- Well-aligned to mildly crowded anterior teeth
- Flat to mild curve of Spee
- Normal to mildly proclined/retroclined incisors
- Minimal transverse discrepancies
- Cases in which decompensation is not required or minimal decompensation is required

- For the model surgery, the maxillary and mandibular casts are positioned in a proper molar relationship and with a positive overbite. The molar relation could be set up in Class I in cases of non-extraction or bimaxillary first premolar extraction, Class III in cases of lower first premolar extraction and Class II in cases of maxillary first premolar extraction. Once the molar relationship has been established, the overjet should also have been determined.
- The inclination and angulations of upper incisors determine the pattern of extractions. If upper incisors are excessively inclined, then premolar extraction needs to be planned in order to allow post-operative retraction of upper incisors. As a rule of thumb, if the upper incisor to occlusal plane angulation is less than 53–55°, extraction must be considered [20].
- The transverse dimension often creates a special challenge when performing model surgery in surgery-first cases. The upper and lower midlines must be coincident or close to it post-surgery, and proper buccal overjet must be established bilaterally.
- Once surgery is completed, the post-operative orthodontic treatment can begin anytime between 1 week and 1 month post-operatively in order to take the advantage of RAP.

Envisioning the final dental occlusion based on the present occlusion is the key factor in success of SFOA. The interim transitional occlusion achieved on preoperative model set-up must be stable enough to allow predictable splint preparation and skeletal movement. *It is highly recommended that at least three point contacts are achieved between upper and lower teeth when planning for interim transitional occlusion*. In situations where such transient occlusion cannot be established, it is advisable to commence some orthodontic movement in order to assuage some of the interferences and allow for a more stable transitional malocclusion to be established.

67.6.2 Specific Guidelines [15]

Anteroposterior and Vertical Decompensation in Class III Cases

- The sagittal decompensation for proclined upper incisors in a Class III case could be achieved by an anterior segmental osteotomy with removal of the maxillary first bicuspids or by clockwise rotation of the maxilla by LeFort I osteotomy to upright the maxillary incisor inclination.
- The anteroposterior decompensation for moderately retroclined and crowded lower incisors in a Class III case could be achieved by setting up the molars in a Class I relationship with an excessive incisor overjet, and then the mandibular incisors could be aligned after the surgery to obtain the desired overjet.
- The sagittal decompensation for severely retroclined and crowded lower incisors in a Class III situation could be achieved by extraction of the lower first bicuspid and anterior segmental osteotomy, setting up the molars in a Class III relationship with an excessive incisor overjet, and then the lower incisors could be aligned after the surgery to obtain a desired overjet.
- A moderate to deep mandibular curve of Spee in a Class III case is better levelled preoperatively or surgically by anterior segmental osteotomy to avoid the upward and forward rotation of the mandible post-operatively. Alternatively, the lower incisors could be intruded, and the upper incisors at the same time could be extruded post-operatively.

Anteroposterior and Vertical Decompensation in Class II Cases

- For a moderate to deep mandibular curve of Spee and proclined mandibular incisors in Class II mandibular retrognathism, the anterior segment of the lower jaw could be levelled and intruded surgically through anterior segmental osteotomy so that the mandible could be advanced accurately.
- Alternatively, the mandible could be surgically advanced to an edge-to-edge incisor relationship and without occlusal contact in the posterior teeth, and then post-surgically, the lower anterior teeth could be orthodontically intruded so that the mandible rotates upwards and forwards for posterior occlusal contact and a better chin projection.

67.7 Treatment Protocol (Table 67.2)

The protocol variations between the conventional orthognathic surgery and SFOA can be clearly appreciated in the Table 67.2 highlighted in Bold fonts. A simulation of pre-

surgical orthodontic treatment using model mounting and set-up will compensate the pre-surgical orthodontic treatment.

67.8 Protocol Variations

Although the sequence of treatment is similar, different protocols are being used to prepare the patient for surgery, perform the operative procedure, and commence the orthodontic treatment.

67.8.1 Timing of Bonding

- Chung C Yu and Villegas [12]—1 week before orthognathic surgery
- Sugawara and Nagasaka [10, 11]; E Liou et al. [15]—Just before surgery
- Federico Hernandez [21]—brackets 10–14 days after surgery

67.8.2 Initial Arch Wires

- Liou et al. [15]—did not place any orthodontic arch wires before surgery
- Sugawara and Nagasaka [10, 11]—preferred 0.019″ × 0.025″ SS wires in 0.022″ slot

Placement of passive stainless steel arch wires bent and adapted to each tooth before surgery will preclude any untoward tooth movement during or immediately after the surgery. The authors wishing to capitalize on the RAP concept immediately after surgery prefer to place active nickel-titanium arch wires prior to surgery. Nonetheless, in doing so, the orthodontist loses an opportunity to observe the stability of the surgical correction prior to beginning of the tooth movement. The rapid acceleratory phenomenon not just influences the tooth movement but also can disturb the alveolar bone [8].

There are also protocol variations regarding the usage of surgical splints after the surgery among the various authors. While some authors suggested the use of the surgical splints only intraoperatively, others have advocated its use anywhere between 1 and 4 post-operative weeks. Nagasaka et al. have used removable Gelb-type splints post-surgery [10]. Kim's preference is to leave the splint in for about 1 month to 1 and a half months post-operatively and if an open bite is observed to use elastics between the splint and the mini-screws placed into the bone or to leave the splint for an even longer time period [8].

67.9 Procedural Guidelines for Model Mounting and Model Set-Up in SFOA (Fig. 67.3)

- Once the treatment planning and diagnosis is completed, impressions are made and customary model mounting is performed with bite registration to scrutinize the present state of the occlusion.
- In the model set-up, teeth that have adapted by natural compensation to the existing skeletal discrepancy are simulated and reorganized into anticipated occlusion similar to the preoperative orthodontic treatment plan. All the teeth on the set-up model are rearranged as if orthodontic treatment is done in the real patient in conventional orthognathic surgery technique into the desired preoperative occlusal relationship.
- Once the desired dental occlusion is set on the models, the amount of the skeletal movement required in the maxilla, mandible or both will become evident. Subsequently, a simulation of the actual orthognathic surgery is performed on the mounted models as in conventional technique. This will indicate the possible occlusal outcome of the standard approach.
- Intermediate and final splint can then be made on these mounted models as they are set up into the planned skeletal movements.
- With the advent of virtual planning and three-dimensional simulation softwares, the same set-up model surgery can be performed by scanning the physical models and bite registration details into the software, and the three-dimensional intermediate and final splints can be printed.

67.10 Surgical Procedures (Fig. 67.4)

The surgical procedures in the maxilla, mandible or chin are themselves performed using described standard techniques, whether it is the conventional technique or the SFOA technique.

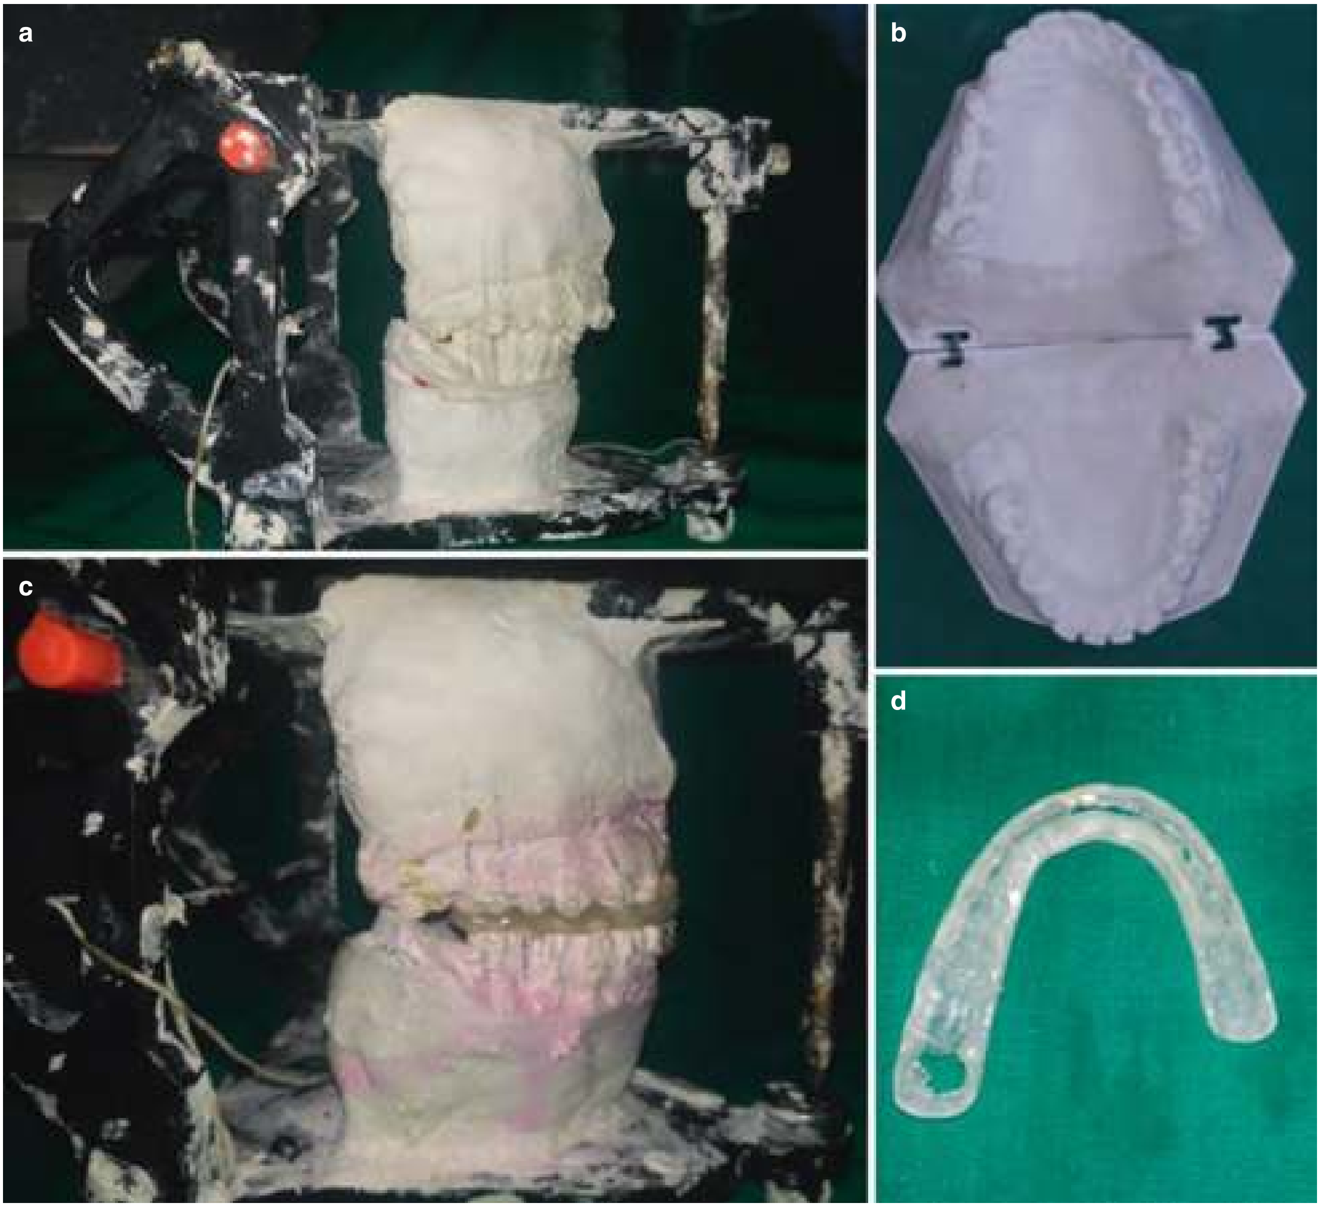

Fig. 67.3 (**a**) Standard model mounting. (**b**) Before the procedure, the teeth that have adapted to the skeletal discrepancy are simulated and reorganized into their predicted location, similar to real pre-surgical orthodontic treatment. (**c**) Simulation of actual orthognathic surgery is then performed. (**d**) Surgical splints fabricated to aid in real-time surgery

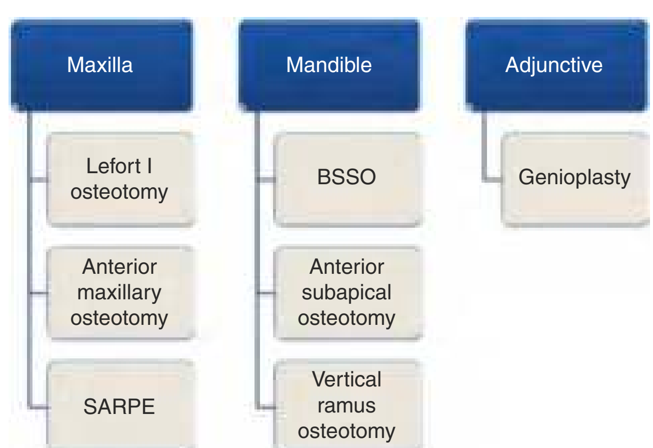
Fig. 67.4 Flow diagram showing various surgical procedures in each of the jaws



67.11 Advantages and Disadvantages of SFOA (Table 67.3)

Systematic review published by Peiró-Guijarro et al. [21] in 2006 reviewed 179 publications and finally selected 11 articles for final reporting. They found that the SFOA technique was most commonly reported in Class III skeletal malocclusion than in skeletal Class II malocclusion with prevalence of about 84.7%. The single largest advantage described was shortened treatment duration time owing to the RAP concept, and the disadvantage was potential error in predicting the post-operative occlusal outcome resulting in greater or lesser surgical movements of the jaws.

67.12 The Future of "Surgery-First" Approach

The future of SFOA technique lies in using augmented skull models, virtual orthodontic set-up to replace the mounted study model set-up and the computer-aided design and computer-aided manufacturing fabrication of intraoperative splints (Fig. 67.5). The 3D virtual orthodontic set-up will help the orthodontist to predict the eventual (at the end of orthodontic treatment) position and the axial inclination of each tooth scrupulously. This is a compelling step before the surgeon's skeletal base correction simulation, since the patient's prevailing occlusion

Table 67.3 Advantages and disadvantages of the surgery-first approach

Advantages
1. Total duration of treatment is shorter
2. The facial profile is improved from the commencement of treatment as a result of skeletal base correction
3. Patient and orthodontist satisfaction rates are high. High patient satisfaction is associated with improved cooperation during post-operative orthodontics
4. Orthodontic decompensation is efficient and effectual in response to the establishment of a proper maxillomandibular relationship and the regional acceleratory phenomenon
5. Surgical movements may not be curbed due to orthodontic constraints. There is more freedom to choose the surgical movement in accordance with the clinical requirement for individual patients
6. Patient recovery takes place expeditiously
7. When sleep-disordered breathing is the main indication for treatment, early maxillomandibular advancement increases the dimensions of the upper airway immediately
Disadvantages
1. Case selection is critical because the baseline occlusion cannot guide treatment objectives. Therefore, high clinical expertise, meticulous prediction of post-operative tooth movement and precise assessment of skeletal discrepancy are imperative
2. The bending procedure for a passive surgical wire is tedious and complex
3. Bonding and removal of the surgical wire are taxing; there is a relatively high bonding failure rate before and during surgery
4. The extent of surgical movements is necessarily greater, because surgical correction needs to make up for dental compensation
5. Impacted lower third molars could add difficulty to surgery
6. ost-surgical fluidity during bone healing could cause skeletal instability, and its impact on relapse has not yet been fully investigated
7. Orthodontic appointments should be scheduled more often than in a traditional approach. This could be stressful for the orthodontist
8. Constant correspondence between the surgeon and the orthodontist is indispensable

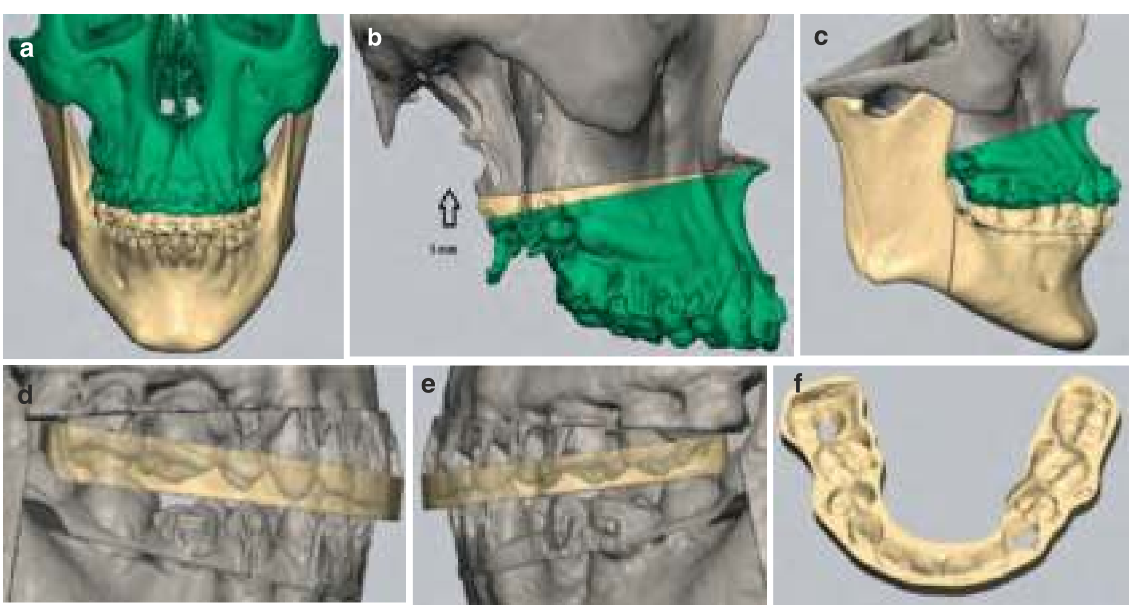


Fig. 67.5 The workflow demonstrating the pre-surgical orthodontic movement set-up (**a**), the surgical procedure on the maxilla (**b**), the procedure on the mandible (**c**), the post-operative ensuing dental occlusion with splint in situ (**d**, **e**) and the design of the final splint (**f**)

cannot serve as a guide for skeletal repositioning as it lies in a compensated state.

Usability of temporary anchorage devices (TAD) and interdental corticotomies is a factor which can add to the future of SFOA. The TAD permits a wider range of orthodontic vectors and avoids premature bracket loading with secondary troublesome dental extrusion. Interdental corticotomies can augment the RAP and further enhance the orthodontic treatment duration.

67.13 Conclusion

Performing orthognathic surgery even before any orthodontic tooth movement (SFOA) offers a unique advantage of addressing the patient's chief complaint at the very beginning, thereby improving the acceptance and compliance of the patient to overall treatment. It also offers the big advantage of significant decrease in total duration time by making use of the RAP. The final outcomes, in the way of facial aesthetics, dental occlusion and stability, are similar when using orthodontics-first and surgery-first approaches. However, it must be remembered that both the surgeon and the orthodontist must trend with care as there is a premium on patient selection and both should be involved as a team during every stage of the treatment, starting from diagnosis to debonding. Surgeon-orthodontist team should know the orthodontic principles and understand the limits of orthodontic teeth movement and must accommodate dental decompensation in their initial treatment planning. The surgeon should be capable of carrying out designated osteotomy and intermaxillary fixation with occlusion bite plate on misaligned dental arches and providing the stability after skeletal reposition. The future of orthognathic surgery is geared towards reducing the overall treatment duration without compromising the final outcome.DisclosureAuthors have no financial conflicts to disclose.

67.14 Case Scenarios

Case Scenario 1 (Fig. 67.6)

Case Scenario 2 (Fig. 67.7)

68 Orthognathic Surgery for Mandible

Varghese Mani

68.1 Introduction

Proper balance and harmony between the different parts of the face—forehead, eyebrows, eyes, nose, ears, cheeks, lips, mouth, jaws, chin, etc.—are the main factors deciding aesthetics. Aesthetic evaluation is mandatory to understand the problems systematically. During the primate evolution, jaws lost many functions, and the size suffered a gradual reduction, which resulted in an orthomorphic face. The facial muscles gained fine expression and smile, the exceptional features of *Homo sapiens*.

Mandible forms the movable lower part of the head. Mandible is attached to the upper part of the head by ligaments and musculature. It articulates with the glenoid fossa of temporal bone through temporomandibular joint, a synovial joint having translator and rotator movements (ginglymoarthrodial). These movements facilitate chewing and grinding functions. In our prehuman ancestors, the body of the mandible was parallel. In humans, since the brain case has expanded, the temporal bones were pushed apart, TMJ followed suit giving the lower jaw a parabolic contour. The Simian shelf reduced to genial tubercles to facilitate speech and to compensate and strengthen the jaw and the chin developed in humans. Metaphorically it is often stated that "the brain case has expanded at the expense of the jaws".

In some people, surgical repositioning of the mandible may be required to achieve an ideal facial form and restore functions such as mastication and breathing.

68.2 Surgical Anatomy of the Mandible (Fig. 68.1a, b)

Mandible is the sturdiest bone of the face with strong basal bone and the alveolar part housing the dentition. The near round protuberances seen bilaterally at the cephalic end of the mandible are called condyles, and they form its articulation with the TMJ. The mandibular condyles articulate with the temporal bone and help in the rotatory and translatory movements of the mandible as well as to transmit forces from the mandible to the skull base. A good understanding of the gross anatomy of the mandible is essential to understand its surgical implications. This needs to include the TMJ, the dentition, the supporting ligaments, and the muscles of mastication (Fig. 68.2a, b) and facial expression.

On the medial aspect of the vertical ramus is the mandibular foramen just posterior to halfway between the anterio-posterior width of the vertical ramus almost in line with the most concave part of the anterior border of the ramus. Just above is the lingula, a triangular prominence to which the sphenomandibular ligament is attached. Mandibular neurovascular bundle enters the mandibular foramen on the lingual side of the mandible and runs below the tooth roots in the body of the jaw, in the inferior alveolar canal. It curves upward and backward by about 2 mm and gives out the main branch, mental nerve, below the second premolar area, and gives sensory supply to the lower lip and chin [1].

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_68) contains supplementary material, which is available to authorized users.

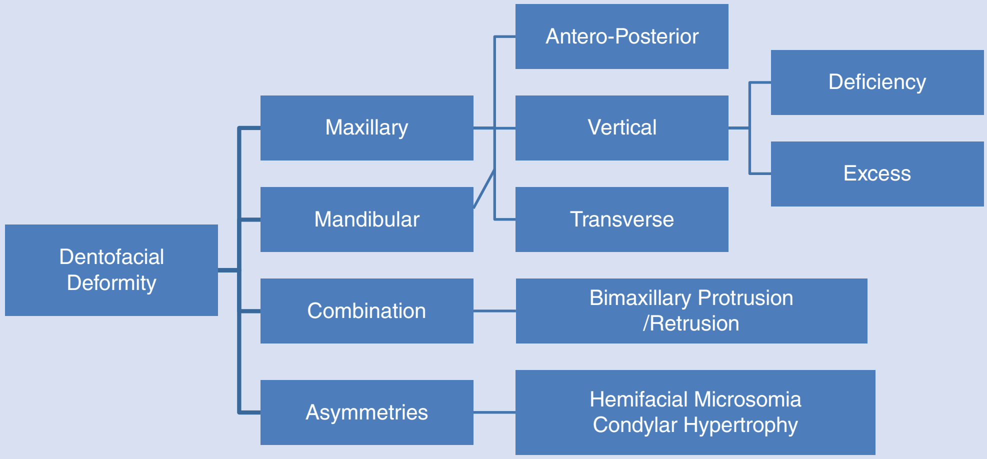
68.3 Classification of Deformities of the Mandible (Table 68.1)

Table 68.1 Classification of dentofacial deformities



> Deformities of the jaws can be associated with the dento-alveolar complex, the skeletal base or both.
>
> They may be either an excess or a deficiency.
>
> These problems can occur in three different vectors: Antero-posterior, Transverse and Vertical

Before venturing into the classification of the jaw deformities it will be appropriate to assess the relationship of the lower jaw to the rest of the face. Certain parameters are used to assess the deformity objectively. Clinical evaluation is the most important of them all. Face has to be assessed frontally and laterally.

Profile analysis of the face is the most important of them all—it could be convex, straight, or concave. Convexity can be due to protruded maxilla or retruded mandible/chin. Concave face can be due to retruded maxilla or prognathic mandible/chin (Fig. 68.3a, b, c).

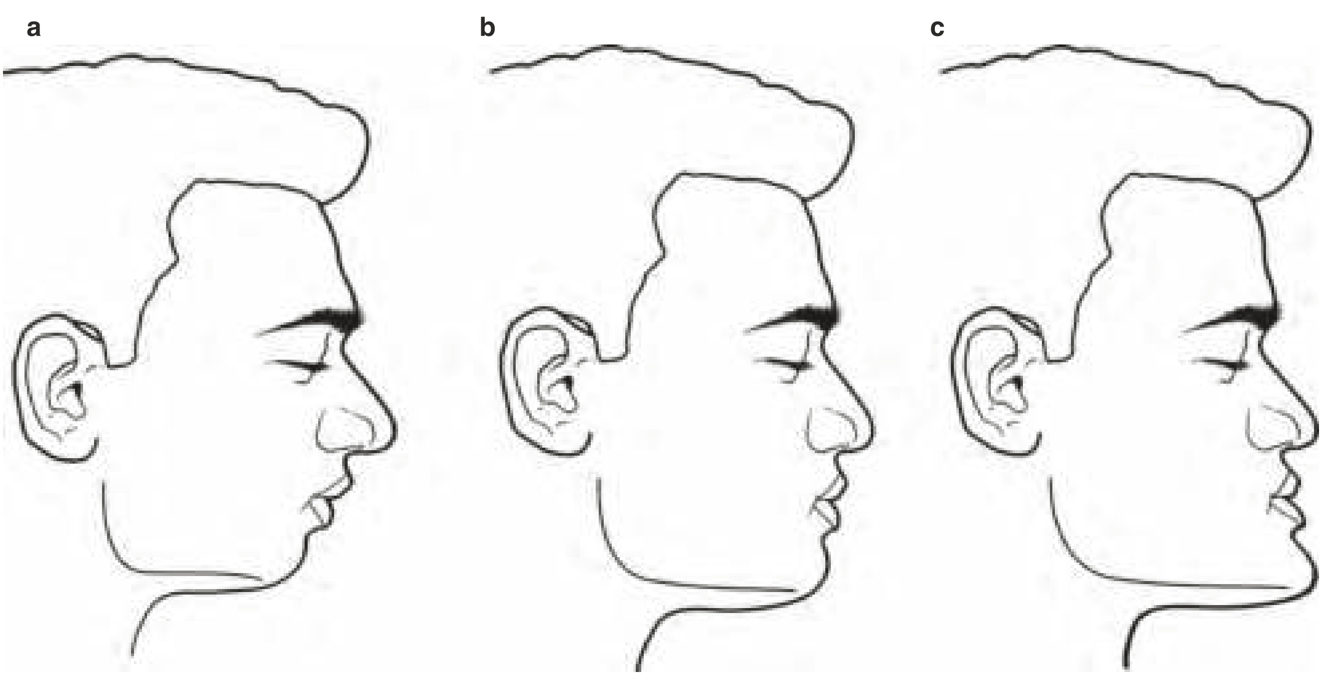


Fig. 68.3 On profile analysis face can be convex (**a**), straight (**b**), or concave (**c**)

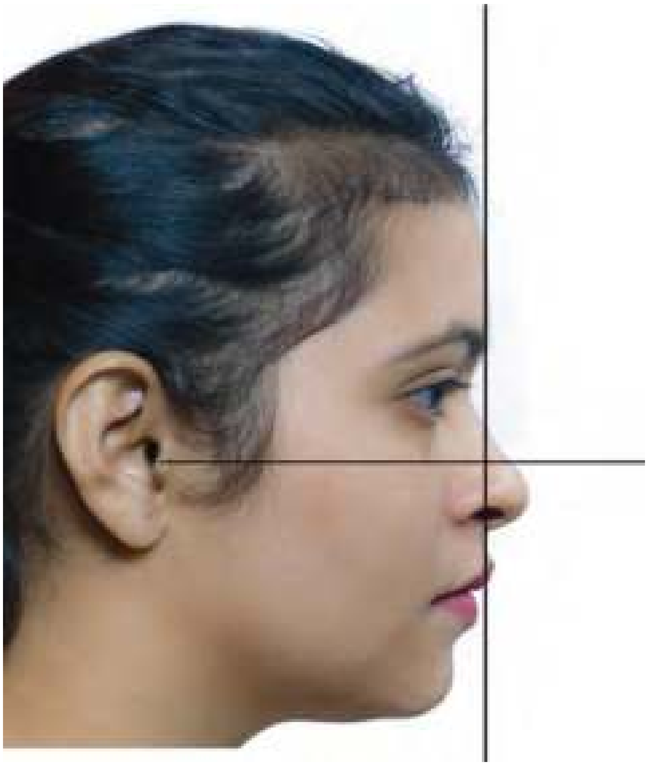

Fig. 68.4 Subnasale perpendicular to FH plane

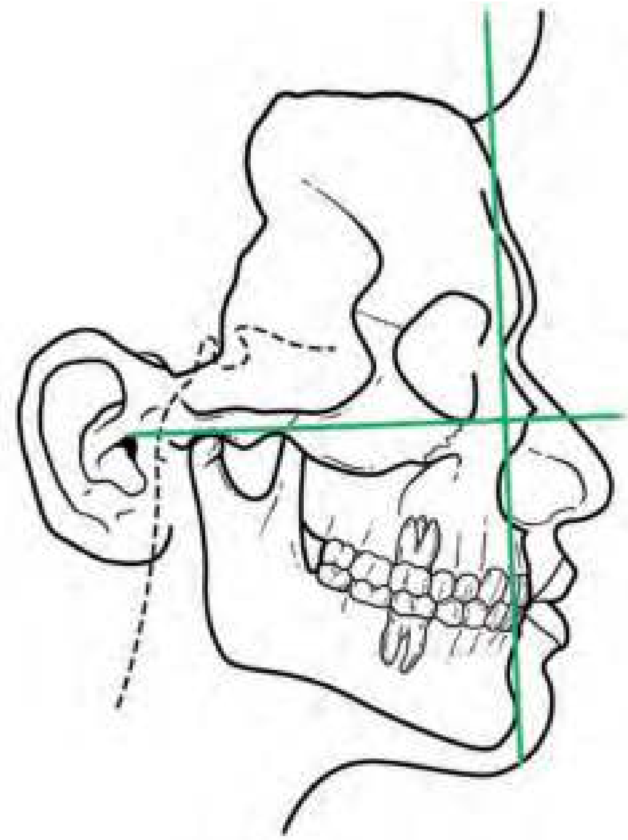

Fig. 68.5 Nasion perpendicular to FH plane

Subnasale perpendicular is another important tool for assessing the profile. A line is drawn perpendicular to the Frankfort horizontal plane through the point Subnasale. This line is expected to go through the upper vermilion border, 2 mm anterior to the lower vermilion border and 4 mm anterior to the soft tissue (Fig. 68.4) Pogonion. +/–2 mm is considered to be within normal limits. This is an important assessment tool for understanding the sagittal relationship of both the maxilla, mandible and dentition.

Likewise another perpendicular line is drawn from Nasion. (N. Perpendicular). This line is ahead by 5.3 ± 6.7 mm in males and 6.9 ± 4.3 mm in females. This indicates the position of mandible. Regarding the bony pogonion this line is ahead by 4.3 ± 8.5 mm in males and 6.5 ± 5.1 mm in females. This indicates the position of the chin. Angle SNB is 80 ± 2 normally. Less indicates retruded mandible and more indicates protrusion of mandible. All these measurements are in relation to the cranial base, the portion that is not changed in routine orthognathic surgery. (Fig. 68.5) (Refer Chap. 66 for further details).

- Mandibular prognathism
  - (a) Skeletal
  - (b) Dento- alveolar
- Mandibular retrusion
  - (a) Skeletal
  - (b) Dento- alveolar
- Mandibular Transverse Deformity
  - (a) Broad
  - (b) Narrow
- Chin Deformity-Excess
  - (a) Vertical
  - (b) Transverse
  - (c) Antero posterior
- Chin deformity deficient
  - (a) Vertical
  - (b) Transverse
  - (c) Antero posterior
- Deep bite deformity
- Open bite deformity(Apertognathia)
- Asymmetry

Specific conditions like presence of deep bites and open bites can occur with these clinical situations and may help us understand the dentoalveolar compensations that occur with them. Assessment of patients is done with facial analysis and cephalometrics.

68.3.1 Mandibular Excess

Common cause for mandibular excess is either developmental or genetic. Very large mandible may be associated with acromegaly.

The clinical features associated with mandibular excess are the following:

1. Prognathic mandible.
2. Anterior cross bite.
3. Elongated face.
4. Relatively long lower third of the face
5. Stomion-menton length—proportionately long.
6. Concave facial profile.
7. Lower lip and chin are more anteriorly placed than normal (SN perpendicular)
8. Class III relationship of occlusion.
9. Angle SNB—more than 82°.

68.3.2 Mandibular Deficiency

It is often due to genetical or developmental reasons. Ankylosis of temporomandibular joint, trauma to mandibular condyle and aplasia of condyle can also cause deficiency in mandibular growth.

Clinical features associated with mandibular deficiency are the following:

1. Bird face appearance.
2. Severe over jet.
3. Class II relationship of dentition.
4. Crowding of lower anterior teeth.
5. Flaring compensation of lower anterior teeth.
6. Face appears small.
7. Lower third of the face is short.
8. Stomion-menton is proportionately short.
9. Labiomental fold is usually absent.
10. Chin neck angle is obtuse.
11. Angle SNB—less than 78°.
12. Angle FHP N P—less than 82°.

68.3.3 Deformities of Chin

Deformities of chin could be three dimensional—vertical, anterio-posterior, or horizontal.

Vertical and anterio-posterior excess of chin are usually associated with mandibular prognathism. Though in prognathic mandible, chin appears prominent, it need not be so in objective analysis. Hence it is essential that the chin be assessed independently in relation to the other structures. To assess the vertical discrepancy, the best technique is to measure the length from stomion of the lower lip to the menton and compare this to the length obtained from measuring the subnasale to stomion of the upper lip, in rest position. The former should be double the latter normally.

68.3.4 Facial Asymmetry

The reasons for facial asymmetry are many.
A few of the etiological factors are the following:

1. Hemifacial microsomia/dysplasia
2. Unilateral cleft lip and palate, and other unilateral clefting syndromes
3. Childhood trauma especially to the condyle
4. Discrepancy in blood supply to the maxillofacial region
5. Habits
6. Early unilateral loss of teeth
7. Faulty use of functional appliances
8. Pathologies and childhood surgeries of the face

Asymmetry could be pan facial or limited to certain areas. Frontal analysis is the ideal method to assess asymmetries. Drawing vertical and horizontal parallel lines on the face will help to locate the area of asymmetry. This can also be done using a grid. PA cephalogram and frontal photographs are helpful in analyzing facial symmetry.

Orthognathic surgery to the mandible involves numerous procedures that facilitate the correction of deformities of the mandible and its dentoalveolar complex in all planes of space. This encompasses a wide array of techniques which may be classified based on the anatomical location they are applicable to.

Osteotomies of the Mandible

1. Dentoalveolar complex
   (a) Anterior subapical
   (b) Total subapical
2. Midline symphyseal osteotomy
3. Body osteotomy
4. Ramus Osteotomy
   (a) Vertical sub-sigmoid osteotomy—intra- and extraoral
   (b) Sagittal split ramus osteotomy (BSSO)
5. Subcondylar osteotomy

The discussion of all the techniques is beyond the scope of this chapter, and hence, detailed description of the vertical ramus osteotomy, the sagittal split ramus osteotomy, and theÚnterior subapical osteotomy are provided here.

68.4 Ramus Osteotomies

Movement of the mandible in the antero-posterior direction is usually achieved by ramus osteotomy. Limberg in 1925 reported subcondylar oblique osteotomy [2]. Thomas, Robinson, Shira, and others described buccal osteotomy which involved the ramus. Later, Caldwell and Letterman (1954) described vertical subcondylar osteotomy by extraoral approach, which became very popular [3]. This technique minimized trauma of the inferior alveolar neurovascular bundle.

In 1927 Wassmund described the inverted "L" osteotomy. Though the primary indication was mandibular prognathism, many surgeons advocated vertical osteotomy and certain modifications like inverted "L" osteotomy [4] and "C" osteotomy for advancement of the mandible [5]. Bone grafting has to be done to fill the gap created (Fig. 68.6).

In 1937 Lane described a sagittal osteotomy. Obwegeser modified the Lane's technique in 1955, and the technique of sagittal split osteotomy is credited to him. Sagittal split is a versatile technique and has the following superiority over others [6]. It gives great flexibility in repositioning the distal tooth-bearing segment. There is better cancellous bone contact, which enhances healing. The alterations in the position of the condyles and muscles of mastication are minimal. There is no extraoral scar. Injury to the marginal mandibular nerve is avoided. However, chance of injury to the inferior alveolar neurovascular bundle is high [7].

Dal Pont made the modification to sagittal split by a vertical cut through the lateral cortex [8]. Hunsuck extended the medial cut only to a point above the lingula. This minimized trauma to overlying tissue [9].

68.4.1 Extraoral Vertical Ramus Osteotomy

This was one of the most popular procedures for correcting mandibular prognathism. Rigid internal fixation techniques and certain modifications like "C" osteotomy and inverted "L" osteotomy have been used for advancement of the mandible. After "C" or "L" osteotomy, the gap created while advancing or rotating the distal segment is filled with bone graft [10].

The major disadvantages are the external scar and the possible inadvertent damage to the marginal mandibular nerve. With judicious care, these problems can be minimized. Better visibility is the major advantage (Fig. 68.7).

Surgical Technique:
Submandibular skin incision is placed, about 1.5 cm below the angle of the mandible. The incision is taken down to the platysma, which is then divided. Marginal mandibular nerve lies below the platysma running parallel to and often below the lower border of the mandible, crossing the facial vessels superficially as it passes upward. Attempt should be made to identify this structure and preserve it.

After identification and protection of the marginal mandibular nerve, dissection is carried down to the bone. The periosteum is incised over the angle. The periosteum is reflected superiorly to the level of the sigmoid notch on the lateral aspect of the ramus. Coronoid process may be cut in cases when more than 1 cm of posterior movement is required (Fig. 68.8).

Lateral aspect of the ramus is inspected for a small bulge corresponding to the lingula. This helps to identify the mandibular foramen. Osteotomy is performed posterior to the anti-mandibular foramen bulge so that the mandibular nerve is not injured. (The position of the bulge is arbitrary and not definite.) A vertical bony cut is made starting at the sigmoid notch and progressing to the lower border near the angle of the mandible. Condylar segment is separated from the distal part of the mandible and is detached from the medial pterygoid muscle. The condylar part is

Fig. 68.6 Inverted "L" osteotomy of the ramus used for advancing the mandible

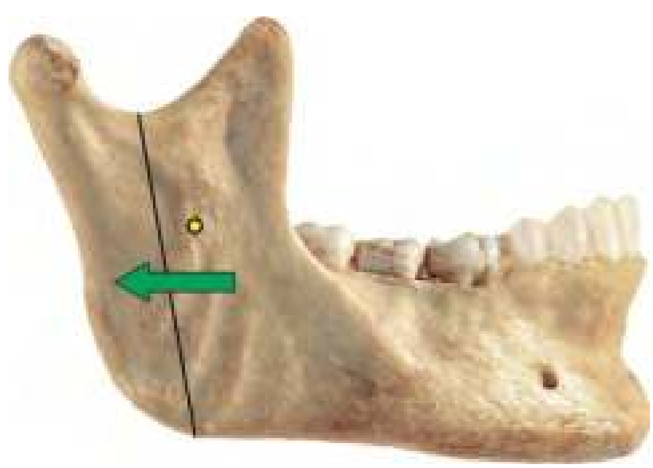

Fig. 68.7 Subsigmoid vertical osteotomy was the most popular technique before the introduction of sagittal split osteotomy. This technique is used for correcting mandibular prognathism

Fig. 68.8 When the push back required in subsigmoid vertical osteotomy is more than 1 cm, sectioning of the coronoid process helps in better stability

laterally placed on the distal segment. After packing the wound, the same steps are followed on the contralateral side.

The mandible is repositioned into the desired position with the help of the splint, and intermaxillary fixation is done. The site of surgery is again approached. Some surgeons prefer to leave the condyle as such on the lateral aspect without any transosseous wiring. There is no consensus regarding the decortication of the opposing surfaces.

Removal of bone or decortication may be done if it helps the condyle to achieve a proper position within the glenoid fossa with minimal displacement. Decortication helps better contact of the cancellous bone enhancing healing. Stabilization of the fragments by transosseous wires or screws and plates can be done. Rigid internal fixation eliminates intermaxillary fixation. Except in rigid internal fixation, intermaxillary fixation for a period of 4–6 weeks is mandatory. After the fixation is removed, elastics may be used to guide the movements.

Wound closure is done in layers. Skin may be closed by monofilament 6-0 or smaller sutures. A pressure dressing is applied for the first 24–48 h. Drain is usually not necessary and, if done, has to be done through a separate stab incision below the main incision. Sutures are removed after 5–7 days, and the wound is supported by dressing for a period of another 1 week, if required.

Complications are usually rare. Bleeding may occur due to injury to the retromandibular vein or masseteric artery where it crosses laterally through the sigmoid notch. Bleeding can be controlled by routine methods like pressure packs, ligation, etc. Injury to the marginal mandibular nerve is another possibility. A transitory deficiency in the function of the lower lip may be anticipated due to traction on the nerve. This often recovers completely. In case of sectioning of the nerve, micro-surgical repositioning is advised.

If care is taken in closure, and infection is avoided, scar formation is minimal. If scar is formed, revision may be done subsequently (Fig 68.9a–d).

68.4.2 Sagittal Split Osteotomy

Sagittal split osteotomy (SSO) can be employed for correcting both retrognathism and prognathism. Modifications by Dal Pont, Hunsuck, and Epker have made the procedure simpler and more acceptable biologically. Schuchardt and Lane described sagittal split osteotomy of the vertical ramus [11]. It was Obwegeser who popularized it. His medial cut was above the mandibular foramen, and his lateral cut was below that of Schuchardt's and extended to a part just above the angle, at least 25 mm below the lingual cortical cut. Obwegeser and Trauner in 1955 described the bilateral sagittal split osteotomy [6].

Dal Pont in 1961 made a major modification by extending the cut anteriorly and making the vertical cut just below the second molar [8]. Hunsuck in 1968 modified the cut in the medial cortex of the vertical ramus, limiting the cut to just behind the mandibular foramen. Postoperative complications got reduced [9] (Fig. 68.10a, b).

Bell and Schendel and Epker extended the vertical cut on the buccal side to the lower border of the mandible reducing the incidence of wrong splits [12, 13]. A reciprocating osteotomy saw, which is specifically meant for the inferior border (right and left) may be used to perform inferior border osteotomy [14].

Performing an inferior border osteotomy results in much lower incidence of persisting inferior border defects. Hence, during advancement of the mandible, it is advisable to exclude the lingual cortex in the split. Piezosurgery has been compared with conventional surgical drills/saws by several authors for BSSO. They have reported substantially longer surgery time for piezosurgery. Image-guided surgery has also become popular in the recent years, and this allows the surgeon to track the position of the instruments and segments during the operation in real time. Modern intraoperative navigation systems are being used in orthognathic surgery also [15].

A. Incision and Dissection:

Incision is placed over the region of the ramus to the mid ramus. It is carried over the external oblique ridge, extends up to the first molar region, and curves down to the buccal vestibule.

Initially only the mucosa is incised over the ramus region. Retracting the tissue buccally, before incision, prevents the exposure of the buccal pad of fat, a troublesome interference, during surgery. Sharp dissection at the ramus is continued to the periosteum, using scissors, knife, and periosteal elevators.

Periosteal elevation of the lateral aspect of the mandible at the molar region is performed down to the inferior border. On the ramus, lateral dissection may be kept minimal but enough to achieve proper visibility and access.

Medial dissection is done very carefully on the medial side of the ramus. The level of the lingula and the entry of the inferior alveolar nerve into mandibular foramen are visualized. This is usually in level with the deepest concavity along

Fig. 68.9 Mandibular prognathism corrected by subsigmoid vertical osteotomy of the ramus on both sides to set back the mandible. (**a**, **b**) Preop pictures, (**c**, **d**) postop pictures

the anterior border of the coronoid and ramus. With a small flexible Freer Elevator, the tissue is dissected taking care not to perforate the periosteum on the medial aspect. Dissection should be above the level of the mandibular foramen. Using a bigger elevator, the medial aspect of the mandible above the lingula is exposed subperiosteally. (Perforation of the periosteum not only induces bleeding but may injure the mandibular nerve.) Sigmoid notch is identified for better orientation. Subperiosteal dissection should be minimal, but enough to retract the tissues medially without much traction on the mandibular neurovascular bundle [16].

B. Osteotomy (Videos 68.1 and 68.2):

Osteotomy is initiated by cutting the cortical bone above the lingula on the medial side. This cut should extend behind the mandibular foramen but need not be up to the posterior border of the ramus (about half to two-thirds of the anteroposterior dimension of the ramus). The cut is taken downward along the external oblique ridge to the second or first molar region. The depth of the cut should be minimal, just enough to reach the cancellous bone (Figs. 68.11 and 68.12).

Conventionally the vertical cut is made at the second molar region as the bone is thicker there. The CT analysis conducted by Y Tsuji et al. on prognathic mandible demonstrated that the mandibular thickness of the mandible increased along the mandibular foramen toward the mandibular body. The mandibular canal was located relatively lingually at all sites. They also observed that marrow space, located on the buccal side, was thicker at the region of mandibular body [17].

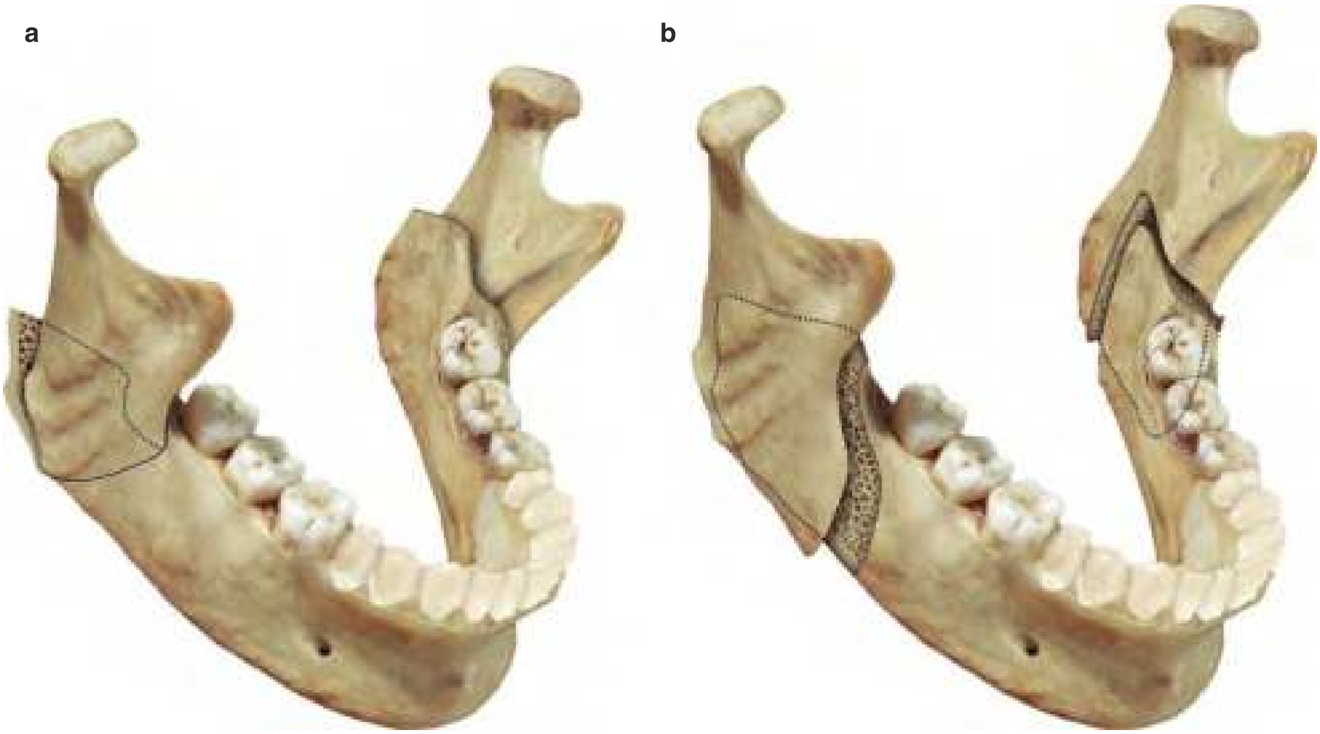

Fig. 68.10 Bilateral Sagittal Split Ramus Osteotomy (BSSO/BSSRO). (**a**) Obwegeser split: Initially the medial cut in sagittal split osteotomy extended up to the posterior border, and when the distal segment was pushed back, the margin used to jut out, which had disadvantages like relapse tendency and injury to the retromandibular tissues. (**b**) Hunsuck split: At present the medial cut is taken above the mandibular foramen much short of the posterior border but behind the foramen. The complications are much less (also see Fig. 65.12b)

Fig. 68.11 The medial cut is taken above and behind the mandibular formen and deepened to the cancellous bone

Fig. 68.12 The cut is extended obliquely through the anterior border of the mandible to the buccal plate and taken downward at the level of the first or second molar region, up to the inferior border. Only the cortex need be cut. Deeper cuts could injure the inferior alveolar nerve and may cause wrong splits (also see Figs. 69.31 a–c and 70.24 c, d)

A study on cadaveric mandible by Promma et al. reported that the thickness of buccal cortex to the mandibular canal is about 6.5 and 5 mm at the second molar and first molar regions, respectively [18].

Some surgeons prefer to take the cut more forward to the first molar region. This gives better accessibility for intraoral plating. When the vertical cut is made, it is mandatory to protect the soft tissue over the inferior border by using a channel retractor. If the vertical cut includes the inferior border, the direction of the split is controlled. A rotary instrument or a reciprocating saw is used for cutting. Once the cortical cut is completed, a small spatula osteotome is malleted to the site beginning from the medial cut to the vertical cut. Osteotome should be directed laterally just beneath the cortical plate so that the neurovascular bundle is not injured. Larger osteotomes are used, and slowly the fragments are pried apart using a smith spreader (Fig. 68.13).

As the splitting takes place, the neurovascular bundle is visualized, and care is taken to maintain it to the medial fragment. If it is attached to the proximal segment, the NV bundle is freed with a periosteal elevator. Next the fragments are pried apart using the spreader. The procedure is repeated on the opposite side.

Sagittal split osteotomy can be used for either mandibular advancement or setting back. If mandibular advancement is to be done, the medial pterygoid muscle is separated from the inferior border of the distal segment with a periosteal elevator. When the mandible is set back, medial pterygoid and masseter may have to be stripped, if needed, to prevent the displacement of the condylar segment posteriorly. Posterior stripping of the pterygomasseteric sling in SSO should be minimized to the antegonial notch. In excessive stripping, possibility for avascular necrosis increases [19].

Fig. 68.13 A spreader is used to split the mandible at the ramus region

When the tooth bearing segment (distal segment) is pushed back, the buccal plate of the condylar segment (proximal segment) overlaps the distal. This overlapping part is excised, and the proximal segment is allowed to rest on the cancellous part without any tension (Fig. 68.14).

Pushing the mandible backward reduces the space in the oral cavity. The tongue may not have enough space, and sometimes this induces tongue thrusting, snoring, etc. Some authors advocate reduction glossectomy to improve function related to airway speech and mastication. They also opine that reduction glossectomy improves aesthetics and controls unfavorable mandibular growth [20].

Mommaerts reported that mandibular lengthening done through endoscopic surgery, with transoral osteosynthesis, reduced stripping of the periosteum and therefore consequent edema [21]. In certain clinical situations Unilateral sagittal osteotomy is performed. Refer case scenario in Fig. 69.31 (Maxillary orthognathic surgery Chap. 69) where an unilateral sagittal osteotomy was combined with maxillary osteotomy to correct canting of the maxilla.

C. Stabilization and Fixation:

Rigid internal fixation (RIF) using plates and screws or lag screws is the preferred way of fixation. Prior to RIF, the position of the jaw is adjusted, and intermaxillary fixation is done with splint in position. Both fragments are allowed to be in passive position before RIF is performed. Intermaxillary fixation (IMF) is removed after rigid fixation. However, some surgeons prefer to keep the IMF for 1 week. For rigid fixation 2.5 mm four-hole mini plate with gap is used for push back (Fig. 68.15). Longer plates are used for advancement. Multiple lag screws can also be used. Skeletal rigid fixation has been shown to reduce relapse following mandibular advancement [22–24] (Figs. 68.16a, b, c, and 68.17a, b, c).

Fig. 68.14 Excess of the buccal plate is cut off when the intention is to push the mandible backward

Rachmiel et al. in their study found improved stability with four-hole plate and monocortical screws, with a relapse rate of about 18% only [25].

Based on a 10-year experience of using bioresorbable plates in orthognathic surgery, Laine P et al. opine that these devices are safe to be used. Relapse rate with bioresorbable screws is the same as with metal in SSO [26]. Another method of fixation is wiring. If resorting to wiring, intermaxillary fixation has to be kept for 5–6 weeks. Maturation of soft and bony tissues continues at the surgical site and approximates that of non-surgical sites at 12 weeks postoperatively [27–29].

Fig. 68.15 Rigid fixation after sagittal split osteotomy of the mandible using mini plate

The inferior alveolar nerve is less likely to get damaged when monocortical screws are used. These screws also allow for readjustment if there is any inadvertent malposition during surgery can be readjusted more easily [30]. An in vitro study on sheep mandibles found that both mini plates and bicortical screws resulted in a similar level of stability [31]. (Figs. 68.18a, b, c, d, 68.19a, b, c, and 68.20a, b, c).

D. Wound Closure:

Wounds are irrigated well and bleeding is controlled by routine methods. If there is continued bleeding drain is indicated. Wounds are closed by 3-0 Vicryl sutures.

E. Postoperative Sequelae:

Edema is expected after sagittal split osteotomy. It resolves within 2 weeks. Edema at the angle is the last to resolve. Suction drainage minimizes tissue edema following mandibular surgeries. Betamethasone administration significantly reduces postoperative edema. Widar H. et al. has also observed less bleeding intraoperatively, but no difference in neurosurgery disturbances [32].

Diminished sensation over the lip is experienced by most of the patients and is mainly due to traction on the neurovascular bundle. If there is no injury to the neurovascular bundle, sensation returns within a few weeks. More than two-thirds of the patients experience some sensory deficit even after 1 year. However, most of the patients get adjusted to this altered sensation and are satisfied with the overall result. Limitation of movements of jaw in all direction after osteotomy is often experienced. Sagittal split advancements often cause significant limitation of range of motion [33].

Fig. 68.16 Bilateral sagittal split osteotomy to set back the mandible, with rigid fixation. (**a1**, **b1**) Preoperative photographs. (**a2**, **b2**) Postoperative photographs. (**c1, c2**) Pre and post operative lateral cephalograms with superimposed tracings

Fig. 68.16 (continued)

Physiotherapy following rigid fixation showed minimal limitation [34].

F. Complications:

Important complications associated with sagittal split osteotomy are:

1. Bad split
2. Injury to the neurovascular bundle
3. TMJ problems
4. Excessive bleeding
5. Relapse

1. Bad Split:

A systematic review of fracture patterns in sagittal split was analyzed by Steenen and Becking and reported 2.3% bad splits in sagittal splits. The most common was buccal plate fracture of the proximal segment and lingual plate fracture of the distal segment. Coronoid and condylar neck fractures were seldom [35].

Wrong split usually occurs in cases where the last molar is removed at the time of surgery. Hence it is advised to have the third molar removed (if needed) about 6 months

Fig. 68.17 Case of mandibular prognathism with maxillary deficiency, managed by maxillary advancement and mandibular set back by BSSO. (**a1**, **b1**) Preop pictures. (**a2**, **b2**) Postop pictures. (**c1**) Preop cephalogram. (**c2**) Postop cephalogram

prior to the osteotomy. If the lingual cortical plate is broken, soft tissue separation from the lingual plate should be kept to the minimum, so that the blood supply is not jeopardized. Patients with a shorter ramus and buccolingually thin mandible are more susceptible to wrong split during SSO [36]. Advanced age can increase the risk of a bad split. Use of a spreader helps to reduce the incidence of wrong splits.

2. Injury to the Neurovascular Bundle:

Care should be taken to maintain the continuity of the neurovascular bundle. If it is transected, ideally the cut ends are micro-anastomosed. However, in common practice, where a micro-surgeon may be unavailable, it is advisable to perform direct suturing to attain epineural approximation. With a repositioned and repaired neurovascular bundle, the sensation is recovered though the period it takes is longer.

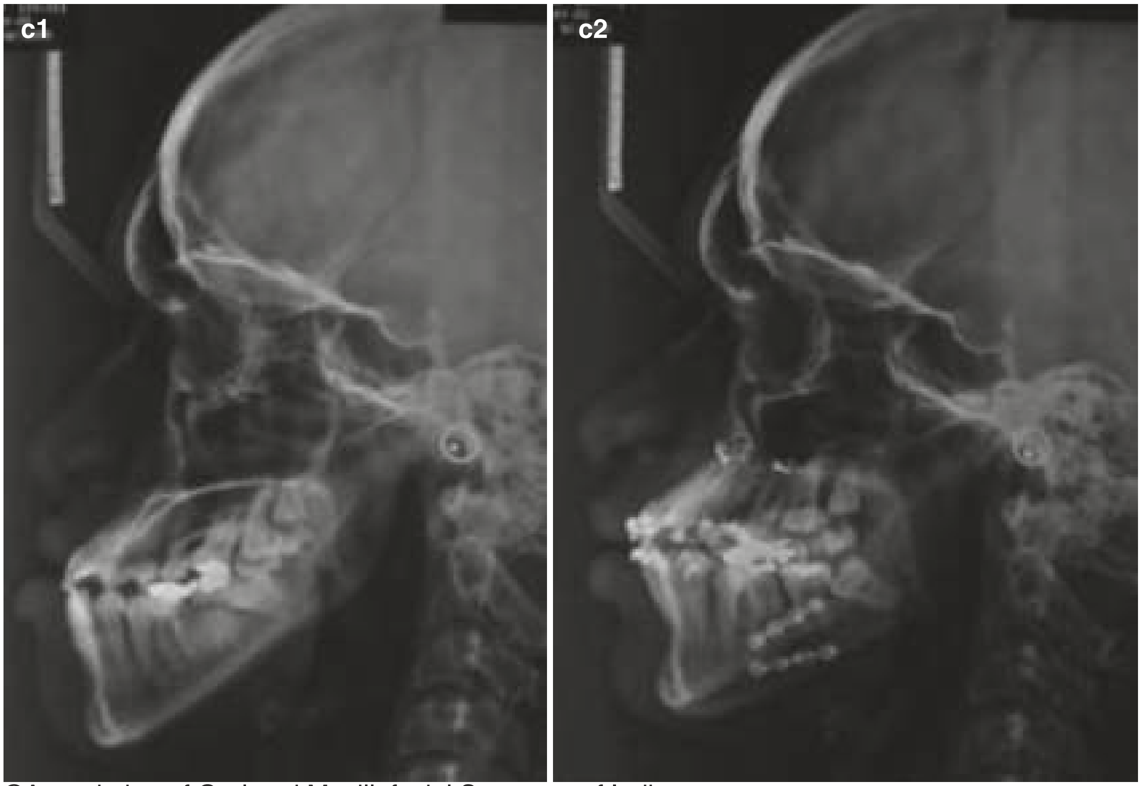

Fig. 68.17 (continued)

Long-lasting neurosensory deficiency (NSD) was underestimated by the surgeons as compared to the patient's subjective symptoms. Long-lasting NSD was reported as 7.5% (Questionnaire) and 3.8% (Record), after intraoral vertical ramus osteotomy, and as 11.6% (Questionnaire) and 8.1% (Record) after sagittal split osteotomy [37]. Vertical subsigmoid osteotomy with rigid fixation may be considered as a viable alternative if it is important to avoid alterations in sensation, whereas BSSO maybe preferred if retromandibular scar is of concern. Neurosensory disturbance, after SSO with additional genioplasty, is more than after SSO alone [38].

3. TMJ Problems:

Care should be taken while plating the segments. Improper plating can pull or push the condyle to an untoward position. Postoperative X-rays are taken to assess the situation. If needed, the displacement has to be corrected by returning the patient to surgery. Displacement of the condyle from the fossa is one of the main reasons for relapse [24, 39] (Fig. 68.21).

Beukes J. et al. in 2016 studied condylar rotational tolerance in BSSO treatments and reported a range of 10°–15° after orthognathic surgery.

Unilateral SSO is a safe procedure in lateral prognathism of mandible due to unilateral condylar hyperplasia or traumatic malocclusions [40]. The condyle that was not operated on, only rotated 3–4° within the glenoid cavity, and it was established that this is within the range of functional articular adaptation [41]. Mendez-Manjon R. et al. observed that mandibular advancement by BSSO can positively displace the condyle especially on the posterior aspect [42].

In their study Borstlap et al. observed that in sagittal split advancement postoperatively, 8% of patients showed postoperative condylar resorption. Patients of relatively low age are at risk of condylar alterations or resorption. Occurrence of pain and TMJ sounds in the first few months postoperatively are highly indicative of condylar changes to occur in the preceding months [43]. Predisposition in females for condylar resorption after sagittal split osteotomy may be attributed to

Fig. 68.18 A case of left unilateral ankylosis of the TMJ resulting in trismus and facial deformity. Treated by release of ankylosis by gap arthroplasty, temporal myofacial flap interposing, and extended lateral sliding genioplasty. (**a**) Pre operative picture before ankylosis correction (**b**) frontal view with facial asymmetry (**c**) after release of ankylosis, (**d**) after correcting facial asymmetry

the modulation of biologic response, by estrogen and prolactin [44]. Mobarak compared the skeletal stability of postoperative changes in low angle and high angle Cl II patients following mandibular advancement. High angle had more horizontal skeletal relapse due to condylar movement in a superior direction. Changes in intercondylar angle and width after BSSO advancement or set back may influence TMJ function [45–48].

4. Excessive Bleeding:

Bleeding can be from inferior alveolar neurovascular bundle, medullary bed, and facial vessels or rarely from retromandibular vein. Bleeding from the former two can be controlled by local measures; but the facial vessels will have to be clamped and tied, for which an extraoral incision may be required. Using the channel retractor with a cup to hold the inferior border and cutting with a Steiger-type carbide bur (this has side cutting and rounded cutting end and cuts bone with minimal injury to the soft tissue) prevents injury to the facial vessels.

Injury to the retromandibular vein is very rare and is due to inadvertent injury to the soft tissues behind the mandible. Bleeding can be controlled by absorbable gelatin sponge. Excessive oozing can cause significant edema, and if oozing is present, a drain may be placed.

68.4.3 Vertical Ramus Osteotomy: Intraoral Approach

It was Caldwell and Letterman who developed the intraoral vertical ramus osteotomy in 1954 [3]. Later in 1964, this was described by Moose [49] and Winstanley in 1968 [50], and modifications have been suggested by many others. Intraoral approaches medially and laterally to ramus were described [49, 50]. Herbert and associates in 1970 described the use of special oscillating saw and popularized the intraoral technique to reach the ramus (Fig. 68.22).

The procedure overcomes the disadvantages of extraoral vertical ramus osteotomy. The advantages are the following: (1) external scar is avoided and (2) there is no injury to the marginal mandibular nerve. The advantages over sagittal split osteotomy are that injury to the mandibular neurovascular bundle is avoided. The main disadvantage is the difficulty in access and visualization of the area. However, there is a delay in healing and possibility of projection of antegonial notch [51]. Mandibular nerve hypoesthesia can be expected to improve faster in young patients than the older ones. So IVRO may be a better option for elder patients [52].

Surgical Technique

A mucosal incision is made along the anterior border of the mandibular ramus. This is extended to the coronoid process and extended laterally up to the first molar area and subperiosteally dissected to expose the sigmoid notch, inferior border, and the posterior border of the ramus. Two fibro-optic lit Bauer retractors (left and right) are used—one on the sigmoid notch and the other at the angle area to get excellent exposure of the ramus. An oscillating saw angled at 105° is used to do the osteotomy. The cut is made posterior to the ante lingula prominence and directed superiorly to the sigmoid notch and inferiorly to the mandibular angle.

If circummandibular wiring fixation is planned, the medial aspect of the ramus above the lingula is dissected subperiosteally to the posterior border. The width need only be enough to pass the wires.

Osteotomy, as in the extraoral approach, extends from the sigmoid notch to the inferior border behind the entry of the mandibular nerve. The intraoral vertical cut should be made no more than 5–7 mm anterior into the posterior border. This will be behind the mandibular foramen [53]. According to some, ante lingual prominence as a landmark is unpredictable [54].

Fig. 68.20 Case of open bite managed by BSSO. (**a1**, **b1**) Preoperative pictures. (**a2**, **b2**) Postoperative pictures. (**c1**) Preoperative lateral cephalogram. (**c2**) Postoperative lateral cephalogram

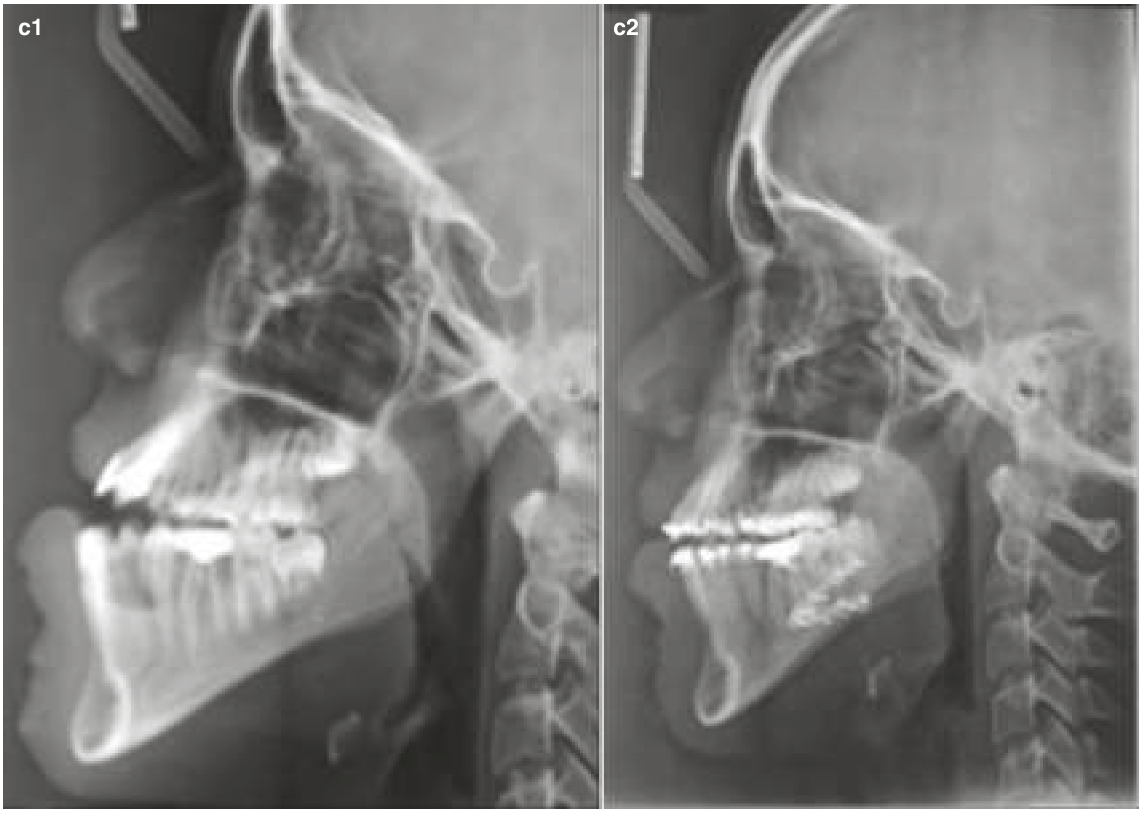

Fig. 68.20 (continued)

Fig. 68.21 Displacement of the condyle due to torquing as demonstrated here in a vertical ramus osteotomy, is the most common reason for TMJ problems

For better access, as well as visibility and mobility of the fragments, the coronoid process can be separated using a reciprocating saw. The coronoid process is allowed to retract with the temporal muscle.

An appropriate retractor with a cup at the end can be held hooked to the posterior border, and the soft tissue is held retracted laterally. Care should be taken to orient the cut and also to prevent injury to the soft tissues.

After the osteotomy, the condylar segment is overlapped laterally over the mandible. Medial pterygoid attached to the medial aspect may be stripped in the anterior region of the segment to facilitate tension-free positioning of the condylar segment. The same osteotomy is performed on the opposite side, and intermaxillary fixation is maintained for 6 weeks. Extraoral approach for vertical subsigmoid osteotomy is advocated for large mandibular set back of greater than 10 mm [55, 56].

Over correcting the mandibular set back by 2 mm to provide compensation for relapse is also recommended [57]. The use of skeletal wire fixation seems to stabilize the initial movement, but does not influence long-term relapse [58].

Ghali and Sikes have reported that IVRO improves TMJ functions and relieves TMJ symptoms more effectively when compared with SSRO, due to the final position of the condyle more anteriorly and inferiorly which

Fig. 68.22 Diagram for intraoral subsigmoid vertical osteotomy

results in an increased joint space and better disk-condyle relationship [59].

Raúl González-García described endoscopically assisted intraoral vertical ramus (IVRO) and subcondylar (ISCO) osteotomies for the treatment of symmetric mandibular prognathism. He claimed the use of saw and bone chisel under the continuous control of the endoscope provides a safer approach since the osteotomy is controlled during the whole process and provides complete visualization of the osteotomy site [60].

Stabilization, Fixation, and Wound Closure

Most surgeons use circummandibular or transosseous wires. Rigid internal fixation using plates is rather difficult to place and carries greater risk of injury to the mandibular nerve. Lag screws or mini plates are sometimes used.

Intermaxillary fixation for a period of 6 weeks is advised, if rigid fixation is not used. Wound closure is done as in sagittal split, adhering to the basic principles.

TMJ Considerations

Radiographically there is an anterior downward and forward movement of the condyle after ramus osteotomy. However, there is a tendency to return to its preoperative position [61–63]. Double contouring of the condyle after 6 months was reported which is attributed to condylar remodeling [64]. Remodeling of the glenoid fossa also has been documented [65]. Complications and their management are very much similar to those of sagittal split.

68.5 Body Osteotomy of Mandible

This was one of the earlier procedures used for mandibular prognathism. Blair reported a body osteotomy at the premolar level for mandibular prognathism in 1906 [19]. Since the advent of the ramus procedures, body osteotomy has lost its popularity. However, in certain conditions, body osteotomy may have to be resorted to.

Surgical Procedure

Depending on the site of osteotomy, soft tissue dissection varies. The basic principle is to reflect the buccal mucoperiosteum down to the inferior border taking care not to injure the mental nerve, but at the same time, exposing it.

The next step is to remove the buccal cortical plate from the mental foramen region backward to behind the osteotomy/ostectomy site for release of the neurovascular bundle. The tooth at the osteotomy site is extracted.

Using a fissure bur, the outer cortical plate is marked and a window is cut. Using curettes and chisels, the cancellous bone around the neurovascular bundle is removed. The nerve is released using a nerve hook. Anterior continuation of the inferior alveolar nerve (the incisal branch) is severed. This helps in better retraction of the nerve. Continuation of the mental nerve is preserved. Mucoperiosteum on the lingual aspect is elevated and protected by a periosteal elevator. Osteotomy is completed adhering to the basic principles. The same procedure is repeated on the contralateral side. Body osteotomy at the molar level is almost outdated since the advent of sagittal split osteotomy.

Body osteotomy anterior to the mental foramen can be resorted to in certain specific cases. The main indication of this procedure is lower dentoalveolar protrusion with anterior open bite. “V” osteotomy is done at the first premolar region. This will not reduce the total mandibular length but rotates the anterior segment upward and backward. Maintenance of the arch and occlusion is important. Rigid fixation is mandatory as tendency for relapse is very high due to the pull exerted by the genioglossus and geniohyoid muscles (Fig. 68.23).

Stabilization is achieved by arch bars or by orthodontic means. Fixation using two plates (each plate having a minimum of 4 holes) on each side is advised.

Fig. 68.23 Body osteotomy at the level of the premolar region. Diagrammatic representation

68.6 Symphyseal Osteotomy

Midline osteotomy is used either to narrow or to expand the mandible. Expansion is more difficult than narrowing, due to tissue resistance. Before narrowing the mandible, a space must be created at the symphysis by extracting an anterior tooth (Fig. 68.24). Parasymphyseal step osteotomy approach with a hybrid mode of force application might be the most viable option for true mandibular arch expansion.

68.7 Lower Anterior Subapical Osteotomy

Hullihen performed the first ever anterior subapical osteotomy and published it in 1849 [66]. This procedure was done for a girl who had sustained burns and had the anterior segment of the mandible got distracted anteriorly by the traction of the scar resulting in everted lip, protrusion of teeth, and open bite.

Hofer used anterior subapical osteotomy to advance anterior teeth for correction of mandibular dentoalveolar retrusion [67]. Kole used this technique to correct an anterior open bite.

Lower anterior subapical osteotomy is widely used in the following conditions:

1. To retrude the lower anterior dentoalveolar segment; often used in conjunction with subapical osteotomy in bimaxillary protrusion
2. To close minimal anterior open bite
3. To intrude the anterior segment in deep bite deformity

Fig. 68.24 Midline osteotomy (Diagrammatic representation)

Surgery

Sulcus incision is made and the mucoperiosteal flap is reflected. Subperiosteal tunneling is done at the lingual aspect of the planned osteotomy site. Extraction of tooth (usually the first premolar) is done, if the intention is to retrude the dentoalveolar segment (Figs. 68.25a, b, c and 68.26a, b, c).

Osteotomy or ostectomy is done as planned. Stabilization and fixation are done in the preplanned position using prefabricated occlusal wafer splint or arch wires. Stabilization is done by using lag screws, position screws, or wires. Semi rigid bone plates are considered superior.

In cases where the anterior segment of the mandible is repositioned superiorly, a gap is created at the osteotomy site (subapically). Autogenous bone grafting is advised to fill this gap.

When the osteotomy is planned behind the mental foramen, the neurovascular bundle may be released from the mandibular canal and protected.

68.8 Total Subapical Osteotomy Mandible

Mcintosh in 1974 described total mandibular alveolar osteotomy. In 1942 Hofer [67] described horizontal osteotomy of mandible for horizontal deficiency or excess and asymmetry.

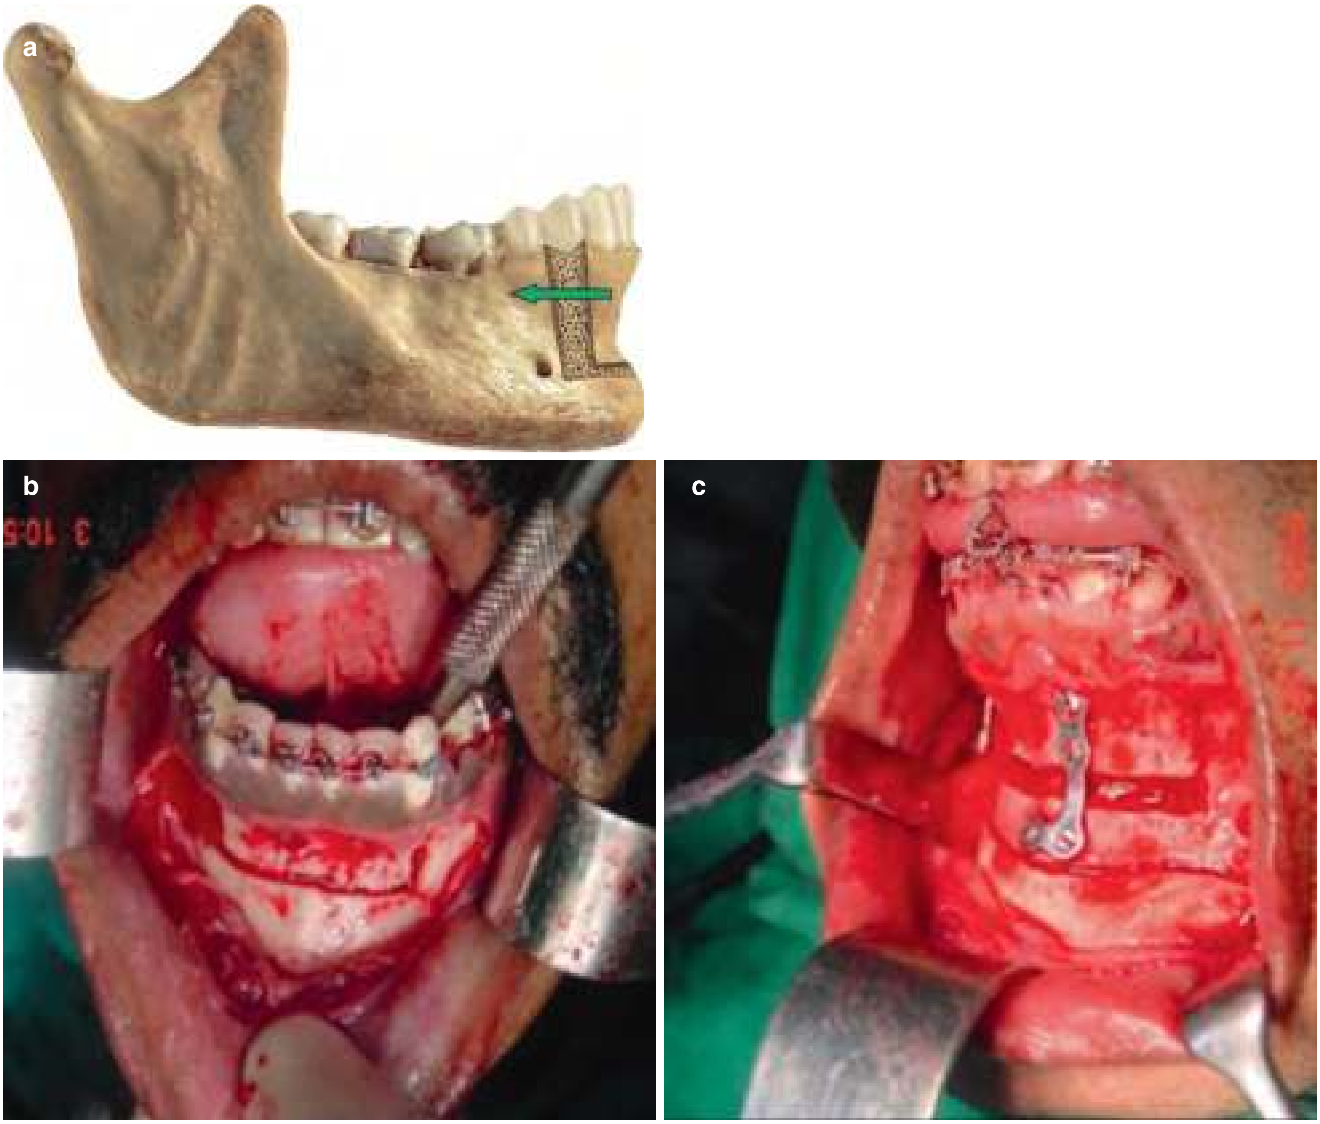

Fig. 68.25 Lower anterior subapical osteotomy. (**a**) Diagrammatic representation. (**b**) Photograph demonstrating the vertical interdental and the horizontal connecting osteotomies. (**c**) Lower subapical osteotomy can also be combined with genioplasty

> Total subapical osteotomy of the mandible is used mailly for the following indications:
> 1. For repositioning the entire dentoalveolar segment.
> 2. When the mandibular length and chin position are compatible with the maxilla and its position, but the deformity is mainly in the dentoalveolar part.

Adequate bone should be present below the apices of the roots.

Surgery (Fig. 68.27a, b, c)

Mucoperiosteal flap is reflected. The neurovascular bundle is released as described earlier (under "Body Osteotomy of Mandible"). Osteotomy is started behind the most posterior teeth. The cut is made using reciprocating saw or bur. Care should be taken not to damage the lingual tissues. Osteotomy is continued anteriorly, without injuring the released neurovascular bundle. About 4 mm of bone should be left below the apices of the teeth to ensure proper blood supply. The dentoalveolar segment is freed and mobilized. Preplanned

Fig. 68.26 Protrusion anterior dentoalveolar segment of mandible treated by lower anterior subapical osteotomy. (**a1**, **b1**) Preoperative pictures. (**a2**, **b2**) Postoperative pictures. (**c1**) Preoperative lateral cephalogram. (**c2**) Postoperative lateral cephalogram

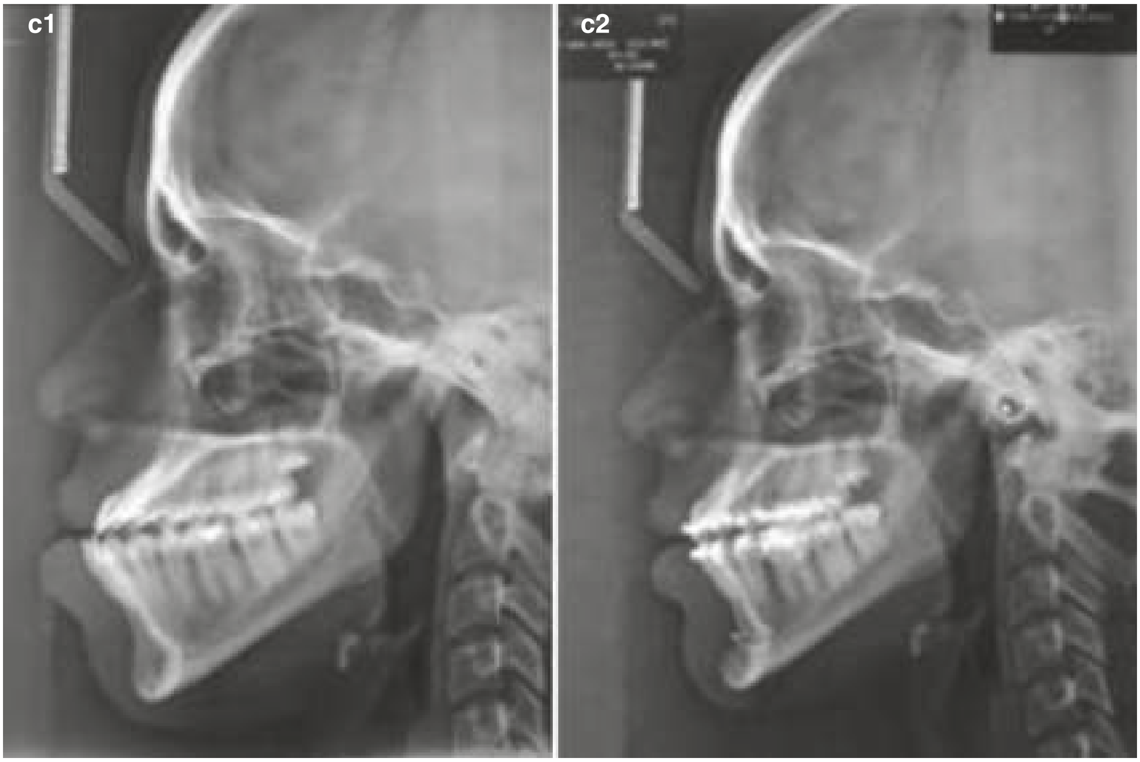

Fig. 68.26 (continued)

occlusion is established. Maxillomandibular fixation is aided by wafer splint. The neurovascular bundle is repositioned and secured in position using struts of bone [68].

Stabilization is done using rigid internal fixation. Postoperative sequelae are usually marked by edema which gets resolved in about 2 weeks. Sensory disturbances, though present, usually recover with time. Injury to the neurovascular bundle may cause permanent anesthesia.

Complications are usually rare. The importance of proper blood supply through the lingual pedicle is of utmost importance. This is mainly through the mylohyoid, genioglossus, and geniohyoid muscle attachments.

68.9 Posterior Subapical Osteotomy Mandible (Fig. 68.28)

The basic plan of the surgery is not very different from that of total subapical osteotomy. The incision is limited to the posterior area. The decompression of the neurovascular bundle is done, and the osteotomy is performed as described earlier.

The main indications are to shift the dentoalveolar segment in question to the required direction in all three dimensions of space, i.e., antero-posterior, vertical, or horizontal.

68.10 Genioplasty

Genioplasty is used for the correction of deformities of the chin. It is possible to reposition the chin in all the three dimensions of space. Hofer in 1942 introduced horizontal osteotomy of the symphysis [67]. By repositioning the inferior mandibular symphysis, a more stable and natural appearance can be attained [69].

Surgical Procedure (Fig. 68.29a, b) (Video 68.3)
Incision is made on the labial mucosa on the lower lip. It is extended from the premolar region to the opposite symmetrical site. The incision is taken to the periosteum, which is reflected to expose the bone. Subperiosteal dissection is done to expose the inferior border of the mandible. Mental nerve is identified and protected.

Osteotomy/Ostectomy
Bony cut is made on the chin about 4.5 mm below the apices of the teeth. The posterior end of the cut should taper to the inferior border, behind and below the mental foramen. (This prevents step defects at the site which may be manifested in the soft tissue also.) The segmented portion is freed from the rest of the mandible but remains pedicled to the digastric and geniohyoid. If the inferior segment is stripped off the periosteum, making it a free graft, intense inflammatory reaction

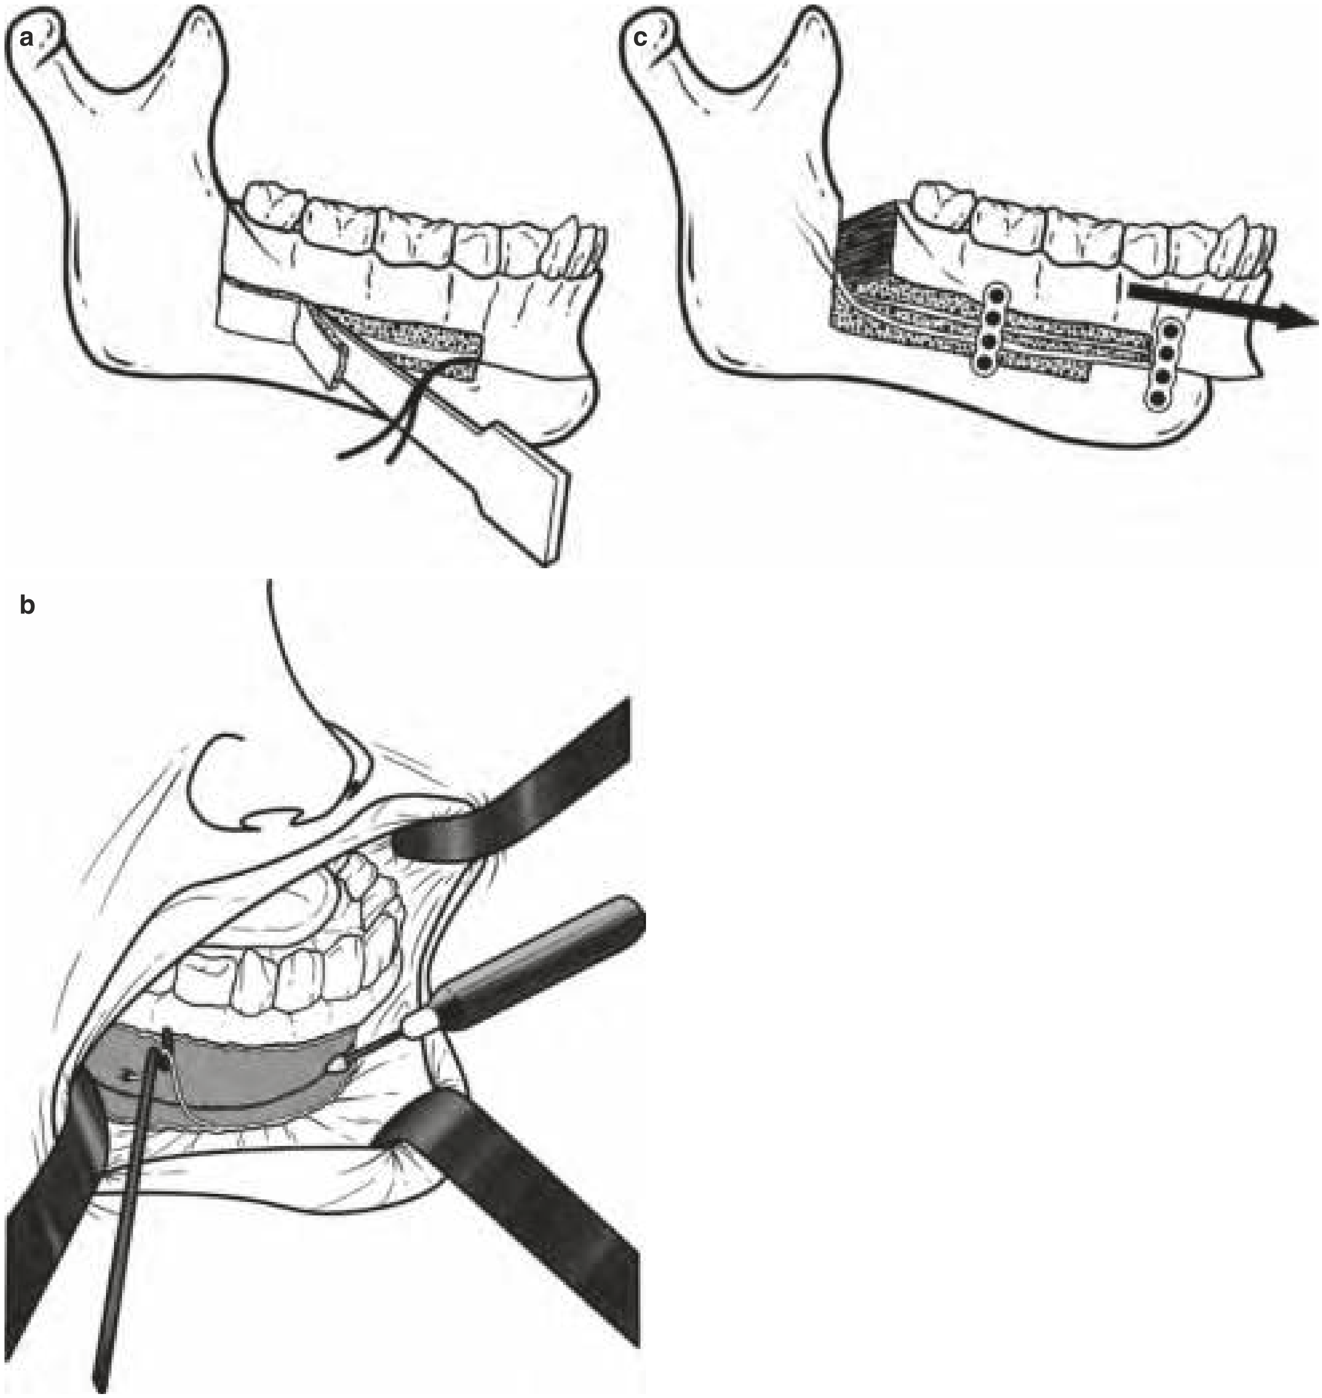

Fig. 68.27 Total subapical osteotomy. (**a**) Neurovascular bundle is released. (**b**) Osteotomy is done using bur or saw. (**c**) The dentoalveolar segment is positioned and fixed rigidly.

and necrosis may occur [70, 71]. The degree of bone resorption and necrosis is indirectly proportional to the amount of pedicle attached to the segment [72].

For vertical reduction, another horizontal cut is made below the original cut, and the measured segment of bone between the two cuts is removed. It is not advisable to cut off the bone from the inferior border as this can imperil the normal contour of the chin. Unilateral vertical reduction/augmentation can be done for correction of asymmetry, since the chin can be moved in all three dimensions (Fig. 68.31a, b).

Increase in the height of the chin can be achieved by bone grafting (preferably autogenous) and rigid internal fixation using plates. Unilateral height increase can be done in asymmetry. However, high morbidity is associated with bone graft and alloplastic materials, such as recurrence, infection, and resorption [73]. Chin can be augmented (augmentation genioplasty) (Fig. 68.30a–c) by bringing the cut inferior segment anteriorly and fixing it by rigid fixation. For major advancement, stepwise augmentation, slicing the inferior border into more than one horizontal segment is advocated (Figs. 68.32 and 68.33a, b, c) (Also refer Fig. 78.42).

Retropositioning of the chin can also be done, but the soft tissue adaptation following posterior positioning of the chin is not 100%. While positioning the inferior border posteriorly, the labiomental fold may get compromised (Fig. 68.34a, b).

Genioplasty can be used for widening and narrowing the chin in the horizontal direction. In mild mandibular asymmetry, the midpoint of the chin may be off the facial midline. By horizontal repositioning of the inferior border, the midpoint of the chin can be brought to the midline of the face, and the mandibular asymmetry can be camouflaged (Fig. 68.35).

Following surgery, the wound is closed adhering to the basic principles. Like in other osteotomies, 3–6 months are necessary for the lip to adapt to the new position and resume normal function. Complications are rare with this procedure. Wound dehiscence occurs in some cases. Meticulous irrigation and aseptic measures can reduce the chances of infection. Sensory loss for a period may be noticed due to traction on the mental nerve. Often sensation is regained within 3–6 months. Rigid fixation technique has reduced the chances shifting of position of the moved segment. Though the reported relapse rates vary in genioplasty, most authors agree that relapse occurs within the first year [38, 70].

68.11 Extended Genioplasty/Mandibular Basal Osteotomy

Mandibular basal osteotomy is an innovative predictable technique for correction of deficiency, excess, and/or asymmetry of the inferior mandibular border, decreasing morbidity, and many other complications of traditional bone grafts and alloplastic techniques [74].

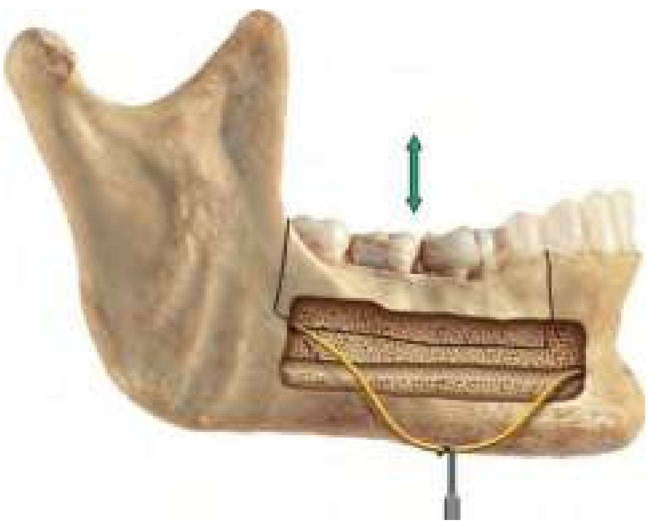

Fig. 68.28 Posterior subapical osteotomy

Fig. 68.29 (**a**) Osteotomized chin can be moved in all the three dimensions. (**b**) Advancement genioplasty

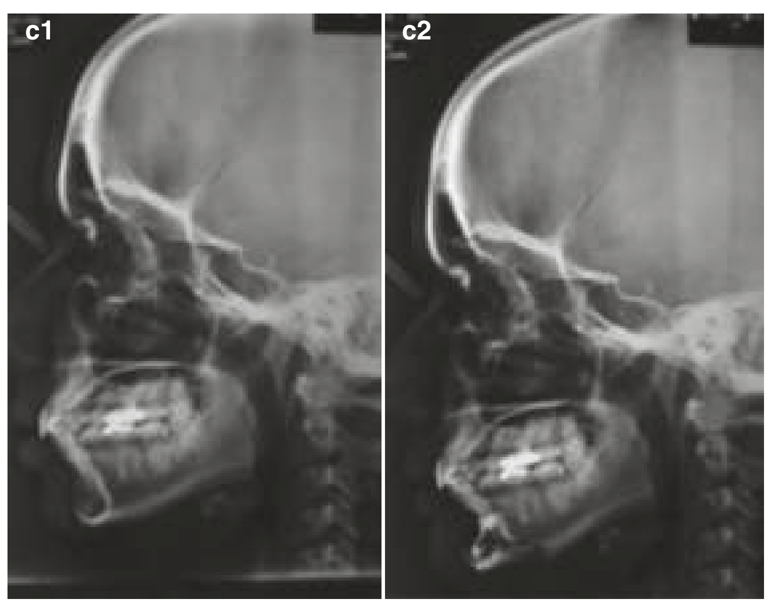

Fig. 68.30 (continued)

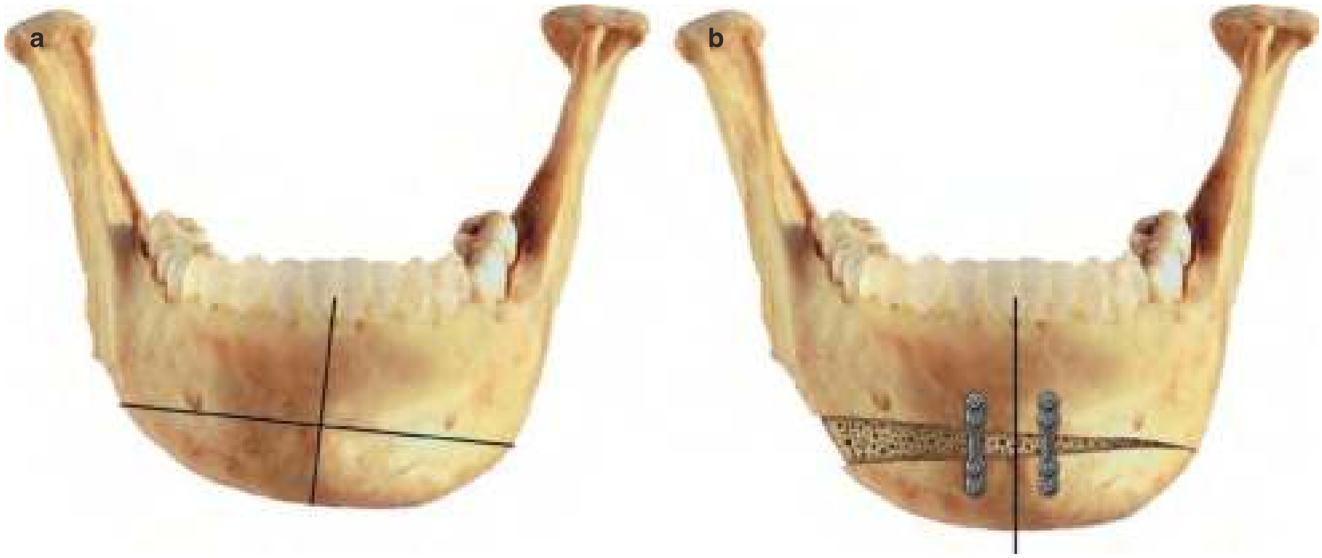

Fig. 68.31 Mild facial asymmetry can be corrected by bone grafting on one side, after osteotomy. (**a**) Pre-operative assessment and (**b**) treatment (osteotomy design)

Fig. 68.32 Major advancement of the chin can be effected by a double sliding genioplasty, which is a step osteotomy of the lower border

In extended genioplasty dissection and exposure of the chin, mental nerve and body of the mandible is recommended by a degloving incision. With complete dissection and mobilization of nerves, an extended osteotomy to the antegonial angle may be carried out (Fig. 68.36a, b). The basal osteotomy below the inferior alveolar canal ensures proper proportionality between the advanced segment and the posterior mandible [75]. By laterally sliding the lower border (extended lateral sliding genioplasty), facial asymmetry can be corrected. This procedure can be used for minimal to moderate hemifacial microsomia and facial deformity resulting from unilateral ankylosis of the temporomandibular joint [76] (Fig. 68.37a, b).

68.12 Distraction Osteogenesis

Distraction osteogenesis is a recent introduction into the field of orthognathic surgery. This technique has revolutionized the possibilities of orthognathic surgery. It was Ilizarov, a Russian orthopedic surgeon, who popularized this technique. The first team to report gradual distraction of human mandible was McCarthy et al. in 1992 [77]. As bone has got regenerative capabilities, it is possible to create new bone and lengthen the bone in a cut segment by slowly distracting it. The technique is very useful in the management of deficiency of bone in the maxillofacial region as this is an excellent method to increase bone quantity. The spectrum of indications for distraction is widening and innovations are coming up in the field rapidly. During distraction certain important principles are to be followed.

It is advisable to complete the osteotomy and mobilize the segment as far as possible and then put back the segment to its original position and distract it gradually. During distraction directional stability should be ensured, in order to counteract the pull of the soft tissue and the muscles [78]. A new terminology "distraction histogenesis" has come into vogue as not only the bone but the surrounding tissues also get lengthened. Geniohyoid muscle can be lengthened to a maximum of 20% of its resting length [79]. It is possible to distract the inferior alveolar nerve as well [80]. It is important that the distracted tissue is attached to vital tissue to maintain

Fig. 68.33 Case of retruded chin corrected by double sliding advancement genioplasty. (**a1**, **b1**) Preoperative pictures. (**a2**, **b2**) Postoperative pictures. (**c1**) Preoperative lateral cephalogram. (**c2**) Postoperative lateral cephalogram

perfusion. Periosteum is rich in osteogenitor cells, and for callus distraction and bone lengthening, the periosteum should be intact, and hence it should be preserved [48].

After osteotomy a latency period of 4–7 days is advised to provide time for the soft tissue to heal. However other factors like age, stability of fixation, type of operative procedure that affects the formation process during the initial stages of distraction, etc. are to be considered before deciding on the latency period [81]. Certain other studies did not show any difference between no latency period and a latency period [82, 83].

Four stages are recognized in distraction osteogenesis—(a) fibrovascular hematoma formation, (b) formation of collagen fibers parallel to distraction vector, (c) bone formation and remodeling of new bone, and (d) formation of solid compact bone. In fast distraction collagen, fibers may lose contact, and bone formation may not take place. In slow

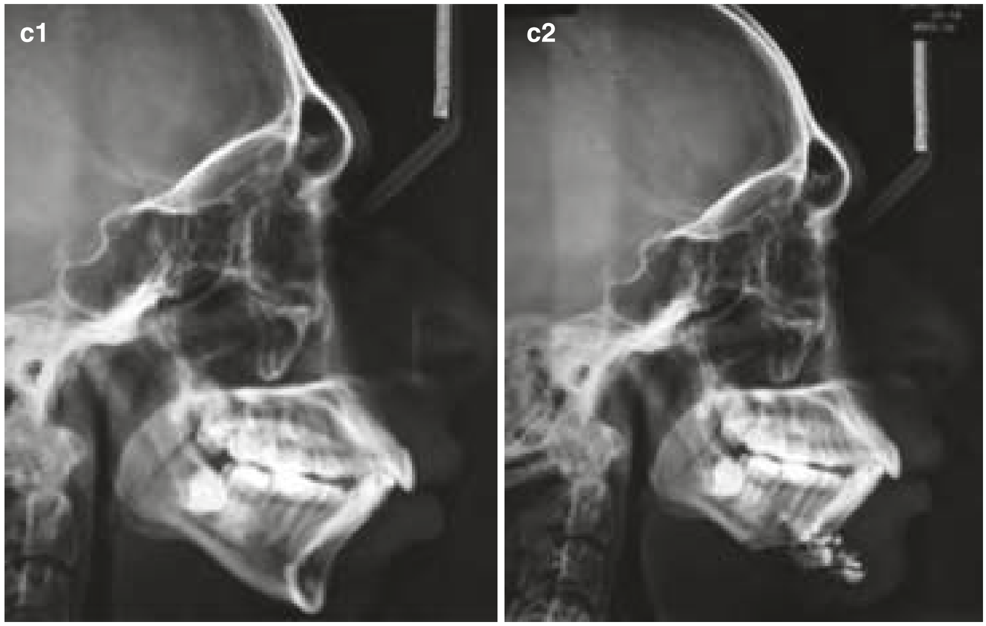

Fig. 68.33 (continued)

Fig. 68.34 Reduction of the chin can also be achieved. However, sharp margins are to be trimmed off. (**a**) Pre-operative planning and (**b**) treatment (osteotomy design)

distraction, consolidation of bone may occur earlier [84]. Karp et al. demonstrated that intramembranous ossification is what occurs predominantly [85]. Distraction of 1 mm per day is the widely accepted rate [86]. Direct current electrical stimulation may be useful in activation and consolidation period [87–89]. Insufficient distraction and defective vectors can compromise the final result. These complications can be, to some extent, managed by manipulating the regenerate bone by the application of orthodontic traction [79, 90–92]. OW and Cheung reported a lower incidence of persistent IAN disturbance (3%) after MDO compared with BSSO, of which the incidence was 28% [93]. In terms of skeletal stability in small to moderate advancements, there is no significant difference between BSSO and DO. DO requires a second surgery for removal of the distractor, which goes in favor of BSSO [94].

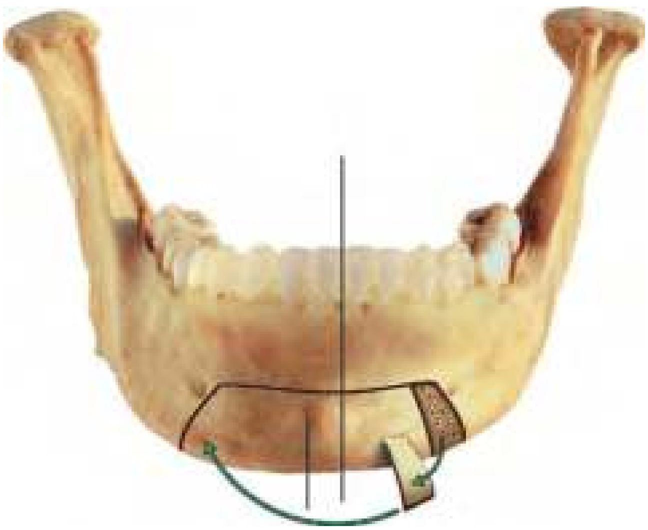

Fig. 68.35 Osteotomy plan for mild facial asymmetry pertaining to the chin

Distraction osteogenesis has got an important role in managing sleep apnea, in cases like micrognathia, Pierre Robin syndrome, hemifacial microsomia, Treacher Collins syndrome, etc. [4, 95]. Due to its complex nature, it is rather difficult to treat unilateral craniofacial microsomia, in growing children. Maxilla, zygoma, mandible, external and middle ear, facial and trigeminal nerves, muscles of mastication, and overlying soft tissues are the structures of the first and second arch which are involved [96] (Refer Chap. 78 on Hemifacial microsomia and Treacher Collins syndrome).

In severe cases, in neonatals, tracheostomy may become necessary. Mandibular distraction is an effective method in resolving upper airway obstruction and decannulation of tracheostomy [97–99]. Rachmiel A. et al. have reported an increase of mandibular volume by 28.4%, increase of upper airway volume

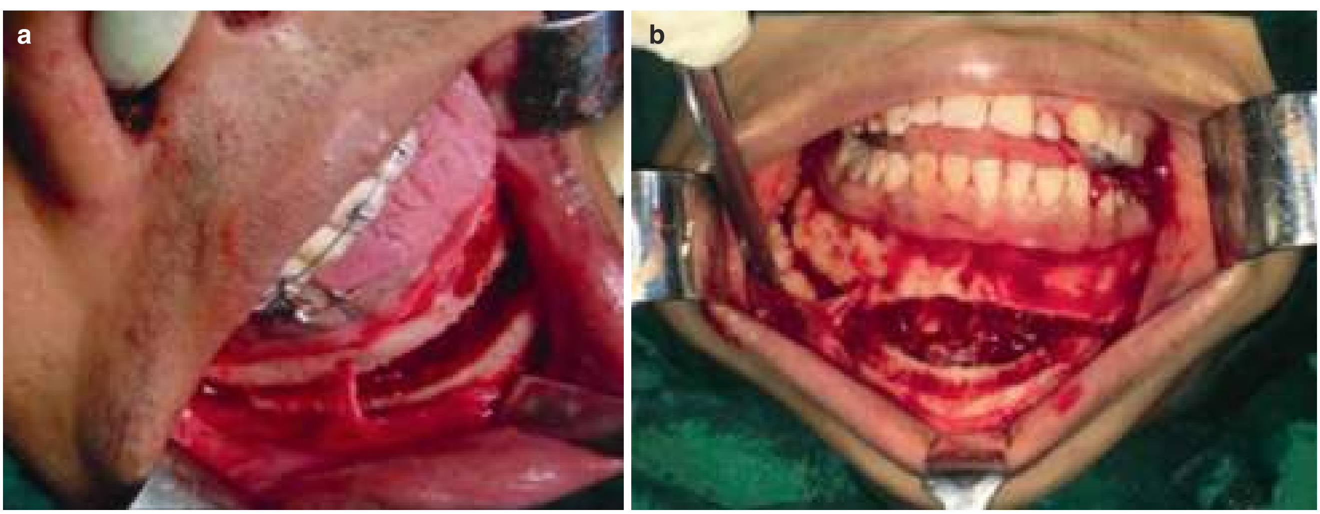

Fig. 68.36 After making a degloving incision an extended genioplasty may be done. it is possible to preserve the mental nerve. (**a**) Oblique view and (**b**) frontal view

Fig. 68.37 Major asymmetry of the mandible can be corrected to a great extent by extended lateral sliding genioplasty. (**a**) Pre-operative plan and (**b**) treatment (osteotomy design)

by 71.92%, and increase in oxygen saturation. This study was conducted in children between 13 months and 7 years of age [25] (refer Chap. 87 on distraction osteogenesis).

In severely hypoplastic mandible multi-stage correction starting from young age may be considered for functional and psychological reasons. Less severe cases may be taken up for single stage correction after the permanent dentition is erupted [100].

68.13 Conclusion

Mandible is a horse shoe-shaped bone hinged to the skull and performs the major function, chewing, and forms the lower part of the mouth which houses the tongue and other musculature. All the muscles of mastication and many other muscles of facial expression are attached to the mandible. Hence mandible is an important structure in both function and aesthetics. Different osteotomies of mandible can move the jaw in almost all the three directions and change the size and shape of the jaw and face to achieve better function and aesthetics. This chapter is intended to elucidate various osteotomy techniques on the mandible.

Disclosure Authors have no financial conflicts to disclose.

68.14 Case Scenarios

Case 1 (Fig. 68.38a, b, c)

Patient aged 22 years, female, reported with complaint of facial deformity with a history of fall when she was about 8 years old. No deformity was noticed, and no treatment was taken at that time, and as she grew up, she started developing deviation of the face.

On examination she had facial asymmetry with deviation of the jaw to left side. She had class II occlusion and deficient chin. Radiographs revealed under developed and deformed condyle on the left side. The mandible was shifted to the left side due to underdevelopment of the mandible on left side (Fig. 68.38a1, b1, c1).

Treatment: Pre-surgical orthodontic treatment with sagittal split osteotomy and extended lateral sliding genioplasty with rib bone grafting on right side.

Postoperative pictures after 1 year (Fig. 68.38a2, b2, c2).

Case 2 (Fig. 68.19a, b, c)

Patient aged 19 years reported with complaint of protruded teeth and facial deviation with no relevant history.

On examination, she had vertical maxillary excess with mandibular prognathism. Other clinical findings included incompetent lips, convex facial profile, acute nasolabial angle, and facial asymmetry with deviation of chin toward right side. Radiographs revealed vertical and anterioposterior maxillary excess with mandibular prognathism and deficient chin.

Preoperative pictures (Fig. 68.19a1, b1, c1)

Treatment plan: Pre-surgical othodontic treatment followed by surgery.

Surgery: LeFort 1, anterior maxillary osteotomy, bilateral sagittal split osteotomy, and genioplasty were done for the patient under general anesthesia.

Postoperative pictures after 1 year (Fig. 68.19a2, b2, c2)

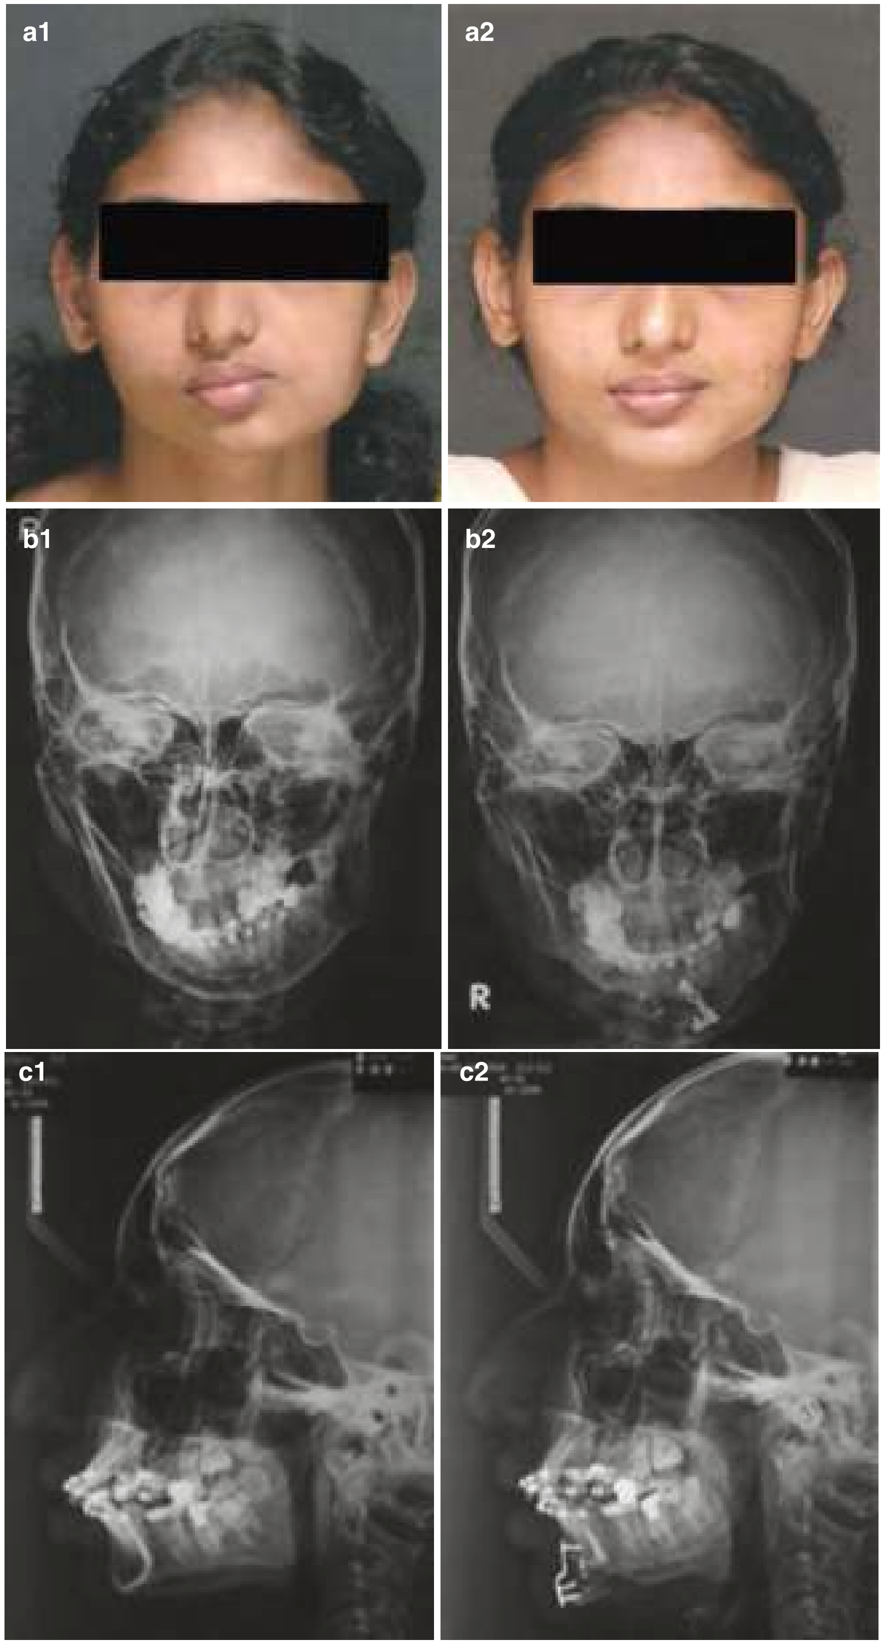

Fig. 68.38 Mandibular asymmetry corrected by extended lateral sliding genioplasty. (**a1**) pre operative frontal view. (**a2**) post operative frontal view. (**b1, b2**) pre and post operative Frontal cephalogram. (**c1, c2**) pre and post operative lateral cephalogram

Orthognathic Surgery for the Maxilla-LeFort I and Anterior Maxillary Osteotomy

69

Ashok Dabir and Jayesh Vahanwala

69.1 History of Maxillary Osteotomies

Maxillary Osteotomies
One does not know a science completely without knowing its history.
Auguste Comte (1798–1857) [1]

The Le Fort I-Type Maxillary Osteotomy
The development of modern maxillary orthognathic surgical procedures had diverse historical origins and contributions. The removal of nasal and nasopharyngeal polyps via hemi maxillary osteotomy was being undertaken in Europe in the mid-nineteenth century, notably by the German surgeon Bernhard Rudolf Konrad von Langenbeck (1810–1887) in Berlin [2]. The first maxillary procedure that would today be described as a total Le Fort I-type osteotomy appears to have been undertaken in 1868 by the American surgeon, David Williams Cheever (1831–1915) in Boston City Hospital to provide surgical access for removal of a large nasopharyngeal polyp [3]. One year prior to this, in 1867, Cheever had undertaken a down-fracture of the right hemimaxilla for similar surgical access in another patient, who had made a complete recovery [4]. The total down-fracture of the maxilla at the Le Fort I level performed in 1868, described as Cheever's "double operation," though technically successful, had an unfortunate postoperative outcome in that the patient subsequently died 5 days later, though probably not as a direct result of the maxillary procedure [5, 6].

In 1901, a French surgeon from Lille named René Le Fort (1869–1951) conducted experiments using blunt trauma to intact cadaveric faces, from different directions and varying magnitudes, and thereby described the natural planes of maxillary and facial fractures [7, 8] now known as the Le Fort classification of facial fractures. The names of the Le Fort I-, II-, and III-type osteotomies are due to their similarity to the Le Fort fractures.

In 1927, Wassmund carried out a maxillary osteotomy at the Le Fort I level, without pterygoid plate disjunction or mobilization at the time of surgery [9]. He used elastics to close an anterior open bite, without placing a bone graft, which subsequently relapsed. In 1934, Axhausen in Berlin described advancement of the maxilla at the Le Fort I level, which was incompletely mobilized, again with postoperative elastic traction [10].

Wassmund was the first to apply osteotomies at the Le Fort I level for correction of midfacial deformities [11]. The technique was subsequently modified by several surgeons including Axhausen [12], Schuchardt [13], and Willmar [14]. In 1965, Obwegeser improved the precision of the Le Fort I osteotomy by suggesting complete mobilization of the maxilla so that repositioning was achieved without tension [15, 16]. The operation was slow to gain popularity until 1973, till Bell's description of the remarkably resilient maxillary blood supply [17]. With advancement in technique and the introduction of safe hypotensive anesthesia, the Le Fort I osteotomy has been increasingly utilized over the last four decades. Over the years, various modifications of the osteotomies, ORIF methods and bone grafting to the mobilized maxilla, have continued to evolve and progress.

69.2 Surgical Anatomy

The paired maxillae are made up of a body and four projections: frontal, zygomatic, palatine, and the alveolar process. The maxilla forms the inferior and medial borders of the

orbits. The infraorbital foramen is located at an average distance of 7.8 mm, positioned inferiorly to the infraorbital rim in women and 8.5 mm in men [18]. The vascular and sensory supplies to the cheek, lateral aspect of the nose, and upper lip exit the bone from this foramen.

The anterior alveolar processes surround the piriform apertures and join to form the anterior nasal spine in the midline. The anterior nasal spine is the most anterior inferior attachment for the cartilaginous nasal septum, which extends posteriorly along the nasal crest and articulates with the vomer.

The maxillary sinuses are housed in body of maxilla. Anteriorly, palatine process of each maxilla and posteriorly, horizontal lamina of palatine bone form the hard palate. The greater palatine foramen is located on each side approximately 10 mm posteromedial to the second molar.

The nasolacrimal duct travels within the bony wall between the nasal cavity and the maxillary sinus before terminating below the inferior turbinate. It can be injured during the Le Fort I osteotomy or during an inferior turbinectomy performed to allow superior repositioning of the maxilla (Fig. 69.1) [19, 20].

Posterolaterally, the maxilla articulates with the pyramidal processes of the palatine bones and the pterygoid plates of the sphenoid bone. This pterygomaxillary junction extends superiorly as a fissure, which ends at the pterygopalatine fossa. The terminal portion of the internal maxillary artery traverses the pterygopalatine fossa and gives off several branches that can be encountered during a Le Fort I osteotomy (Fig. 69.2a, b). The average distance between the infe-

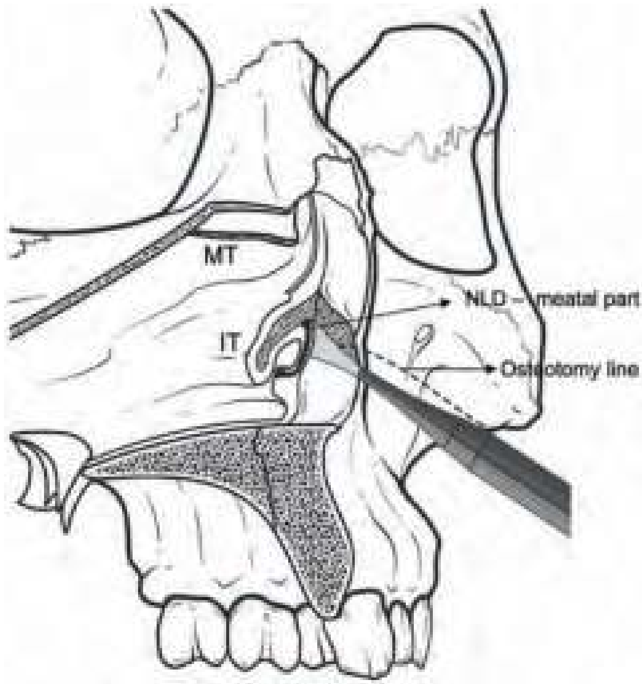

Fig. 69.1 Relationship of the nasolacrimal duct to the Le Fort I osteotomy cut. The meatus of the nasolacrimal duct is unlikely to be injured if the osteotomy is made just beneath the infraorbital foramen and into the piriform rim at the level of the inferior turbinate (IT). *MT* middle turbinate

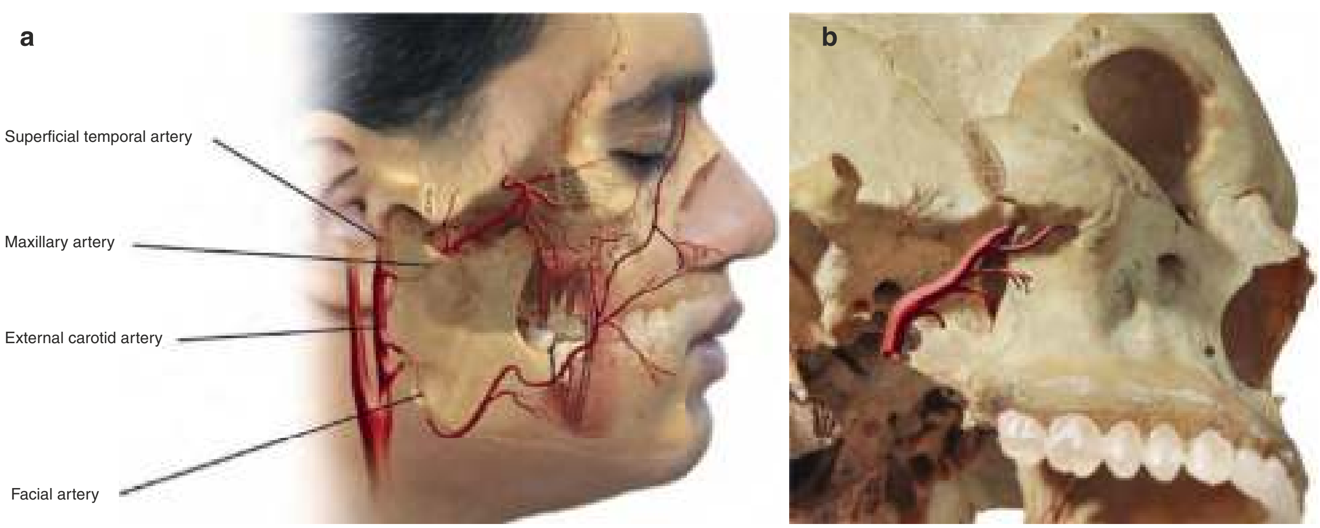

Fig. 69.2 (**a**) Branches of external carotid artery, (**b**) terminal branches of internal maxillary artery

rior extent of the pterygomaxillary junction and the posterior superior alveolar artery is 15 mm, the infraorbital artery is 32 mm, and the descending palatine artery is 25 mm. The descending palatine arteries travel through the perpendicular plate of the palatine bones and are located approximately 34 mm posterior to the piriform rims and within 10 mm medial to the pterygomaxillary fissures [21].

Osteotomies of the lateral nasal walls and at the pterygomaxillary fissures must be completed carefully to avoid injuring these vessels. The internal maxillary artery is 23–25 mm above the base of the junction of the maxilla with the pterygoid plates, with an average diameter of 2.5 mm. In addition to the direct vascular supply of the maxilla by the descending palatine arteries, there is a rich collateral vascular network from the soft palate supplied by the ascending pharyngeal arteries and the ascending palatine branches of the facial arteries (Fig. 69.3). The risk of damaging the artery can be minimized by ensuring the pterygoid osteotome is directed downward toward the palate and is less than 1.5 cm above the inferior part of the fissure [22, 23].

Bell's work revealed that ligation of the bilateral descending palatine arteries does not compromise the vascularity of the maxilla as long as the soft palate pedicle is preserved [24, 25].

The pterygoid plexus of veins is located between the temporalis and lateral pterygoid muscles and between the medial and lateral pterygoid muscles. It receives tributaries corresponding to the branches of the maxillary artery and drains into the maxillary vein. Venous bleeding from this plexus may be encountered during the posterolateral maxillary dissection and pterygomaxillary disjunction.

The risk of damaging the artery can be minimized by ensuring the pterygoid osteotome is directed downwards towards the palate and is less than 1.5 cm above the inferior part of the fissure [22, 23].

Bell's work revealed that ligation of the bilateral descending palatine arteries does not compromise the vascularity of the maxilla as long as the soft palate pedicle is preserved [24, 25].

S. Bruneder et al. studied a special type of arterial variation of the Le Fort I segment's blood supply. Individuals with this special arterial anatomy may clinically be at high risk for hypoperfusion and avascular segment necrosis after surgery. Individualized operation planning that takes the patient's arterial anatomy into consideration may help to prevent ischemic vascular complications of the Le Fort I segment and improve operative outcomes in at-risk patients [26].

S. Salmanet et al. studied Dynamic analysis of maxillary perfusion during Le Fort I osteotomy using indocyanine green and concluded that there was a statistically significant decrease in perfusion, as assessed by intraoperative dynamic angiography, to the anterior maxilla following maxillary down-fracture. Patient age, conventional versus segmental Le Fort I osteotomy, changes in mean arterial pressure and/or heart rate, and preservation of the descending palatine vessels had no statistically significant effect on perfusion [27].

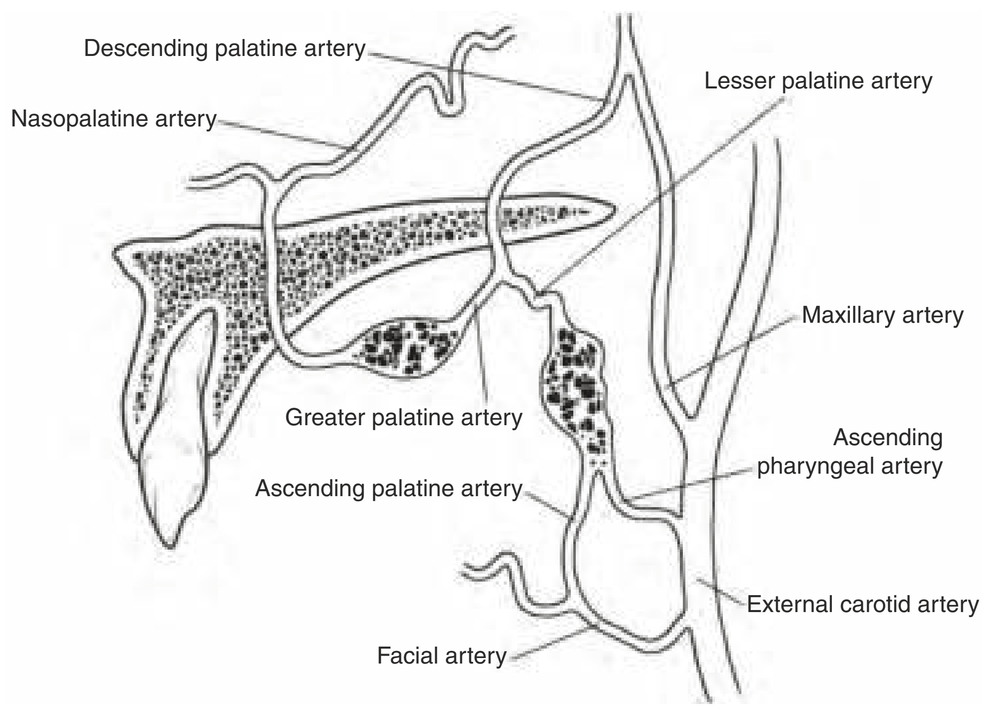

Fig. 69.3 The vascular supply of the osteotomised LeFort I segment. The ascending pharyngeal arteries and the ascending palatine branches of the facial artery

The patient's sex and aspects of the skeletal and craniofacial pattern have an influence on the pterygomaxillary area and descending palatine canal anatomy. A preoperative computed tomography analysis involving this evaluation could reduce the risk of surgical complications. A preoperative CT analysis should be performed on an individual basis and should identify the differences between the two sides in the same patient to allow a safer surgical procedure during Le Fort I osteotomy [28].

69.3 The Anterior Segmental Maxillary Osteotomy

The first anterior segmental maxillary osteotomy (ASMO) was reported at the beginning of the twentieth century by Günther Cohn-Stock [29], wherein he tried to surgically "correct a marked overjet and overbite of the central maxillary teeth." In his pioneering article in 1921, he described the evolution of his idea to perform an osteotomy of the anterior segment of the maxilla while preserving the vestibular pedicle and, in a later design, also the palatal artery [29].

After Cohn-Stock's original report, three variations of the procedure were developed by Wassmund [9], Wunderer [30], and Cupar [31]. These variations were designed to maintain sufficient blood supply to the maxilla while giving adequate access for instrumentation [32, 33].

In 1927 Wassmund [9] improved Cohn-Stock's design by creating a direct approach to the labial premaxillary cortex using three vertical incisions and subperiosteal tunnelling for completion of the labial osteotomy without reflection of labial or palatal flaps. Both the labial and palatal blood supply are maintained; however, the osteotomy is made in a relatively blind fashion. This method may be indicated for closure of multiple interdental spaces [33] and for anteroposterior repositioning of the premaxilla [34]. It was found to maintain the best vascularity of the repositioned segment in comparison to all other ASMO methods [35].

In 1954 Cupar [31] described a different approach for down-fracture of the anterior maxilla: exposure of the labial aspect of the maxillary bone by a vestibular circumferential cut and labial flap to facilitate the labial osteotomy under direct vision. A palatal osteotomy was performed through a tunnel, maintaining the palatal blood supply. This technique is indicated for superior repositioning of the anterior maxilla in cases of vertical maxillary excess.

In 1963 Wunderer [30] advocated reflection of a palatal flap without fracturing of the anterior maxilla and maintenance of the labial blood supply. Direct access for the palatal osteotomy is the main advantage of this technique, especially if posterior segments of the premaxilla must be removed.

Therefore, this technique may be indicated for setback of the anterior part of the maxilla. Blood flow studies have demonstrated that the transpalatal approach causes the greatest decrease in blood supply to the anterior maxilla [36]. However, transpalatal soft tissue incision and labial osteotomies impair vascular supply to the anterior maxilla from the greater palatine vessels and the superior alveolar vessels, respectively, leaving the labial collaterals as the sole blood supply to the anterior maxilla [37].

In 1977 Epker modified the Cupar technique for down-fracture of the anterior maxilla. He used only labial flaps and vertical tunnels labial to the teeth to be extracted, which were usually premolars on both sides [38]. Epker's modification enables repositioning of the anterior maxilla superiorly, posteriorly, and inferiorly. The main advantages of the Epker modification include preservation of the palatal pedicle, ease of placement of internal fixation, provide access to the nasal septal structures to prevent buckling of the nasal septum with superior repositioning of the maxilla, and a direct approach for removal of palatal bone. When required, bone grafting for stabilization of an inferiorly positioned anterior maxilla may also be done using this method.

The segmental Le Fort I osteotomy should not be excluded from the technical armamentarium in orthognathic surgery. On the contrary, the literature consulted suggests it to be a useful tool for the three-dimensional surgical correction of maxillary malposition [39].

69.3.1 Technique (Video 69.1)

Anaesthetic and Positioning Considerations: Controlled hypotensive anesthesia has been shown to reduce bleeding from mucosal and bone edges that contain a rich network of small vessels, which cannot easily be identified and controlled with surgical techniques. In healthy patients, a reduction in mean arterial pressure (MAP) of 30% below the patient's baseline with a minimum MAP of 50 mmHg is safe [40]. In bimaxillary surgery, postoperative blood transfusions are necessary in 13–48% of patients who do not have controlled hypotension during the operation [41, 42]. The need for transfusion has been nearly eliminated by using this technique. Placement of an indwelling bladder catheter for intraoperative monitoring of urine output as a marker of renal perfusion should be considered when using controlled hypotension. After induction of general anesthesia, the patient is nasally intubated. Because intraoperative maxillomandibular fixation is essential to establish the postoperative position of the anterior maxilla, oral intubation is less desirable and should be avoided. The endotracheal tube must be sufficiently below the level of the vocal cords to prevent unintended dislodgement during premaxillary manipulation. A shoulder roll is inserted to extend the neck without creating hyperextension. A sterile preparation and draping is performed, leaving the orbits and nasion exposed. After the planned mucosal incision is marked, local anaesthetic with vasoconstrictor (lidocaine with 1:100,000 epinephrine) is infiltrated in the labial sulcus. Palatal injection should be avoided so as not to induce vasoconstriction in the palatal pedicle.

69.3.2 Exposure

A horizontal buccal sulcus incision is made by diathermy or a #15 scalpel blade in one strike to the bone in the deepest section of the buccal vestibule, circumferentially from right to left second premolar. Next, the periosteum is reflected superiorly to expose the entire canine fossa and piriform aperture bilaterally. Inferiorly, minimum mucoperiosteal stripping should be done, to maximize blood supply to the osteotomized maxilla. The alveolar mucoperiosteum should be undermined to the crestal bone only at preplanned osteotomy or ostectomy sites. The nasal mucoperiosteum should be carefully separated from the nasal cavity floor to prevent intraoperative bleeding, postoperative oronasal communication, and fistula formation. The cartilaginous nasal septum is separated from the nasal groove of the maxilla to facilitate its manipulation later.

69.3.3 Extractions and Horizontal Osteotomies

As per surgical plan, maxillary premolars are extracted on each side. Then, a reciprocating saw or piezo-surgical saw is used to perform horizontal osteotomies. These bone cuts should run posteriorly from each side of the piriform rim, including the lateral maxillary walls and the lateral nasal cavity walls. The nasal mucosa is protected with a curved periosteal elevator. Due care should be taken to avoid injury to the infraorbital nerve during retraction of the upper mucoperiosteal flap. The posterior limit for these osteotomies is the planned vertical osteotomy/ostectomy, usually the first or second premolar (Fig. 69.4a–d).

Figure 69.4b and Fig. 69.5 indicates the horizontal and vertical osteotomies/ostectomies that are performed using a #701 bur, mini-saw, or piezo. Precise bone removal should be done to ensure an accurate postoperative position and sufficient intersegmental bony contacts.

Meticulous tissue handling is of paramount importance at this stage. Failure to preserve buccal mucosa may lead to an impaired blood supply to the down-fractured maxilla or establishment of an oroantral fistula, in addition to periodontal compromise of the adjacent teeth.

69.3.4 Final Osteotomy and Down-Fracture of the Premaxilla

After completion of the planned osteotomies and ostectomies under direct visualization, the final osteotomy is done using an osteotome. Neither a palatal incision nor a mucosal undermining is done at this stage. A palpating finger is positioned on the palatal mucosa, and the transpalatal osteotomy is completed with an osteotome. Down-fracture of the premaxilla is accomplished with a bone hook. Additional transpalatal and nasal ostectomies may be necessary at this stage and should be finalized under direct access gained to the nasal aspect of the down-fractured premaxilla. Careful separation of the mucoperiosteum from the posterior segment of the palate facilitates setback of the anterior segment and prevents it from becoming detached from the anterior segment, compromising the blood supply (Fig. 69.6a, b).

69.3.5 Midpalatal Osteotomy

If indicated for transverse widening or narrowing of the premaxilla or closure of a diastema, a midpalatal osteotomy is performed with an osteotome or piezo-surgical saw (Fig. 69.7a, b).

69.3.6 Fixation

After completion of the ostectomies, maxillary teeth are placed into a preformed acrylic occlusal wafer, which is wired to the maxillary dentition. Temporary maxillomandibular fixation then is done, and a standard 1.5 or 2.0 maxillary plating system is used at the maxillary buttresses to fixate the bone segments in their planned postoperative position (Fig. 69.8a–c).

69.3.7 Closure

After thorough irrigation of the surgical site with saline, the mucosal incisions are closed with 3-0/4-0 vicryl suture. If indicated, alar cinch and V-Y closure of the buccal incision are performed at this stage. Maxillomandibular fixation is removed at the end of the procedure. The maxillary surgical wafer may be kept in place for 6 weeks for additional stability of the maxillary segments and occlusal guidance (Fig. 69.9a, b).

(see Fig. 69.10a2 for clinical profile view)

69.4 Le Fort I Osteotomy

69.4.1 Operative Technique (Video 69.2)

There are many acceptable modifications to the Le Fort I osteotomy, and the sequence of steps may vary from surgeon to surgeon. Figures 69.10a, b and 69.11a, b demonstrate a patient who has undergone a Lefort 1 with anterior maxillary osteotomy and mandibular subapical osteotomy for addressing her Vertical Maxillary Excess and dento-alveolar protrusion. The following is a description of the authors' preferred approach.

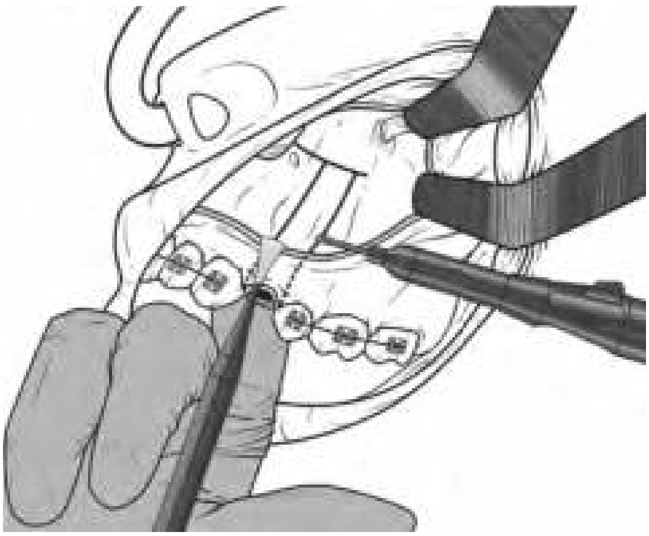

Fig. 69.5 Horizontal and Vertical Osteotomy Cuts (5 mm superior to mucogingival junction) Osteotomy marked, Horizontal cut 5 mm above the canine root tip, Vertical osteotomy marked approximate mesiodistal width of premolar

Anaesthetic and Positioning Considerations:
Anaesthetic and positioning considerations must be followed as previously discussed in the anterior segmental maxillary osteotomy technique.

69.4.2 External Reference Marker

An external reference marker is placed at the nasion to facilitate proper positioning of the maxilla in the vertical plane (Fig. 69.12a). Common techniques include insertion of a Kirschner wire or a bone fixation screw. Less invasive methods include marking with a skin scribe, a suture or tape, but these may be less reproducible due to skin mobility at the site. Occasionally a soft tissue landmark such as the medial canthus can also be used as a guide to measure from the incisal edge of the anterior teeth (Fig. 69.12b)

External reference points have been shown to be superior to internal references (lines or burr holes placed on the maxilla above and below the osteotomy), which are prone to inaccuracy due to the complex three-dimensional movement of the maxilla [43, 44]. Preoperative measurements are then obtained from the reference site to reproducible midline and lateral maxillary landmarks, typically the maxillary dental midline and the bilateral canine cusp tips or orthodontic brackets.

69.4.3 Surgical Exposure

Local anesthesia with vasoconstrictor is infiltrated labially and buccally from the pterygoid plate region, forward to the midline bilaterally. A full-thickness mucosal and periosteal

incision is made in the soft tissue extending from the buttress of the zygoma on the either side, 3–4 m above the mucogingival junction with attention in the midline to a V-shaped incision to allow for aesthetic closure [45, 46] (Fig. 69.13). The incision can be made with a scalpel or electrocautery Colorado needle. While layered incisions serve no advantage for the dissection, electrocautery seems to control some hemorrhage at the time of the incision.

Retraction is maintained with down-turned Obwegeser retractors, and the superior mucoperiosteal flap is elevated with a #9 Molt periosteal elevator. The anterior nasal spine, piriform rim, infraorbital foramen, lateral maxillary wall, and zygomaticomaxillary junction are exposed. Exposure of the posterior maxillary wall and pterygomaxillary junction is next performed with a Molt periosteal elevator, placed parallel to the maxillary teeth and advanced posteriorly below

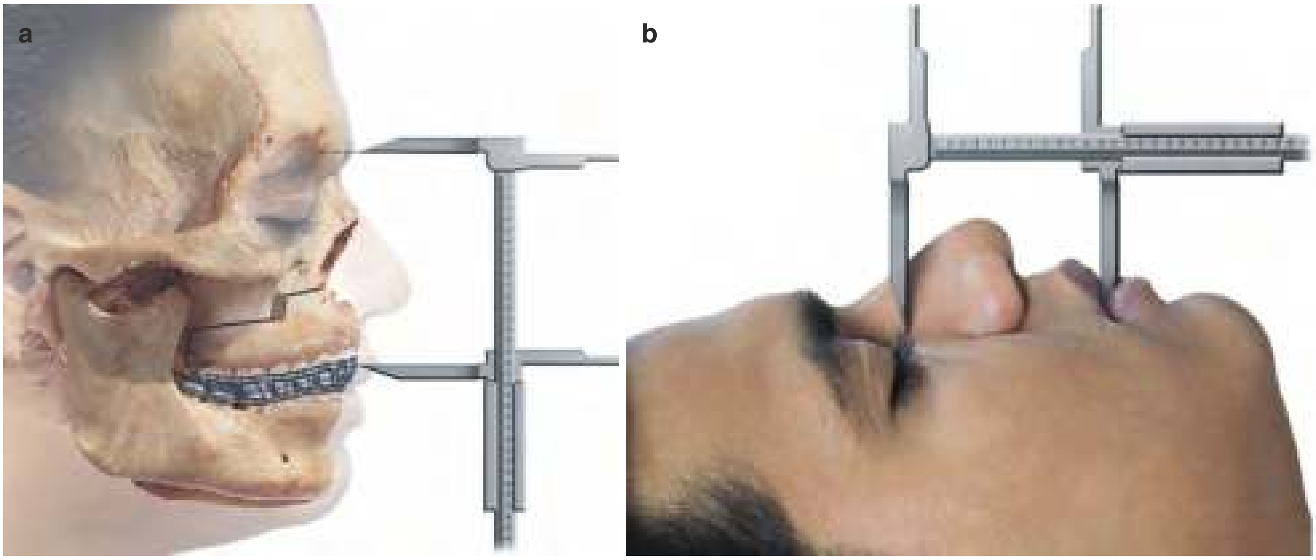

Fig. 69.12 (**a**, **b**) (**a**) External reference marker (skeletal landmark). A stable extraoral reference point is established with a 0.035-inch K-wire placed in the nasion. A caliper is used to measure the vertical distance from the K-wire to the brackets of the central incisor teeth, and these measurements are recorded. (**b**) A extraoral reference point at medial canthal (soft tissue landmark). A caliper is used to measure the vertical distance from medial canthal to the brackets of the central incisor teeth

Fig. 69.13 Maintain a small inverted "V" shape over the midline frenum, with the lateral extension of the incision being 5mm above the muco-gingival junction, from first molar one side to the other

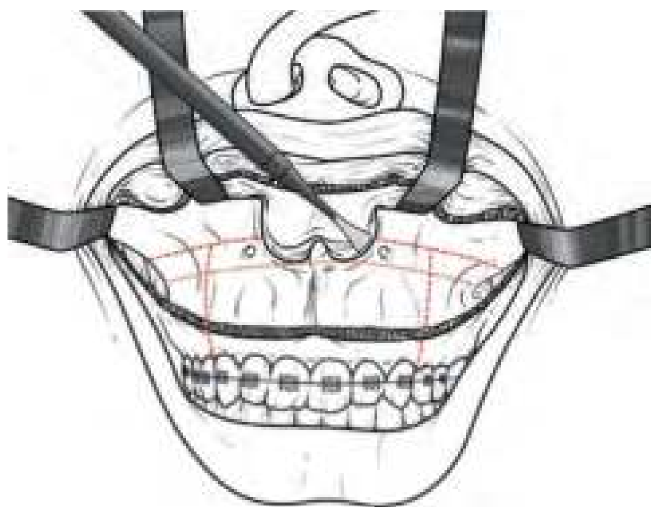

Fig. 69.14 Exposure of the maxilla is achieved with a full horizontal vestibular incision superior to the mucogingival junction. With appropriate retraction, the infraorbital nerves, piriform rims, posterior maxilla, and anterior nasal spine will be identified

periosteum until the pterygomaxillary junction is encountered. The periosteal elevator on the bone and in a subperiosteal plane is maintained with angulation as it proceeds posteriorly to incline inferiorly or toward the hamular process of the sphenoid bone. This alleviates the potential problem of entering the pterygomaxillary fissure and concomitant increased hemorrhage [23, 47].

The nasal/septal mucosal dissection is performed after the bilateral maxillary osteotomies have been completed and involves elevation of the nasal mucosa with a curved freer elevator to the posterior palatine bone (Fig. 69.14).

As may be preferred by some surgeons, reference marks are placed vertically in the lateral wall of the maxilla, or bone reference holes are placed a standardized distance apart (15 mm seems to be a reasonable distance) vertically in the buttress and in the pyriform rim region (Fig. 69.15) [48–50].

Alternatively, a non-threaded Kirschner wire or Steinmann pin is placed in the nasal dorsum, and a reference measurement is taken from that Kirschner wire to the anterior dentition to allow for determination of the amount of superior repositioning of the anterior maxilla [51, 52].

With the use of a Tessier caliper, the vertical distance (height) between the medial canthus and the mid-maxillary incisor crown is measured on the left and right sides and recorded; this generally measures between 55 and 70 mm (Fig. 69.12). This is a reproducible relative measure of the anterior vertical maxillary height [53].

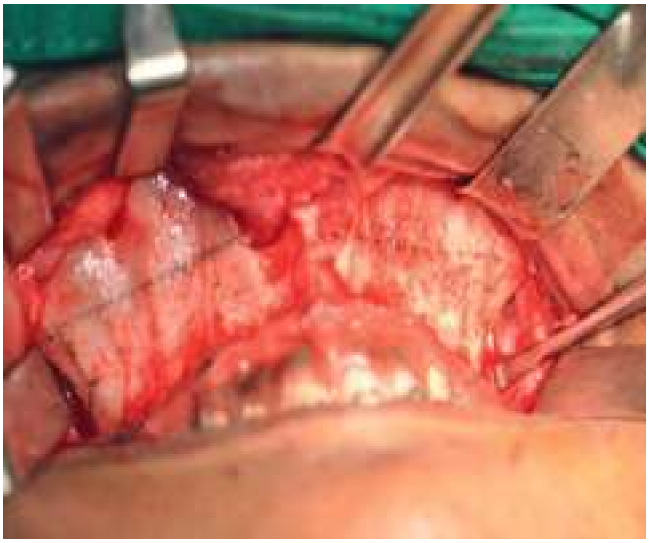

Fig. 69.15 Marking of osteotomy cuts, horizontal cut minimum of 5 mm above the apices of the teeth, step or sloping downward and backward toward to maxillary pterygoid plates or Le Fort I level with step-ladder cut

69.4.4 Bony Osteotomies

69.4.4.1 Lateral Osteotomies

A 701 straight fissure bur or reciprocating saw creates the lateral maxillary osteotomy from the lateral nasal rim to the zygomaticomaxillary junction. The osteotomy starts 3–4 m above the nasal floor and is carried to the depth of the maxillary sinus, back to the pterygomaxillary junction, approximately 30–35 mm above the bracket on the first molar tooth. Cuts are made at least 5 mm above the roots of the teeth and can be made higher as needed. A vertical step at the first molar is carried inferiorly for 5–10 mm (step osteotomy permits grafting in the zygomaticomaxillary buttress area subsequently, if required) [54], and then it is continued in a horizontal plane to the posterior maxilla ending in front of the pterygomaxillary junction (Fig. 69.16a, b).

69.4.4.2 Pterygoid Plate Separation

A 6- to 8-mm-wide, curved osteotome is placed in the pterygomaxillary junction, with the leading edge angled inferior, medial, and anterior. It is positioned in the junction with the horizontal osteotomy centered over the middle of the osteotome.

A finger can be placed palatally at the junction of the hamulus with the tuberosity, and the mallet is used to drive the chisel through the junction. The end of the osteotome should be palpated on the palatal side as it comes through the junction, but it should not penetrate through

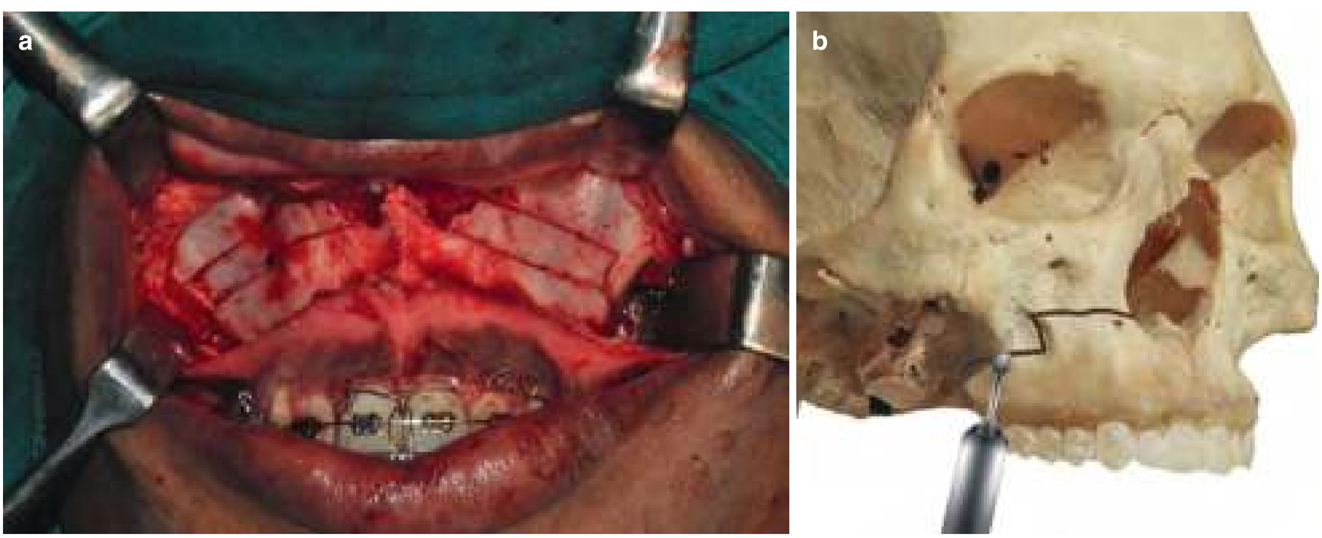

Fig. 69.16 (**a**, **b**) (**a**) The lateral maxillary wall osteotomy is carried posteriorly from the piriform rim to the pterygomaxillary junction, (**b**) with a vertical step ladder cut in the first molar region. The osteotomy is placed at least 5 mm superior to the root apices

Fig. 69.17 A curved osteotome is placed in the pterygomaxillary junction, with the superior edge of the osteotome just above the horizontal osteotomy. A finger is placed on the palatal side of the junction, and the osteotome is gently tapped through the junction until palpated on the palatal side, without perforating the soft tissue

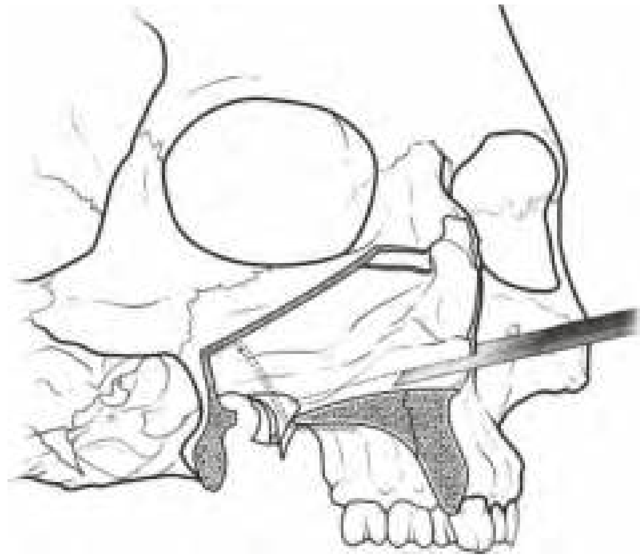

Fig. 69.18 The lateral nasal wall osteotomy is completed from the inferior piriform rim to the anterior portion of the pyramidal process of the palatine bone. Care is taken to avoid a complete osteotomy through the pyramidal process in order to prevent injury to the greater palatine artery and nerve. The right maxilla has been removed to show the desired cross-section clearly

the palatal tissue. There should be minimal resistance to separation, and if significant resistance is encountered, the osteotome position should be evaluated and repositioned (Fig. 69.17).

The scientific literature cites examples of damage to the cranial nerves during the Le Fort I osteotomy [55–58].

69.4.4.3 Lateral Nasal Wall and Septal Osteotomies

A small safe-sided osteotome initiates the lateral nasal osteotomy at the piriform rim in the anterior extension of the lateral maxillary osteotomy. A mallet drives the osteotome posterior, parallel to the nasal floor, below the inferior turbinate. One must take care not to go beyond 25 and 30 mm in depth during osteotomy. The lateral nasal wall diverges (widens) posteriorly, and the osteotome must follow that divergence. Minimal resistance will be encountered until the pyramidal process of the palatine bone is encountered. At this resistance point, the osteotome can be driven another few millimeters to influence the fracture plane through this structure during down-fracture (Fig. 69.18). The nasal septum osteotomy is next performed with a guarded U-shaped osteotome. The osteotome is introduced at the top of the nasal spine and is driven inferiorly and posteriorly along the nasal floor to separate the maxilla and palatine bone from the septum (Fig. 69.19).

Fig. 69.19 The septal osteotomy is completed from the anterior nasal spine through the vomer bone posteriorly, with the guarded prongs on the septal osteotome angled inferiorly. Care is taken to retract the nasal mucosa to minimize injury and bleeding to the soft tissue. The right maxilla has been removed to show the desired cross-section clearly

69.4.5 Down-Fracture and Mobilization

Once the osteotomy cuts have been completed, some mobility should be readily evident, and down-fracturing be easily

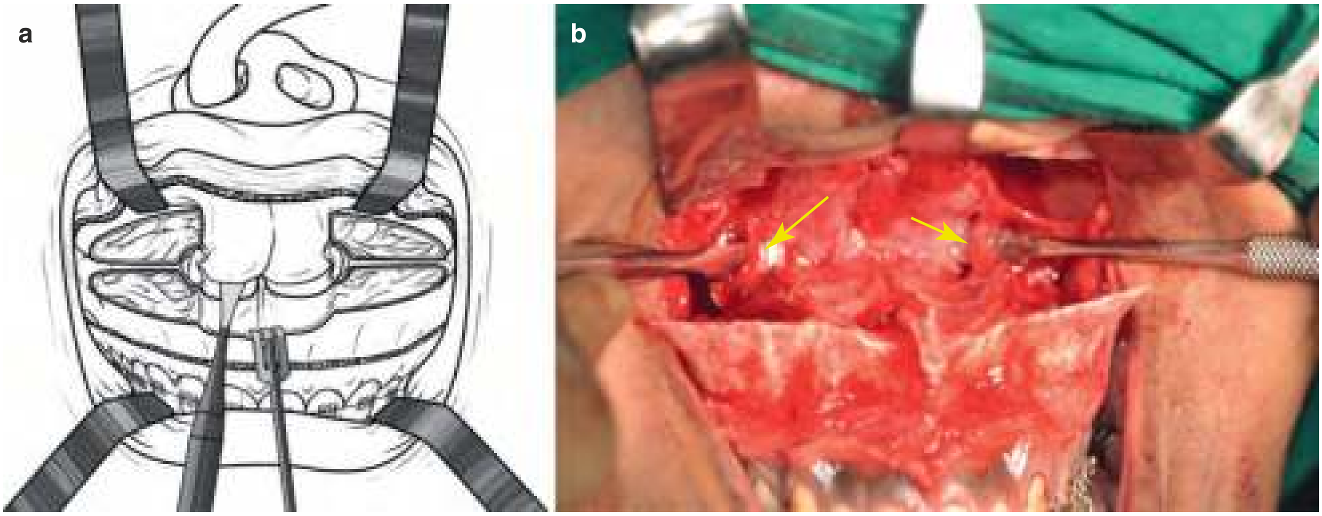

Fig. 69.20 (**a**, **b**) (**a**) Once the maxilla is mobilized, the nasal mucosa can be completely freed from the maxilla in the piriform rim region, (**b**) The greater palatine nerve and artery can be visualized and protected during posterior bone removal from the lateral nasal wall area (yellow arrows) (also see Fig. 65.12a)

done with either bilateral manual digital pressure in the canine fossa or with instrumentation support at the piriform rim. Slowly separate the maxilla by pulling the anterior portion inferiorly while observing the nasal mucosa to avoid tears. If significant resistance is encountered, revise the osteotomy cuts thoroughly to ensure complete separation. To avoid complications related to pterygomaxillary disjunction, we prefer to extract maxillary third molar and make a vertical osteotomy cut through the socket connecting the horizontal cut on the posterolateral surface of maxilla.

Precious et al. (1991) did a study of 138 consecutive Le Fort I osteotomies with successful down-fracture of the maxilla by digital pressure alone (with no serious complications except transient epistaxis that responded to local packing) [59, 60].

Once the down-fracture is completed, place a Seldin elevator or tongue depressor behind the tuberosity, and pull the posterior maxilla forward. This will fully mobilize the maxilla from its attachments. For large advancements, freeing the tissue from the nasal side of the posterior maxilla in the soft palate area will provide significantly more forward mobility. In addition, in repeat maxillary surgery, mobilizing the maxilla will most likely be more difficult, and time must be spent freeing hard and soft tissue attachments to ensure passive movements and surgical stability.

69.4.6 Removal of Posterior Interferences

Removal of posterior interferences should be done immediately after down-fracture which will make it easier to set the maxillary position later. The maxillary bony septum is reduced most easily with a bur. The lateral nasal wall can be reduced with a rongeur, bur, or reciprocating saw. While protecting the descending palatine nerve and artery with a curved freer (Fig. 69.20a, b), the pyramidal process of palatine bone is most safely reduced with the reciprocating saw or bone file. Sometimes a thin spatula osteotome can be used. Finally, the posterior tuberosity, anterior pterygoid plate, and posterior lateral maxillary wall can be reduced with a bur or reciprocating saw (Fig. 69.21). If the superior movement of the maxillary is more that 6 or 7 mm, a partial inferior turbinectomy may be indicated to allow a passive impaction. The nasal mucosa is incised with a scalpel blade along its inferior surface in an anterior-posterior direction. The inferior half of the turbinate is grasped with a large curved hemostat, and a dean scissor is used to excise this portion. Complete removal of the inferior turbinate is rarely necessary and can result in unpleasant clinical side effects. Electrocautery is used to coagulate the incised edge of the turbinate to minimize bleeding. The nasal mucosa is then sutured with a running 4-0 vicryl suture.

69.4.7 Placement of Surgical Guide

A prepared surgical guide is necessary to ensure accurate positioning of the maxilla. The guide is generally ligated to the upper teeth with 26–28 gauge wire. The upper and lower teeth are then wired together with 26–28 gauge wire, elastics, or power chain (Fig. 69.22).

69.4.8 Removal of Anterior Interferences

With the maxilla now fixed to the mandible, it is rotated into position by applying posterior and superior pressure on the

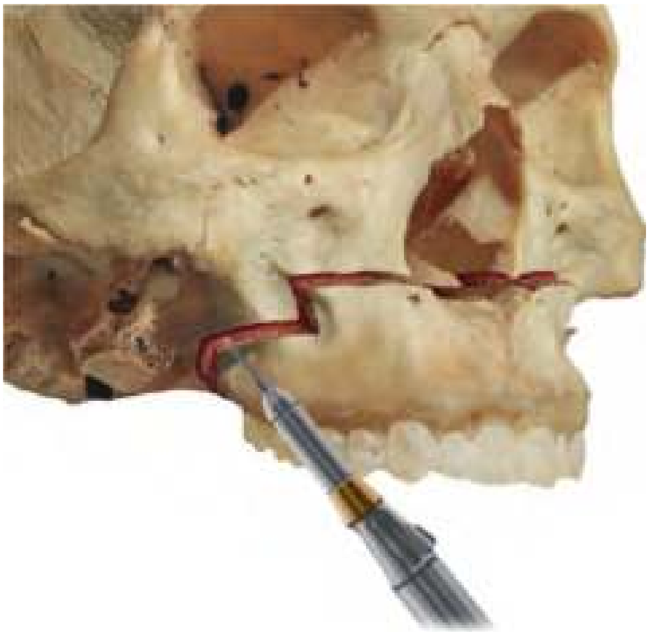

Fig. 69.21 Posterior interferences are initially removed from the posterior septum, lateral nasal walls, pyramidal processes of the palatine bones, and lateral maxillary walls. This allows for passive seating of the maxilla without posterior pivoting

Fig. 69.22 Placement of surgical guide and achieve desire stable occlusion. The lefort I osteotomy and AMO cuts are visible

mandible. To properly rotate the mandible, the surgeon places two fingers at the gonial notch regions of the mandible and the thumb of the same hand at the chin. Upward pressure is exerted with the two fingers at the gonial notches, and the thumb exerts a posterior and downward pressure. This "triangular" finger formation ensures full seating of the condyles during mandible rotation and maxillary positioning. The surgeon then rotates the mandible and maxilla upward, keeping pressure on the two fingers and thumb (Fig. 69.38a–c). Upward rotation is

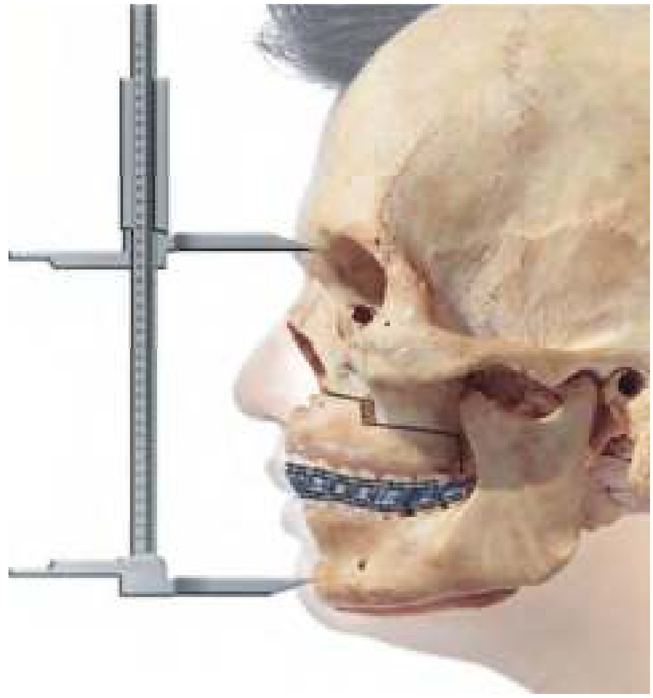

Fig. 69.23 The maxilla is rotated into place and anterior interferences are removed to ensure full seating of the condyles at the desired vertical position. Seating of the condyles of the mandible is achieved with superior pressure at the gonial notches and posterior pressure at the chin. Once the correct vertical maxillary positioning is achieved, the mandibular-maxillary complex can be reproducibly rotated with the condyles in the fossa without any bone or soft tissue pre maturities (Also see Fig. 69.12a, b)

stopped as soon as the first contact is detected, and this interference is reduced accordingly. Anterior interferences can be easily reduced with a bur. The caliper is used to check the vertical distance from the anterior brackets to the K-wire and interferences are reduced accordingly. Closely observe the nasal septum for early inferences and deviation. When all the bony interferences have been completely removed, utilizing the "triangular" finger formation, the mandible and maxilla can be easily rotated up into a stable reproducible position, with the condyles fully seated (Fig. 69.23).

69.4.9 Fixation, Grafts, and Final Measurements

With the maxilla positioned, four miniplates are accurately bent to passively fit across the osteotomy in the piriform and anterior buttress areas of the maxilla. Typically, there are two fixation holes above and below the osteotomy in each bone plate, for placement of four screws. Thin bone or large bone gaps may require more fixation screws in each plate or even require additional plates. Bone grafts can be adapted into the

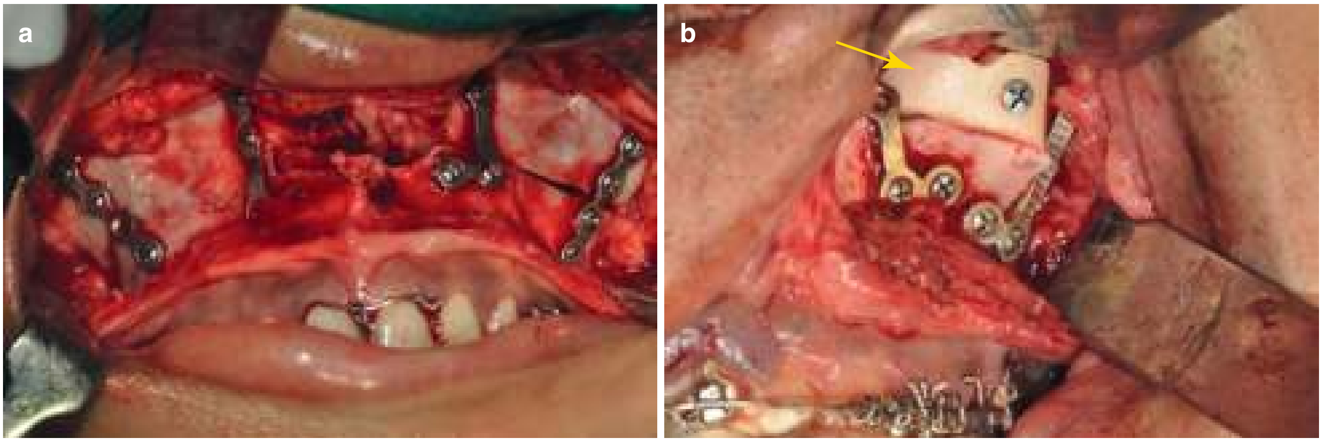

Fig. 69.24 (**a**, **b**) (**a**) Rigid fixation with four plates provides vertical and horizontal stability to the maxilla. The nasal septum should be free of deviation, and the occlusion should be reproducible once interdental fixation is released. Bone plates are used to stabilize the osteotomy bilaterally at the nasomaxillary and zygomaticomaxillary buttress areas. (**b**) Autogenous bone grafts have been adapted and fixated in the osseous gaps to optimize bone healing and minimize postsurgical relapse. Grafting may be indicated in complex movements, especially large advancements and down grafting cases (yellow arrow)

osteotomy gaps, and press-fit into position, or rigidly fixed if necessary [61]. Once the fixation has been competed, final measurements with calipers are made to confirm proper vertical placement (Fig. 69.24a, b).

69.4.10 Checks to Be Made Before Plate Fixation of the Maxilla

1. Ensure there are no bony interferences.
2. Check that the teeth are occluding into the splint correctly (particularly posteriorly, ensure the tongue is out of the way) and the condyles are seated correctly.
3. Check there are no soft tissue/septal interferences.
4. Check the nasal septum is in center (suture or cut groove into anterior nasal spine). Ensure that tears in the nasal mucosa if any are sutured.
5. Check any septal adjustment and piriform aperture bony adjustments have been made.
6. Make sure the maxillary dental midline and transverse maxillary occlusal plane cant are correct.
7. Ensure facial appearance, incisor exposure and aesthetics are optimal.
8. Check occlusion.

Once the maxillary fixation is completed, the intermaxillary fixation is released. The mandible is hinged with the condyles fully seated using the "triangular" finger formation. Retractors should be used to hold the cheeks away from the posterior teeth, and the mandible is rotated upward such that the teeth fit into the maxillary splint. The tongue is also manipulated out of the way if it is interfering with closure. There should be a smooth closure into the splint without any shifting or deviation of the occlusion. Contact should occur simultaneously in the anterior and posterior areas.

69.4.11 Closure

Proper closure occurs in three steps.

69.4.11.1 Nasal Cinch Suture (Alar-Base Suture) [62]

With the dissection and exposure of the paranasal musculature during Le Fort I osteotomy, the nasal cinch suture provides appropriate repositioning of the soft tissue to minimize postoperative nasal base widening. A slowly resorbing suture (e.g., 2-0 polyglycolic acid) is placed from an intraoral approach into the alar base bilaterally, pulling the alar bases toward each other when tightened (Fig. 69.25a, b). If properly done, tightening should result in an equal or shorter alar base width when compared to the preoperative width. This will frequently result in an immediate upturned appearance of the nose, a protruded positioning of the upper lip, and edema. These immediate changes are transient and will disappear within a few weeks. Following healing, the procedure results in minimal widening of alar base from the preoperative measurement (Fig. 69.26a, b).

69.4.11.2 V-Y Closure [63]

Typical movements of the maxilla and normal healing of the circumvestibular incision can result in lip shortening,

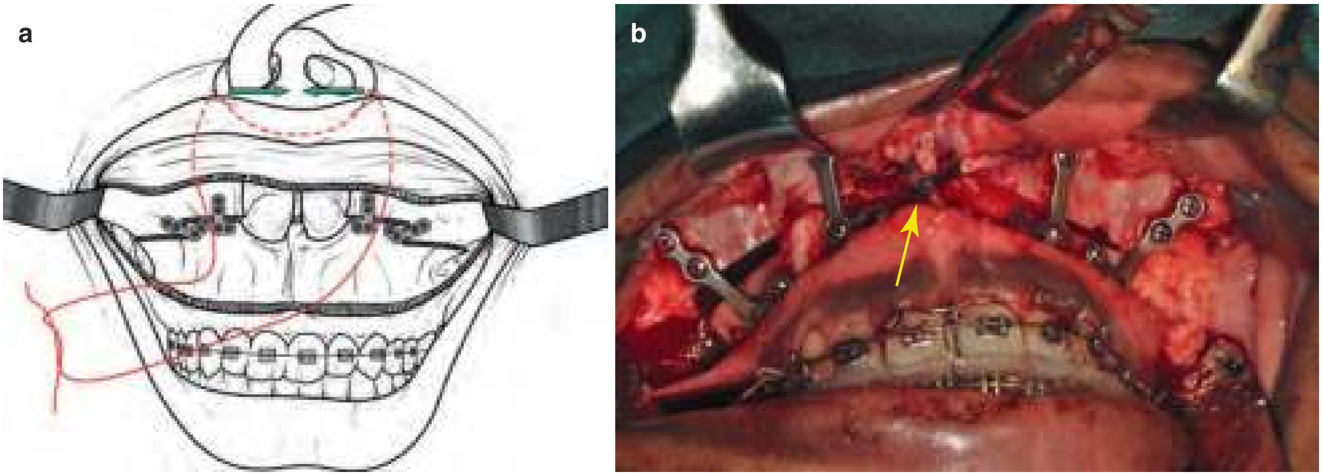

Fig. 69.25 (**a**, **b**) An alar base cinch suture controls the alar base width and counteracts postsurgical widening of the alar base. Care is taken to correctly place the suture in the fibro adipose tissue and transverse nasalis muscle at the lateral nasal base, allowing medial positioning of the alar base during suture tying (yellow arrow)

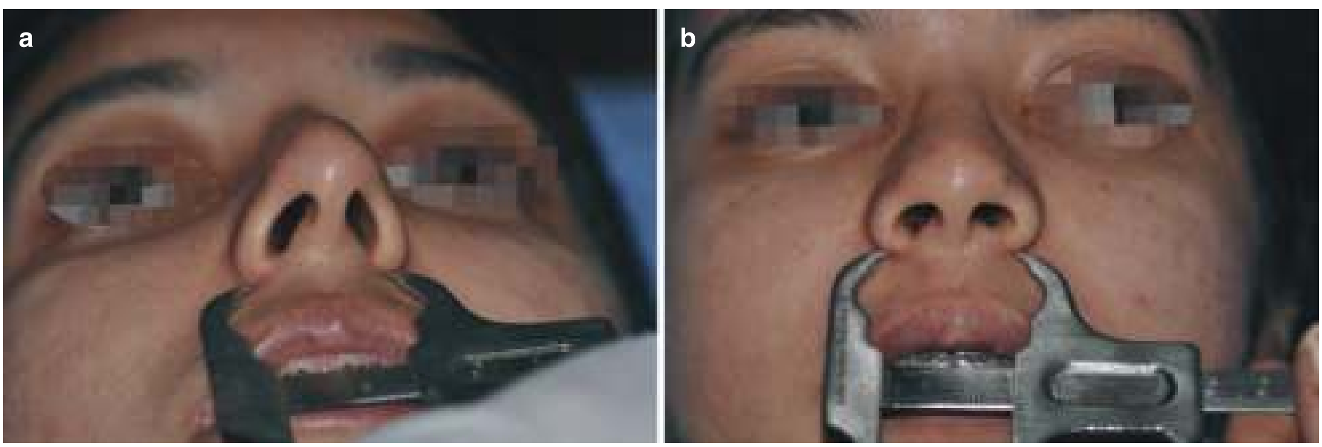

Fig. 69.26 (**a**, **b**) Measuring the alar base pre-surgically (**a**) and post-surgically (after edema subsides and soft-tissue settles) (**b**) and confirming that the size remains same

lip thinning, and decreased vermillion show. The Le fort I incision transects various components of the midface musculature, including the transverse part of the nasalis muscle, the myrtiformis muscle), and the levator anguli oris muscle.

It is important to correctly suture the deep muscular layers in proper anatomic orientation, so that the facial contour may be maintained [64].

The V-Y closure is performed to combat these undesirable changes. With the use of a skin hook, the tissue of the midline vestibular incision is grasped and pulled superiorly. Using a resorbable suture (e.g., 4-0 vicryl), the incision is closed vertically by grasping the tissue 1 cm away from the midline on either side of the skin hook and advancing these edges together by tightening the suture. This provides for a 1 cm V-Y closure. The remaining closure is completed with either a continuous suture or interrupted sutures. The closure generally requires four or five throws of the suture (Fig. 69.27, Fig. 69.9b).

Fig. 69.27 Vestibular soft tissue closure is performed with a running resorbable suture. A midline V-Y closure provides support to the upper lip and rolls the vermillion upward and outward, gives fullness to the lip, and makes a prominent white-roll. Closure is started posteriorly and moved anterior to bring the labial side mucosa forward, which is then, closed in the midline in the form of an inverted "Y" (yellow arrow)

Fig. 69.28 (**a**, **b**) A case of vertical maxillary excess treated with superior positioning of the maxilla showing frontal, right lateral and left lateral views. (**a1, a2, a3**) Pre-surgical photos of the patient; (**b1, b2, b3**) post-surgical photos of patient (Also see Figs. 69.29 and 69.39 for the full case series images)

69.4.11.3 Vestibular Closure

The remaining vestibular closure continues from the posterior portion of the incision. A running resorbable suture (e.g., 4-0 vicryl) is passed in a simple running fashion. Figures 69.10, 69.11, 69.28a, b, 69.29a, b, 69.30a, b and 69.32a, b depict the results achieved by the technique described above for different clinical indications. Figure 69.31 demonstrates steps involved in peforming a Lefort I osteotomy in a bimaxillary setting.

69.5 Quadrilateral (Quadrangular) Osteotomy

This high-level osteotomy is a variant of the Le fort I osteotomy and extends up to the lower part of the zygoma, to a point just below the infraorbital nerve bilaterally.

The indications for this osteotomy are midface retrusion, including excessive scleral exposure.

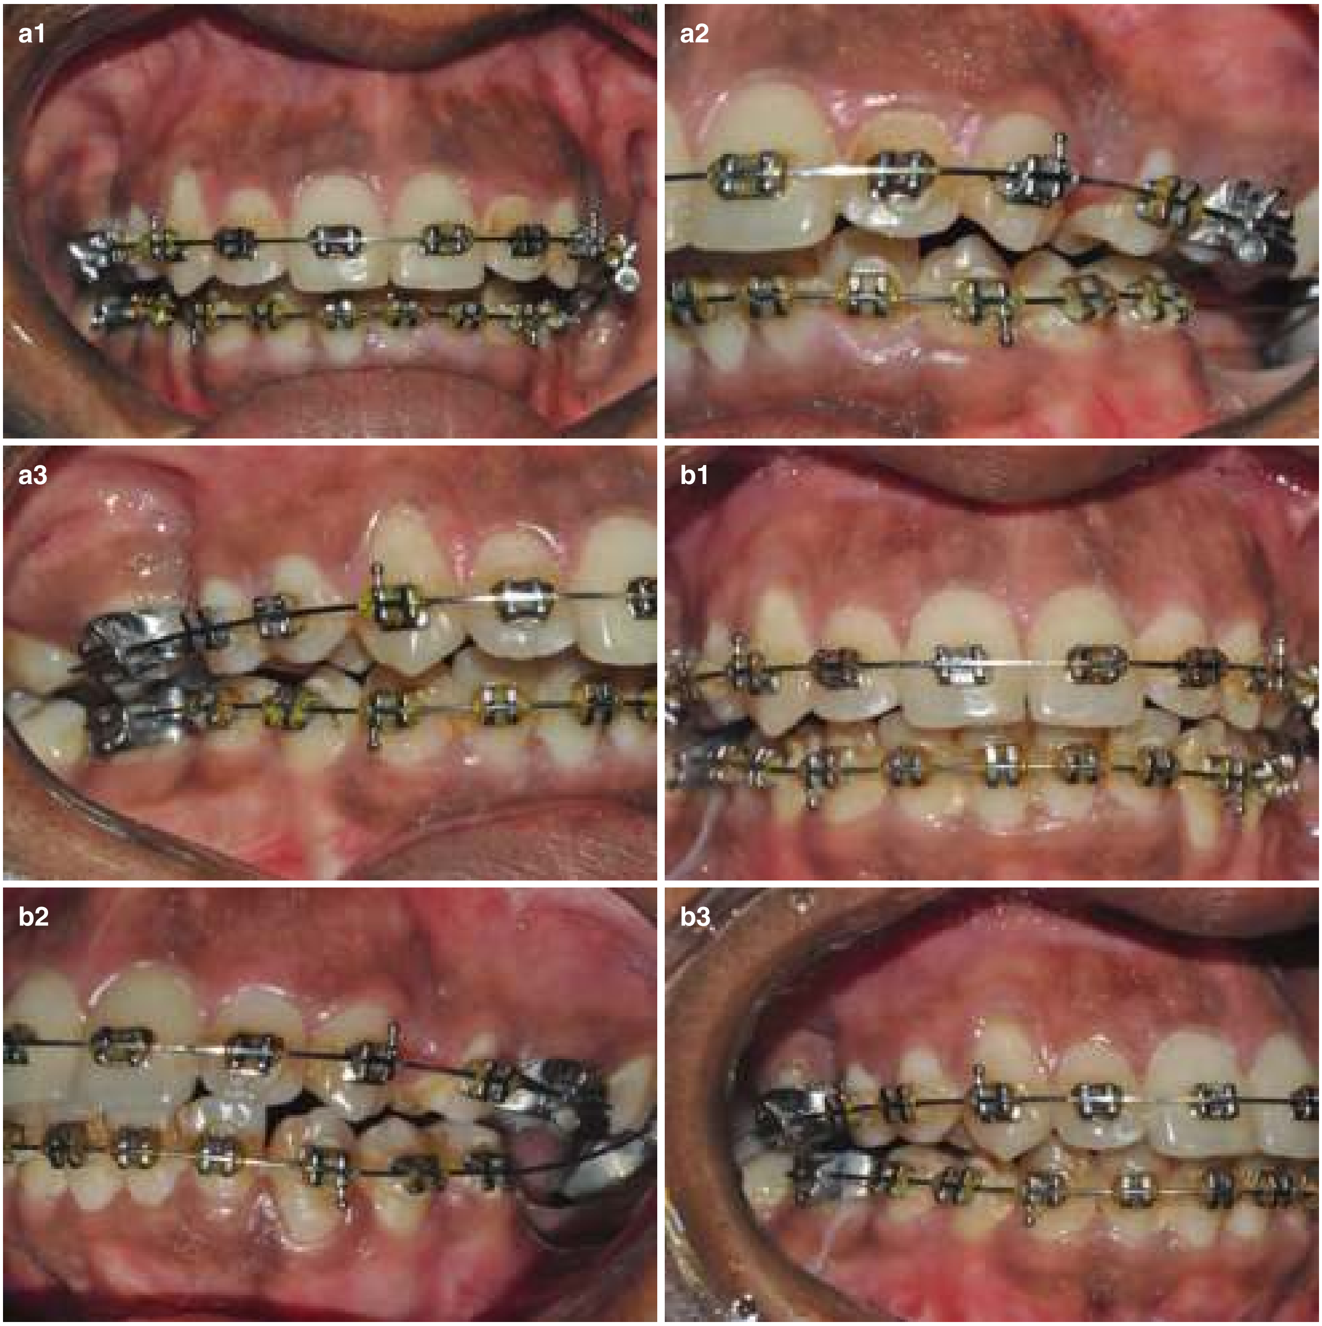

Fig. 69.29 (**a**, **b**) (**a1, a2, a3**) Pre-surgical occlusion of the same patient as in Fig. 69.28, treated with LeFort I superior repostioning. (**b1, b2, b3**) Post-surgical occlusion of the same patient

The benefits of the quadrangular osteotomy are that it improves the appearance of midfacial retrusion and flattening and improves zygomatic prominence and support for the lower eyelid. This osteotomy has minimal surgical morbidity and has acceptable outcomes. This may therefore be considered, especially in Asian patients, as a viable treatment alternative for midfacial advancement without augmentation of the malar region [65].

If the cuts are made from high to low a significant inferior movement of the maxilla can be achieved thus reducing the necessity for an interpositional bone graft (which would be required following a maxillary set down) and alloplastic onlay grafts for the zygomatic regions. It is more stable than conventional inferior positioning of the maxilla as there is good bone contact with native bone and no bone graft. This osteotomy also produces less rotation of the nasal tip than the conventional Le Fort I osteotomy. However, it is important to recognize that if there is a mild facial asymmetry in the maxillary region, this asymmetry can be emphasized with this high-level cut as the maxilla is advanced. The surgical technique is the same as for the conventional Le Fort I osteotomy, but significant sharp dissection of the masseter muscle from

Fig. 69.30 (**a**, **b**) Patient with maxillary occlusion cant and asymmetry (also see Figs. 69.31, 69.32 and 69.40)

the zygoma is required to expose the prominence of the zygomatic bone. The bony cuts are demonstrated in Fig. 69.33. The cuts are made just below the infraorbhital nerves.

The bone over the zygomatic prominence is thick, and control over the shape of the cuts is easier using a burr and a saw. This ensures that the bony cut does not propagate upward to the cranial base but instead is directed downward to the normal pterygomaxillary disjunction level. The other steps to complete the bony cuts and down-fracture the Le Fort I cut are made as above. Fixation is with miniplates. However, care must be taken to ensure the plates are not palpable in the infraorbital regions.

69.6 Surgically Assisted Rapid Palatal Expansion (SARPE)

SARPE is a combination of orthodontic and surgical techniques to expand the maxillary arch. This is ideal in patients with of transverse maxillary deficiency, where the palatal suture has completely fused. This concept initially was met with skepticism but later was repopularized through the works of several clinicians, including Issacson and Ingram [66] and Haas [67], as a viable method of treating maxillary transverse deficiency. SARPE is indicated in cases where skeletal maturity has been achieved, transverse maxillary deficiency is present, excessive display of buccal corridors when smiling, and presence of anterior dental crowding. It has been shown that the midpalatal suture undergoes ossification at a wide range of ages [68]. In general, SARPE is recommended for patients who are over 16 years of age [69]. Nonsurgical expansions can be a reasonable consideration for patients younger than 12 years of age.

Before starting the surgery, it is important to confirm the secure placement of the appliance and also the presence of the device key to activate the appliance.

This procedure follows Le Fort I single piece osteotomy.

The maxilla is *not* down-fractured. Relieving of the osteotomies present at the zygomaticomaxillary buttresses is done, as this allows clearance during separation. The midline

Fig. 69.31 (continued)

gingiva is elevated to expose the alveolus. The midline osteotomy is carried out using a sagittal or piezo saw from the piriform rim of the nose, to the alveolus. The mid-palatal suture osteotomy is completed with chisels. The zygomaticomaxillary buttresses clearance is confirmed intraoperatively by activating the palatal appliance (Fig. 69.34a–c). The remainder of the procedure is according to Le Fort 1 single piece osteotomy [70].

Salient Features of SARPE

1. SARPE is usually performed on arches that are V shaped.
2. The scope of orthodontics is limited in masking a skeletal transverse discrepancy that is greater than 5 mm. A segmental Le Fort expansion cannot be carried out for movements greater than 7 mm. If a significant amount of maxillary expansion is required, presumably greater than

Fig. 69.32 (**a**, **b**) (**a1, a2, a3**) Pre-surgical pictures of patient with cant; (**b1, b2, b3**) postoperative asymmetric superior repositioning of maxilla and unilateral sagittal split osteotomy of the mandible to close the open bite created (Also see Figs. 69.30, 69.31 and 69.40)

7 mm, a SARPE procedure is preferred as it would offer more stability.

3. An IOPA X-ray is taken to ensure that sufficient space exists for an interdental osteotomy.
4. Osteotomies performed during a Le Fort I are replicated for the SARPE procedure, without down-fracturing the maxilla.
5. Pterygoid plates are separated for the posterior expansion of maxilla.
6. The zygomaticomaxillary buttresses offer greatest resistance to maxillary expansion. Activation of the palatal appliance must be done within the operating room. This will ensure that the maxilla is able to expand bilaterally, in a symmetric fashion, with no interferences.

Fig. 69.33 It is important to continue the saw or cut with a fissure bur through the inferior part of the zygomatic arch and extend it inferiorly and posteriorly to enable the important back cut to the pterygoid plates. This reduces the possibility of unwanted propagation of fractures to the cranial base

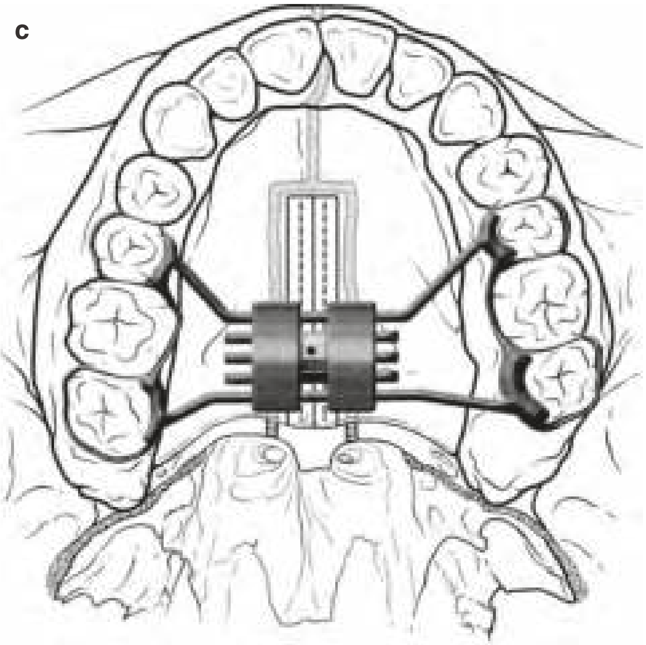

Fig. 69.34 (continued)

7. Overcorrection is recommended to allow for relapse. This is because maximum instability is associated with transverse maxillary expansion.
8. Either a tooth-borne appliance (Haas and Hyrax appliance) or a bone-borne palatal appliance may be used. The tooth-borne appliances may be more acceptable for patients, as they are less invasive and more hygienic. The disadvantage of these appliances is that they can create an occlusal tipping effect at the level of the alveolar bone and teeth. This may be minimized by engaging at least three posterior teeth. On the other hand, a bone-borne appliance offers better control over orthopedic movements at the level of the palate, but it requires a steep palatal vault for anchorage and is more invasive [71, 72].

69.7 Sequence of Bimaxillary Surgery (Fig. 69.31a–m)

A single surgical procedure can be employed to correct skeletal deformities of the mandible and the maxilla as well. The surgeon generally determines the preferred sequence. The authors personal preference is provided below.

1. The mandibular bony cuts are usually performed first, without splitting the mandible. This is followed by completion of the maxillary osteotomy, repositioning and fixation. In the past, fixation was only by trans-osseous wiring. Hence, when the mandible was performed first, its position was arbitrary as it incorporated the mobile proximal fragment (due to the TMJ) based on which the final maxillary position was determined. To avoid this the maxilla was completed first.
2. The mandible is exposed, and the bony osteotomy cuts are completed. However the formal split is not completed.
3. The maxilla is exposed, osteotomy completed and fixed in its final position.
4. The split for the mandible is completed, followed by the reposition of the mandible to the desired position. The mandible is then stabilised and fixed in its final position. This eliminates the possibility of any undesired maxillary movement as the movement of the maxilla is completed based on a stable intact mandible.
5. Finally, the genioplasty cuts are stabilized.
6. The same order must be considered during model surgery and when fabricating the intermediate and final splints for guidance.

The authors personal preference has been detailed above. Alternatively, mandibular splitting may be performed first, and an intermediate splint may be used to to fix the mandible to the unoperated maxilla. The maxilla may then be stabilized to the operated and repositioned mandible. However, it must be noted that stabilization and fixation of the mandible are more challenging than for the maxilla. Rigid fixation may be more challenging if an improper or misdirected split occurs. The procedure may even need to be aborted altogether. However, by stabilizing the maxilla first, the mandible can use appropriately positioned maxilla for stabilization. Therefore, we have always preferred to complete the maxillary surgery before mandibular surgery.

Having listed a general guide above, we reiterate that no dogma should be given regarding the sequence of maxillary or mandibular surgery. Proper planning and preparation will in turn logically dictate the sequence, which must be kept flexible [73].

69.8 Soft Tissue Changes with Le Fort I Osteotomy

Changes in the jaw position in turn lead to changes in the position of soft tissues such as the lips, cheeks, and nose [74]. The lips may show thinning, reduced vermillion show, and may lack adequate lip support [46]. The nasal tip may be upturned, the alar base width may increase, and the nasolabial angle may widen [75] (Fig. 69.35a–c). Soft tissue swelling

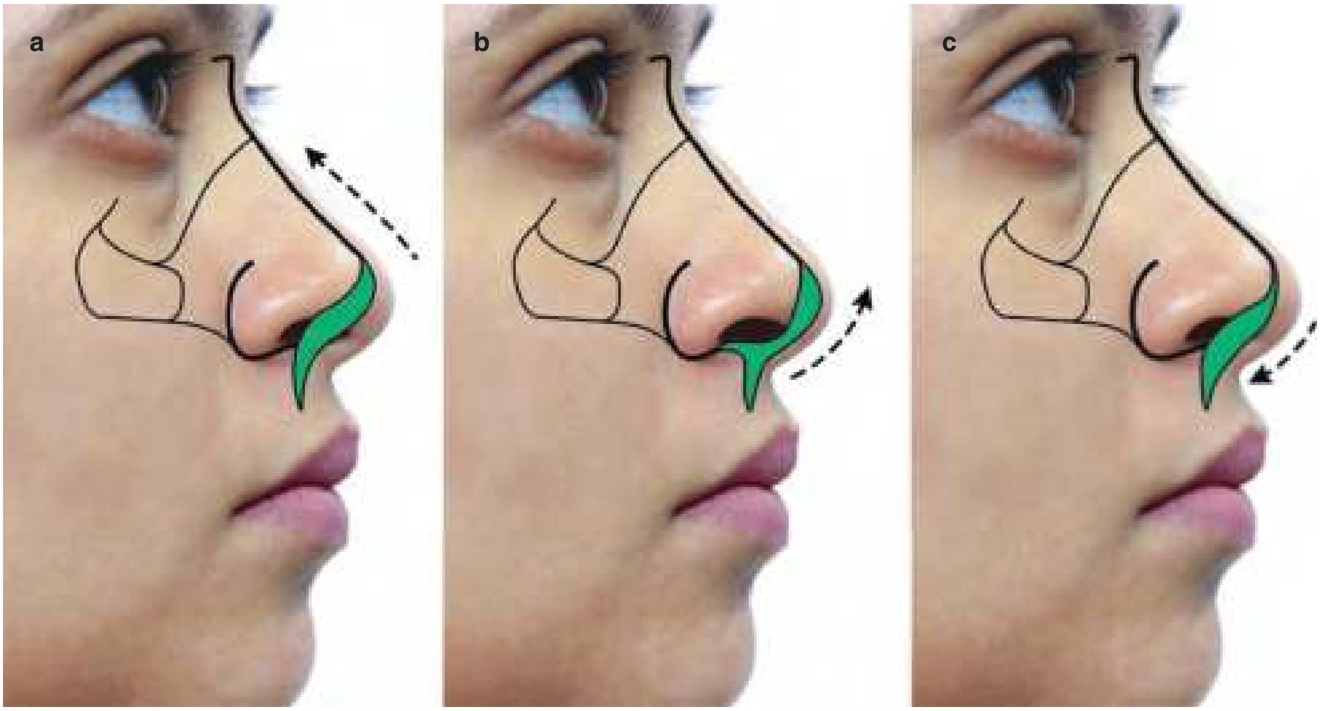

Fig. 69.35 (**a**–**c**) (**a**) reduction of a strip along the caudal septum will shorten the nose; (**b**) reduction involving the nasal tip as shown will increase the nasolabial angle; (**c**) wedge reduction predominantly at the septal base will reduce the nasolabial angle

may take up to a year to resolve, so these changes may not be apparent immediately [76]. In some regions, such as the subnasale, and the lips, greater than 10% change has been documented over 5 years [4]. Nasal changes are quite complex and are therefore unpredictable. Both the structure of the nose (including nasal cartilage connective tissue, anterior nasal spine, and the other nasal cartilages) and the degree of movement of the maxilla play a role in nasal changes. Other patient-related factors, including thickness and morphology of the soft tissue, postoperative healing, age, and ethnicity, can also affect nasal changes, which may either be favorable or unfavorable or beneficial. The nasal width alone increases predictably in Le Fort I osteotomies, and the increase in width depends on the extent of maxillary movement. Adjunctive procedures to limit widening of the nasal width may be performed intraoperatively. These include alar cinch suture and piriform aperture sculpting. Alternatively, the changes may be accepted and later procedures can be performed if necessary. The disadvantage of this is the need for an additional surgical procedure, e.g., alar wedge resection rhinoplasty. The alar cinch suture and V-Y closure (ACVY) is efficient and less invasive in controlling nasolabial changes. Its long-term results need to be evaluated. One study showed that the alar base cinch suture reduced the inter-alar width to its preoperative width following a Le Fort I osteotomy. The suture was stable when evaluated at 12 months and 3 years postoperatively [77]. There have been studies comparing nasal and maxillary vermilion morphology after Lefort osteotomies by simple primary closure, Single VY closure and Double VY closure. The results indicated that better aesthetics are seen in double VY closure cases (See Hackney et al. 1989, Ledezma et al. 2014, in Additional reading provided). However a systematic review in 2014 couldn't reach a conclusion regarding the efficacy of various methods of closure in Lefort Osteotomies.

69.9 Specific Considerations

1. Attempts to study the nasal changes resulting from maxillary movements have demonstrated very variable results. The general consensus is that nasal changes are unpredictable after Le Fort I osteotomy [78].
2. The ascending pharyngeal artery and ascending palatine artery maintain blood perfusion to the down-fractured maxilla.
3. Impacted, unerupted, or erupted wisdom teeth may be removed during the Le Fort I surgery. The curved pterygoid osteotome must be placed posterior to the impacted teeth or through the socket. The technique of pterygoid separation through the socket of the third molar was described by Trimble et al in 1983 (Refer additonal reading).
4. If posterior bony interferences are present, they may cause condylar displacement, condylar distraction, asym-

metrical jaw movements (deviations), malocclusion, and aberrant maxillary position.
5. If the maxilla is not mobilized sufficiently prior to fixation, this may hinder optimal advancements.
6. The zygomaticomaxillary and nasomaxillary buttresses consist of thick struts of bone and are ideal for securing fixation [79].
7. Blood loss is variable but rarely warrants transfusion. A review of over 500 osteotomies concluded an average loss of just under 300 mL, greater for bimaxillary osteotomies and less for single jaw surgery [80].

69.9.1 Adjustment to the Anterior Nasal Spine and Piriform Aperture

Mommaerts et al. reported that the anterior nasal spine is a significant component of nasal tip projection and may be reduced to limit the degree of nasal tip rotation [81]. Betts et al. also stated that changes in the lateral part of the piriform aperture significantly affected the soft tissue of the nasal base and nasal tip projection [82].

It is important not to remove too much of the septum as this can produce a retracted columella, which is a potentially unattractive feature.

Osseous recontouring of the nasal crest of the maxilla and/or resection of a portion of the caudal extent of the cartilaginous septum is recommended to keep interference at bay. Placement of a suture through the anterior nasal spine and cartilaginous septum to prevent its displacement upon removal of the nasoendotracheal tube is beneficial.

69.9.2 Effect of Changing the Inclination (Slope) of the Osteotomy Cut

If the osteotomy cut is made in a parallel direction to the occlusal plane and the maxilla is advanced, the maxillary incisor exposure will increase but the face height will not change. However, if the osteotomy cut starts high posteriorly and slopes downwards toward the piriform aperture, the maxilla will move down the slope as it is advanced, thus increasing the maxillary incisor exposure. The mandible will subsequently rotate in a clockwise direction and the lower anterior face height will increase (Fig. 69.36a, b). The opposite is true for the osteotomy cuts that start low posteriorly and slopes upward toward the piriform aperture (Fig. 69.37a, b).

69.9.3 Impacted Wisdom Teeth

If an impacted maxillary wisdom tooth is indicated for removal, this is done through the sinus floor. Using a rotary drill with a rosette bur, the bone from the sinus floor, which lies above the impacted tooth, is removed. Next, a tapered fissure bur is used, and the bone just adjacent to the impacted tooth is removed. The impacted wisdom teeth may also be sectioned if necessary

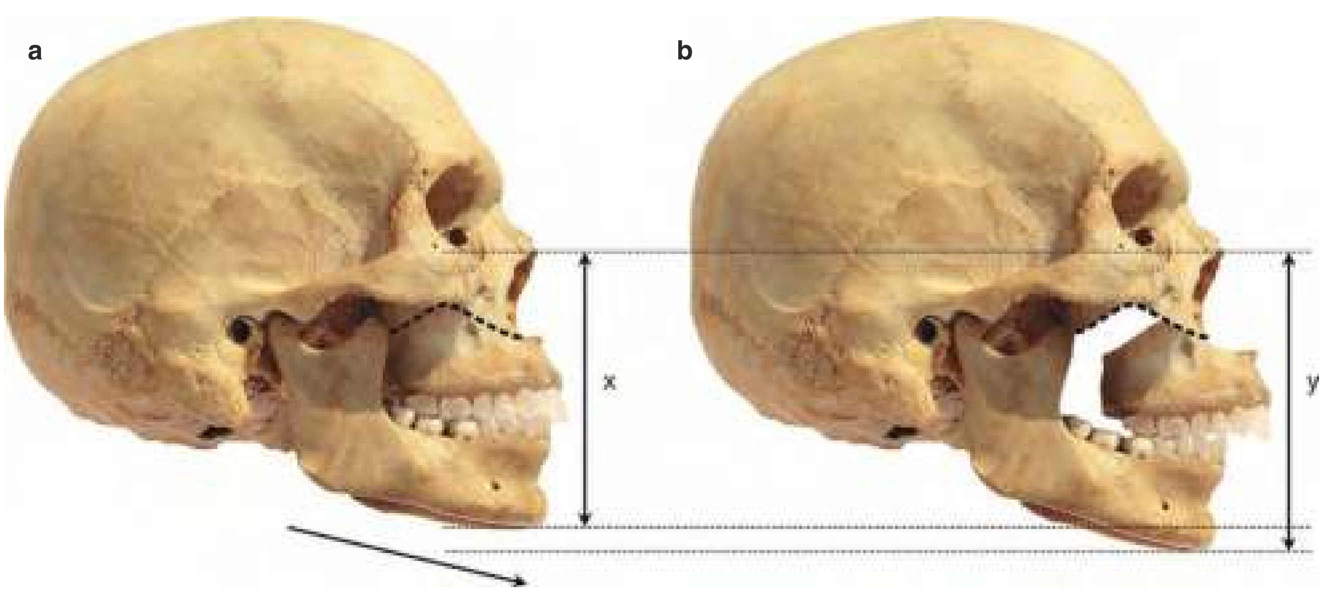

Fig. 69.36 (**a**, **b**) Diagram showing effects of the inclination (high to low postero-anteriorly) of the osteotomy cut when advancing the maxilla—(**a**) osteotomy inclination to increase incisor exposure and potentially increase lower face height, (**b**) advancement of maxilla producing increase of lower facial height due to downward ramp effect

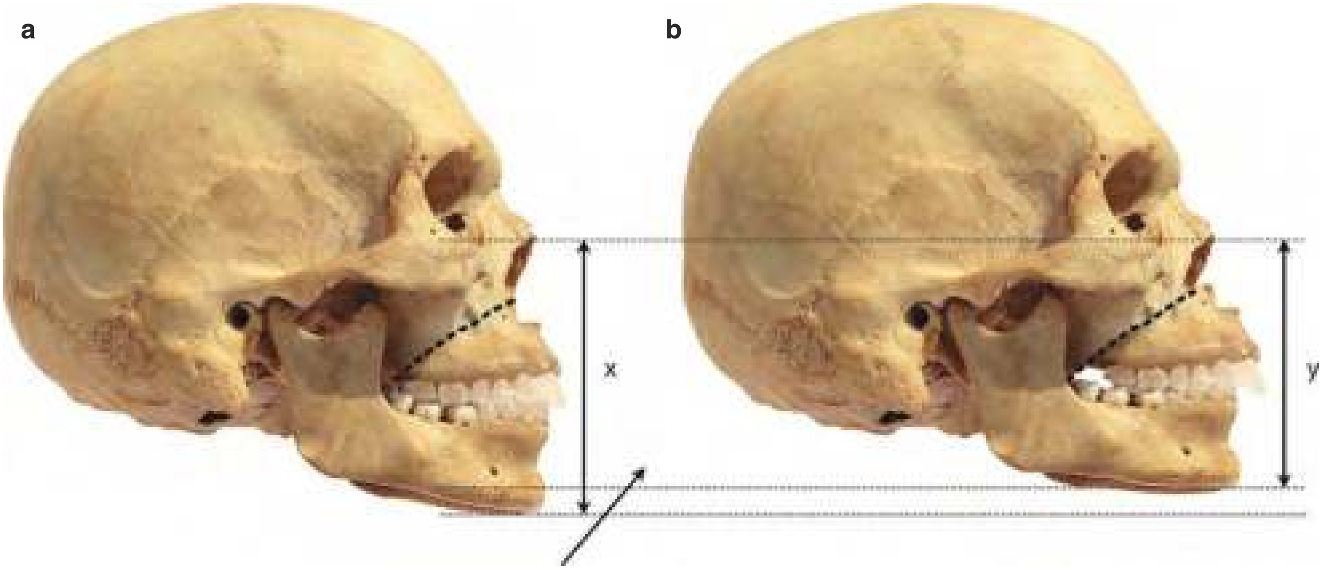

Fig. 69.37 (**a**, **b**) Diagram showing effects of the inclination (low to high postero-anteriorly) of the osteotomy cut when advancing the maxilla—(**a**) osteotomy inclination to reduce incisor exposure and potentially reduce lower face height, (**b**) advancement of maxilla producing reduction of lower facial height due to upward ramp effect

to aid in removal; this usually depends on the developmental stage. The tooth is delivered using a dental elevator. Rarely, perforation through the palatal mucosa may occur.

69.9.4 Erupted Wisdom Teeth

If the maxillary wisdom tooth is completely erupted, this may be extracted prior to down-fracture. This will allow the operator to have a stable "workbench" during extraction. In order to maintain the blood supply to the down-fractured maxilla, the adjacent palatal and labial mucosa must be preserved carefully at the time of extraction.

69.9.5 Considerations of Pre-operative Difficulties

The pre-surgical workup and planning of patients who require corrective jaw surgery required detailed analysis of clinical features, study models, and plane radiographs. Radiographic analysis includes comprehensive assessment of lateral cephalograms, postero-anterior cephalograms, and orthopantomograms. The need for multiple individual planar views has been replaced by the advent of cone beam technology.

69.9.6 Considerations of Operative Difficulties

Horizontal osteotomy of the maxilla should result in a clean pterygomaxillary separation to subsequently allow for down-fracture and mobilization. At this step, the pterygoid plates should ideally remain intact and attached to the skull base. However, in some exceptional cases, such as patients with cleft maxilla, the pterygoid plates are unusually thick and well buttressed. On the other hand, some patients have thin and almost translucent pterygoid plates [83]. Pterygomaxillary synostosis (fusion) may be seen in up to 12% of all patients [21].

If the pterygoid plates fracture at a lower level, this may cause difficulties in down-fracture and mobilization, because of the attachment of the pterygoid musculature. On the other hand, if the plates fracture at a higher level, the fracture may propagate into and along the skull base, which can potentially cause neuro-ophthalmic complications.

On postoperative CT scans, the incidence of pterygoid plate fracture after a Le Fort I osteotomy was found to range from 58 to 75% [84, 85]. However, despite this high incidence, the incidence of fractures propagating to the skull base/orbit is low [83].

Lanigan et al. carried out a study on unfixed fresh cadavers and found that 26% of cases were "difficult down-fracture." They stated that this was probably due to the presence of "thick bony maxillary walls" [83].

These authors stated that if a difficult down-fracture was encountered after a routine Le Fort I osteotomy, then the posterior walls of the maxilla must be sectioned completely using an osteotome. Alternatively, sectioning through the tuberosity could be performed, using a micro-oscillating saw or straight osteotome, as this would avoid the thick posterior walls and aid in pterygomaxillary separation. However, these authors have stated that it would not be possible to totally prevent untoward fractures that could occur during pterygomaxillary disjunction and down-fracture. We emphasize that thorough CBCT imaging should be undertaken preoperatively, as this would familiarize the surgeon with the maxillary morphology.

The following maneuvers may help if the surgeon finds difficulty in down-fracture following osteotomy and disjunction:

1. Revise the osteotomy cuts at all accessible sites, including anteromedial antral, lateral antral, and superior-nasal crest.
2. The maxilla may be "hinged down" to directly visualize the posterior maxilla, after which the cuts in this region may be completed, using a straight 4 mm osteotome.
3. Down-fracture can then be undertaken under direct vision.

O'Regan and Bharadwaj stated that an osteotome or saw must never be used blindly in these situations [86].

69.9.7 Proper Positioning

- Proper positioning can be difficult in isolated maxillary surgery, usually due to unrecognized posterior bony interferences.
- With an unrecognized posterior interference and inadequate effort or improper seating of the condyles, the maxilla can rotate around this interference, resulting in an anterior open bite after release of intermaxillary fixation. The maxillomandibular complex should be rotated with pressure seating the condyles in the glenoid fossa (Fig. 69.38a, b, c).
- Looking for the posterior interferences and eliminating them will result in the intended postoperative occlusion. Prior to any attempt to position the maxilla, effort is devoted to removing bone in the most likely areas of potential posterior interference, that being the area posterior to the second molar and along the perpendicular process of the palatine bone.
- Whether or not there is a potential for interference in the region of the pterygoid plates, per se, depends upon the

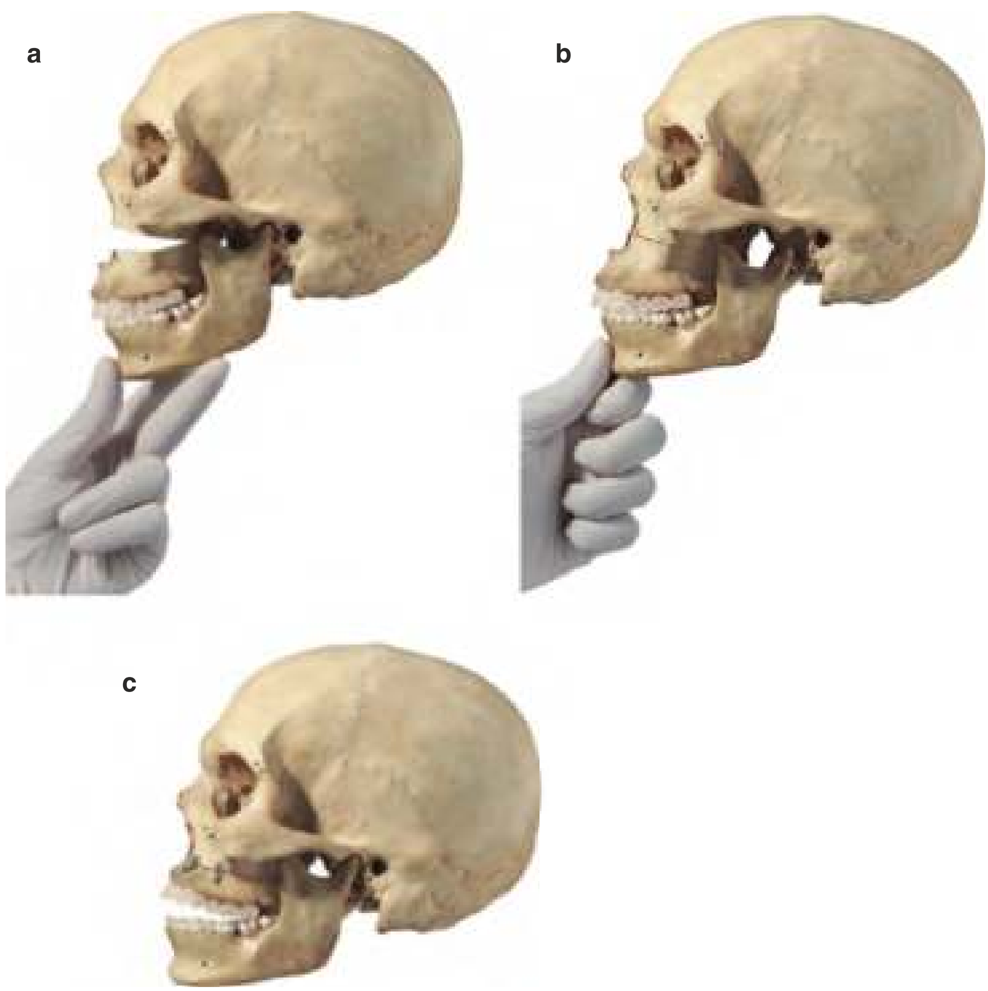

Fig. 69.38 (**a**–**c**) (**a**) The proper method for condylar seating at the time of maxillary positioning prior to fixation. Posterior prematurities are best appreciated with this method. (**b**) Pressure on the chin to push the anterior aspect of the maxillary osteotomy together may rotate the condyles inferiorly and posteriorly while maxillary fixation is applied. (**c**) Upon release of intermaxillary fixation, the condyles may return to the fosse, and an open bite may appear. Unfortunately, this open bite may not appear immediately, especially if postoperative elastics are used to "guide" the occlusion

surgical move. This is much less likely with advancement than it is with other moves such as impaction.

- It is often easiest to adapt the plates for fixation with Le Fort osteotomy and initially secure them only to the inferior fragment. Once all the plates are properly bent and secured to the inferior fragment, the maxillomandibular complex and condyles can be positioned with great care, and the shape and bending of the plates critically evaluated and secured to the superior fragment in succession, while the maxillomandibular complex is held in position.

69.9.8 Nutritional Support

Orthognathic surgery throws up many physiological challenges. These include postoperative facial swelling and catabolism which increase the nitrogen requirements. If these are not met, wound healing may be compromised. A diet fortified with macro- and micronutrients and adequate hydration is therefore essential [87].

Mandibular movements may be restricted in the postoperative period, owing to facial swelling and pain. Meeting the daily nutritional needs and hydration requirements (Table 69.1) may therefore be difficult. Studies have shown that in 6 weeks following surgery, patients can lose between 3.1 and 6.8 kg of weight [88].

It is important to adapt the diet to suit these needs, to promote wound healing, and to minimize postoperative complications. Another important factor in patient recovery is the patient's mood. Adequate nutrition and hydration will serve to improve the patient's mood, thereby diminishing postoperative irritability or depression [89]. Dietician assessment of nutritional status is essential to ensure that the above goals are achieved.

The modification of the diet is a sequential process. This aims at reducing the masticatory forces on the underlying healing bone, which in turn optimizes the conditions for healing.

1. The first 7 days following surgery should consist of a diet rich in energy and protein. This must be in a liquid form, and foods may be completely blended in a food processor to a smooth liquid consistency.
2. After the first week, patients can start consuming food with a small spoon or fork. It is still advised to minimize chewing, and foods may be mashed. The high-energy-high-protein diet must be continued.
3. After the second week, light chewing may be done, and a soft diet is recommended. The jaw muscles may fatigue easily at first, but gradually the muscles adapt to the new position. The soft diet is continued for two months, after which regular diet may be resumed [87, 90–98].

Table 69.1 Recommended postoperative nutrition requirements for patients above 16 years, undergoing orthognathic surgery [87]

	Energy (kcls)	Protein (g)	Fluid (ml)
Male	2500	1 g/kg/day	35 mL/kg/day
Female	2000	1 g/kg/day	35 mL/kg/day

69.9.9 Complications

1. *Hardware failure*: Unstable orthoappliance, splints/wafer, must be tried separately on each arch pre-operatively. Hardware exposure or fracture, palpable hardware, and loosening of screws are certain complications in hardware failure. Management involves removal of hardware with or without replacement, depending on the amount of bone union and time duration after surgery.
2. *Unanticipated fracture of maxilla*: A occlusal splint with a palatal vault extension is essential to counter this complication.
3. *Hemorrhage*: Bleeding commonly occurs from the descending palatine artery and pterygoid plexus. Injury to pterygoid plexus may happen while performing pterygomaxillary disjunction. This may lead to arteriovenous malformations which may cause life-threatening bleeding 2–4 weeks post-surgery. It needs to be managed with selective embolization. Hemorrhage may occur in patients with undiagnosed bleeding disorders.
4. *Deviated nasal septum*: This can occur when inferior septoplasty is inadequate during superior repositioning of the maxilla. It is managed postoperatively with adjunctive septoplasty.
5. *Damage to apices of teeth*: The horizontal osteotomy should be placed at least 5 mm above the apices of the maxillary teeth to avoid damage to the apices.
6. *Malunion and nonunion*: This can occur if fixation is inadequate fixation or has failed.

   Rigid fixation with plates provides the initial stability until bone has united. Bone first unites in the pterygoid region [99]. The most stable maxillary movement is superior repositioning, followed by advancement, and the least stable is inferior repositioning. However, the studies looking at the inferior positioning of the maxilla have been based on the need for bone grafting. Studies have reported relapse rates for maxillary superior repositioning of the maxilla ranges from a mean of 0–18% for the anterior maxilla and 6–7% for the posterior maxilla. Relapse rates for maxillary advancement range from 5 to 15%. As with most orthognathic surgery, relapse is greater with increase in the maxillary advancement. With inferior maxillary repositioning (using bone grafts), there may be 28% anterior relapse and up to 70% posterior relapse [100]. Nonunion is rare and probably associated with failure of the initial plate fixation and poor bony contact. If this persists for greater than 6 months, further surgery with rigid fixation and autogenous bone grafting is recommended [101]. Maxillary advancement and posterior and superior movements are shown to be stable, whereas inferior and transverse movements are unstable [99–110]. The use of autogenous bone grafts and/or hydroxyapatite has been proposed to improve the stability of inferior repositioning of the maxilla [101, 111–117].

7. *Unfavorable aesthetic result*: This results from poor treatment planning or unrealistic patient expectations.
8. *Infection*: Infection may occur in rare cases and is managed with systemic antibiotics with or without placement of a drain and the causative hardware removal. Septic complications have been recorded in 1.1% of osteotomy operations [55].
9. *Dental problems:* As a result of the osteotomy cut, the maxillary teeth lose their nerve supply. Generally, the nerve supply is re-established after 18 months to 2 years [118]. The teeth maintain their viability from the collateral blood supply. Patients should be warned that their teeth and gingivae may be numb for up to 2 years [119]. Osteotomy cuts should be a minimum of 5 mm above the root apices to avoid complications.
10. *Trigeminocardiac reflex (TCR):* The stimulation of trigeminal nerve branches during Le Fort I osteotomy can be a possible cause of the TCR, and transient cessation of the procedure is adequate to allow the heart rate and blood pressure to normalize and dysrhythmia to stop [120].

69.10 Recent Advances (Refer Figs. 66.21 and 78.51)

(a) *Virtual planning in Orthognathic Surgery:* the last decade has seen a tremendous evolution in the field of surgical planning. Computer Assited Virtual Surgical Planning and the use of CAD-CAM designed splints have significantly improved intra-operative accuracy of maxillary repositioning in orthognathic surgery [121].

(b) *Waferless Orthognathic Surgery:* Another technique which has created a paradigm change is the design of custom-fabricated cuttiing stents and patient specific implant for fixation, which help not only perform the osteotomy but also fix the segment in the desired position without the use of occlusal wafers [122].

69.11 Conclusion

The development of modern maxillary orthognathic surgical procedures had diverse historical origins and contributions. With advancement in technique and the introduction of safe hypotensive anesthesia, the Le Fort I osteotomy has been increasingly utilized over the last four decades. Over the years, various modifications of the osteotomies, ORIF methods and bone grafting to the mobilized maxilla, have continued to evolve and progress. The Le Fort I osteotomy of the maxilla is one of the core procedures in orthognathic surgery for the management of facial skeletal deformities. The surgery, often used in conjunction with the bilateral sagittal split osteotomy, is used to correct functional and cosmetic irregularities in all three planes of space and can be utilized in the treatment of a wide range of malocclusions. Traditionally, the surgery has been known for its low technical difficulty and dependable results. Changes in the soft tissue of the nose, lips, and cheeks due to this surgical procedure need due consideration.

The risk of complications is higher in patients with segmental Le Fort 1 osteotomies or anterior movements greater than 9 mm. Efforts to minimize maxillary movement (e.g., with two-jaw surgery) are recommended to reduce complications. An emphasis should be placed on proper pre-surgical orthodontics and solid pre-surgical planning to ensure predictable and stable results. It is also imperative to plan and provide for optimal nutrition as Orthognathic surgery throws up many physiological challenges that may compromise the nutritional status including catabolism, postoperative facial swelling, and increased nitrogen requirements to promote wound healing. The premise of maxillary orthognathic surgery is therefore a multidimensional approach through planning, execution, and postoperative management.

Disclosure Authors have no financial conflicts to disclose. Authors have written consent and reconfirmation from the patients for the use of clinical pictures.

69.12 Case Scenarios

Case Scenario 1 (Figs. 69.28, 69.29 and 69.39a–h)

(A) Chief Complaints

Gummy smile
Long face
Deficient chin
Protruding upper front teeth

(B) Postoperative Result

Competent lips
Normal chin projection
Balanced face

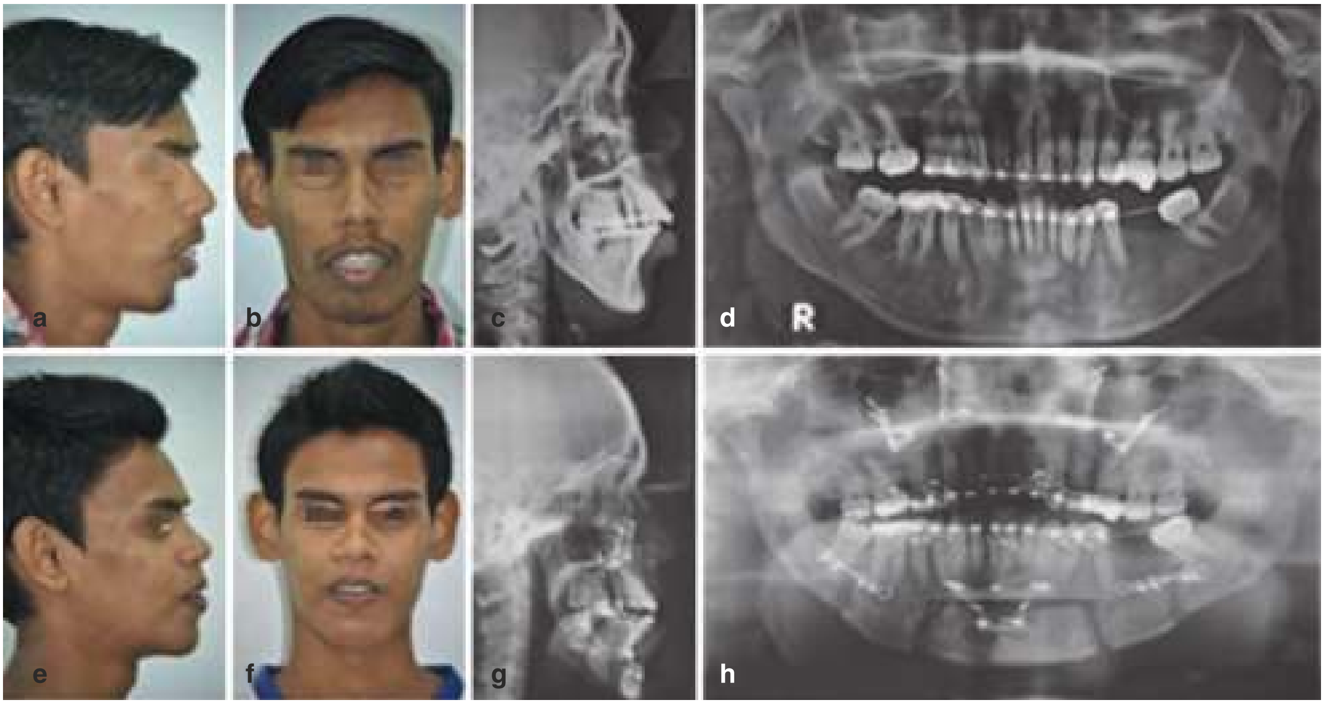

Fig. 69.39 (**a**–**h**) Vertical maxillary excess with mandibular deficiency. Treatment: Le fort I with superior repositioning of maxilla; bilateral sagittal split ramus osteotomy advancement; advancement genioplasty. (**a**) Pre-operative profile picture; (**b**) pre-operative frontal view; (**c**) pre-operative lateral cephalogram. (**d**) Pre-operative OPG; (**e**) postoperative lateral profile; (**f**) postoperative frontal view; (**g**) postoperative lateral cephalogram; (**h**) postoperative OPG showing the implants and the osteotomy cuts in mandible. (Also see Fig. 69.28)

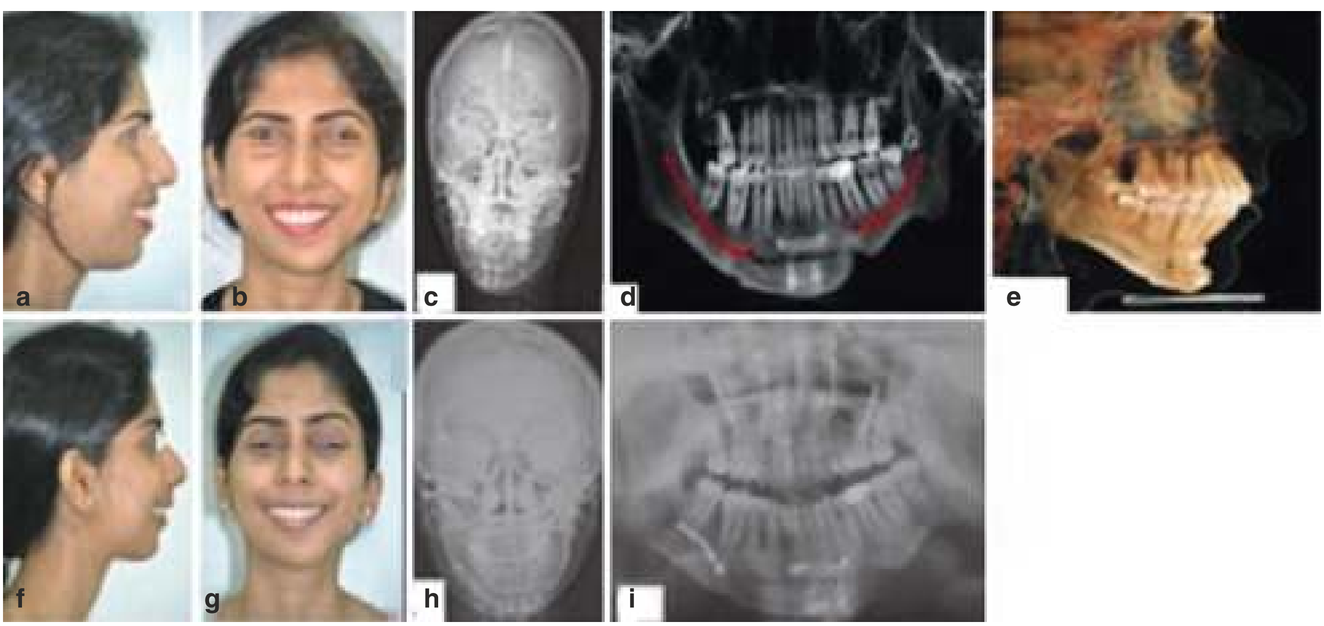

Fig. 69.40 (**a**–**i**) Facial asymmetry with maxillary occlusal cant, deviation of chin (surgery for left TMJ ankylosis and genioplasty done previously elsewhere). Treatment: Le fort I osteotomy for correction of maxillary occlusal cant; right unilateral sagittal split ramus osteotomy to close the open bite. (**a**) Pre-operative profile picture; (**b**) pre-operative frontal view; (**c**) pre-operative PA skull; (**d**) pre-operative OPG; (**e**) pre-operative lateral cephalogram; (**f**) postoperative profile picture; (**g**) postoperative frontal view; (**h**) postoperative PA skull; (**i**) Post-operative OPG (Also see Figs. 69.30, 69.31 and 69.32)

Surgical Procedure

Le fort I osteotomy for superior repositioning of maxilla

Bilateral Sagittal Split Ramus osteotomy for advancement of mandible

Advancement genioplasty

Later rhinoplasty was done.

Case Scenario 2 (Figs. 69.30, 69.31, 69.32, and 69.40a–i)

Chief Complaints

Facial asymmetry

Deviation of chin to left

Incisal/occlusion cant (Fig. 69.30)

Facial asymmetry was secondary to ankylosis of left TMJ. Left side treated with costochondral graft when patient was younger.

Pre-operative Findings

Occlusal cant

Asymmetry of face

The patient presented with occlusal canting visible at the anterior region. This needed to be addressed as it is clinically evident and may affect visual cosmesis.

Judge the incisal cant by drawing an imaginary interpupillary line and its inclination with incisal cant represented by the metal scale held in incisors

Surgical Plan (Figs. 69.31 and 69.32)

Le Fort I osteotomy for superior repositioning of maxilla on right side by 5 mm

Sagittal split osteotomy on right side of mandible to match mandible to maxilla

Facial Asymmetry

70

Neelam N. Andrade, Paul Mathai, and Neha Aggarwal

70.1 Introduction

Physical appearance is of much significance to the humans, as the human mind perceives the slightest form of deviation from normal form, function, and symmetry of the body and especially of the face as it is easily discernible [1]. Facial asymmetry could be defined as a clinically perceptible and significant difference between the two halves of the face. Every individual has some degree of asymmetry which may provide a uniqueness to the face. However, the magnitude and acceptability of the same depend on the location of the asymmetry and the patient's perception of disproportion. Facial asymmetry may also adversely affect the patient's nutritional and psychosocial development [2].

Any abnormality of the soft or hard tissues can lead to asymmetry. This could be a consequence of a congenital anomaly, a developmental, or an acquired defect. Asymmetry can be progressive in nature, while those acquired due to trauma or ablative surgeries are non-progressive [2, 3]. It is prudent for the clinician to consider the aetiology of the asymmetry, the extent, and its severity in all three dimensions in order to provide an optimal treatment plan. Besides, it is important to take into consideration factors such as growth, timing of treatment, and psychological aspirations of the patients when deciding the treatment plan [3, 4].

The present chapter will discuss the etiopathogenesis and classifications, clinical considerations, and diagnosis, evaluation, and treatment planning of facial asymmetries. Few interesting case scenarios will also be discussed for a better understanding of clinical presentations and their management.

70.2 Classification

Understanding the etiopathogenesis and classification of facial asymmetry allows for accurate diagnosis, optimal treatment planning, and improved surgical outcomes. Facial asymmetries are most commonly classified according to aetiology or morphology. Other classifications are based on time of onset, structures involved, and surgical planning outcomes and may even be restricted to the mandible alone. Table 70.1 is a summary of the various classification systems available to us today [5–19].

We have identified three classifications that are essential for the evaluation and treatment planning of facial asymmetries [Table 70.2 by Cheong et al. (2011) [13], Table 70.3 by Wolford et al. in (2009) [11], Table 70.4 by Wolford et al. (2014) [2, 19–21]].

70.3 Diagnostic Evaluation

Facial asymmetry is usually the least at the cranial base level and increases toward the lower levels of the face, with the mandible and chin commonly exhibiting the greatest asymmetry. Hence, the cranial base is used as a reference plane for assessing the type and severity of the asymmetry in the middle and lower thirds of the face. Conditions where the cranial base is also involved like syndromic or non-syndromic craniosynostosis, tumors of the cranium, and midface and Tessier's craniofacial clefts cannot be assessed in a routine manner. The presence of orbital dystopia, unequal pupillary heights, and/or unequal ear heights will make the assessment more challenging [2, 20, 22, 23].

Every clinical examination begins with identifying the chief complaint of the patient followed by a detailed physical and medical evaluation of the patient. In order to better understand the facial asymmetry, it is studied in the sagittal, coronal, and vertical dimensions with the cranial base as the reference plane. Common facial planes that represent the

cranial base are the pupillary plane, the ear plane, and the clinical Frankfort horizontal plane. It is also important to note that patients may hold the head in an abnormal position or use hairstyles and mannerisms to mask the extent of the asymmetry [e.g., a patient with a deficient mandible may tip his head upward in order to improve chin projection]. It is important to identify these compensatory mechanisms during the treatment planning process. Similarly, it can be beneficial to study the lower or middle third individually in comparison with the unaffected upper third [cranial base] by blocking out the part not being studied with an opaque sheet [e.g., card board] [20, 23].

70.3.1 Clinical Evaluation: Frontal, Axial, and Profile

Frontal View

The patient's head is positioned such that the interpupillary plane or ear plane [passing through the bottom of the ear lobes or tragi of the ears] is parallel to the floor. The pupillary plane can also be used for assessing bilateral vertical discrepancies by measuring height differences from the plane to the mandibular angles, chin, nose, and commissures (Fig. 70.1). The facial midline is represented by a vertical plane passing through the nasion or glabella, perpendicular to the pupillary plane and ear plane (Fig. 70.2). It allows to compare the degree of left-to-right asymmetry and transverse facial width discrepancies of various facial structures [e.g., orbits, pupils, malar eminences, nose, commissures, and mandibular angles]. In case of some imbalance in the frontonasal region [e.g., past naso-orbito-ethmoidal trauma], other landmarks can also be used as a reference to identify the facial midline, e.g., half the interpupillary or inter-canthal distance, the subnasal point, or the philtrum [20, 22].

Table 70.3 Wolford's classification of facial asymmetry 2009 [11]

Pseudo-asymmetry	Normal facial asymmetry	Unilateral Overdevelopment	Unilateral Underdevelopment
Occlusal interferences	Genetics	Condylar hyperplasia / Mandibular hyperplasia/Deviant prognathism	Acquired: trauma, infection, TMJ ankylosis, and iatrogenicities [due to tumor resection, radiation, unstable orthognathic procedures and adverse surgical events], failed TMJ alloplastic implants, and failed autogenous tissue grafts
Neuromuscular dysfunction	Intrauterine moulding	Osteochondroma/osteoma	
Habitual posturing	Natural growth variance	Unilateral muscle hyperplasia [masseteric muscle hypertrophy]	
Condylar dislocation		Other benign/malignant tumors	
Temporary unilateral facial swelling due to trauma/infection		Neuromuscular disorders [facial nerve trauma, Bell's palsy, Ramsey-Hunt syndrome, Mobius syndrome, mastoid infections, and cerebral vascular accidents affecting the facial nerve]	Congenital deformities [unilateral cleft lip and palate, hemifacial microsomia, and Treacher Collins syndrome]
			Adolescent idiopathic condylar resorption
			TMJ reactive [inflammatory] arthritis
			Connective tissue and autoimmune diseases

Table 70.4 Wolford's classification of condylar hyperplasia [CH] 2014 [2, 19–21]

CH type	Age at onset	Clinical findings	Imaging	Histology
CH Type 1 [similar to hemi-mandibular elongation]: Type 1A and Type 1B	Puberty	Type 1A Bilateral [BL] or Type 1B Unilateral [UL] accelerated growth; self-limiting; Class 3 occlusion; prognathic mandible	UL/BL elongated condylar head, neck and body; normal condylar head shape	Normally growing condyle; may show chondrocyte proliferation during initial and active phases, with normal bone after growth ceases
CH Type 2 [similar to hemi-mandibular hyperplasia]: Type 2A and Type 2B	Two-thirds of cases begin in 2nd decade	UL vertical elongation of face and jaws; non-self-limiting; ipsilateral posterior open bite; occlusal cant occasionally	Unilateral vertical enlarged condylar head, neck, ramus and body; Type 2A: Enlargement without horizontal exophytic growth of the condyle; Type 2B: enlargement with exophytic growth of the condyle	Osteochondroma; cartilaginous cap similar to that seen in a normal growth cartilage; endochondral ossification; cartilaginous islands in the sub- cortical bone; thickened irregular bony trabeculae
CH Type 3	No specific age	UL facial enlargement	Varies from normal anatomy of condyle; usually presenting as condylar enlargement	Benign tumors, e.g., osteoma, neurofibroma, giant cell tumor, fibrous dysplasia, chondroma, chondroblastoma, and arterio-venous malformation
CH Type 4	No specific age	UL facial enlargement	Varies from normal anatomy of condyle; usually presenting as condylar enlargement with lytic lesions	Malignant tumors, e.g., chondrosarcoma, multiple myeloma, osteosarcoma, metastatic lesion, and Ewing's sarcoma

The patient should be reminded to relax the peri-oral musculature for assessing the tooth to upper lip relation at rest [e.g., patients with vertical maxillary excess will constantly purse their lips to reduce excessive gum and teeth show]. The smile needs to be assessed for the amount of gingival show on either side, tooth to upper lip relation, comparison of dental midline with facial midline and symmetry by comparing parallelism of commissural and pupillary lines. Finally, a tongue blade or thin ruler can be placed between the maxillary and mandibular canines and premolars to assess the presence of a cant in relation to the pupillary plane (Fig. 70.2). Comparing the vertical heights from the pupillary plane to the canine tips on either side can help quantify the cant. An occlusal plane inclination of greater than 4° is said to cause significant perceptible asymmetry.

Assessment of midline structures such as nasal bridge, nasal tip, philtrum, and the chin point should also be carried out. Submental [worm's-eye] (Fig. 70.3) and superior [bird's-eye] views (Fig. 70.4) are very useful in assessing deviation of the abovementioned structures. We can also assess symmetry

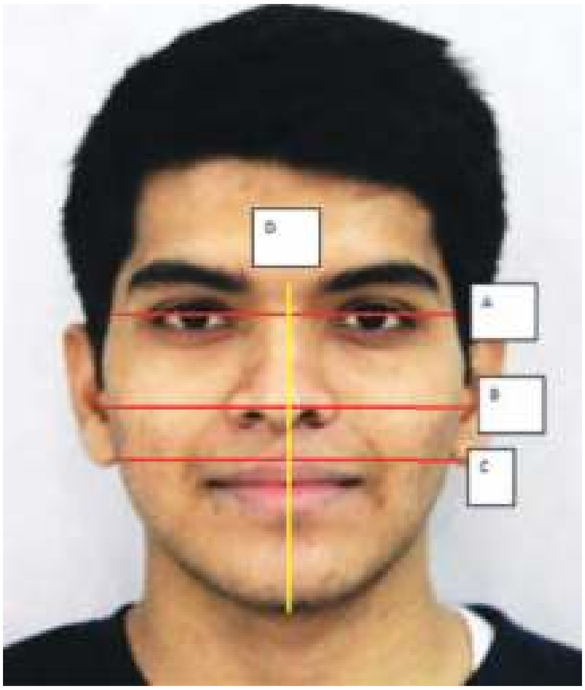

Fig. 70.1 Various facial planes **A** horizontal plane (interpupillary plane) **B** horizontal plane (inter tragal plane) **C** horizontal plane (plane marked through ear lobes) **D** vertical plane (mid-sagittal plane)

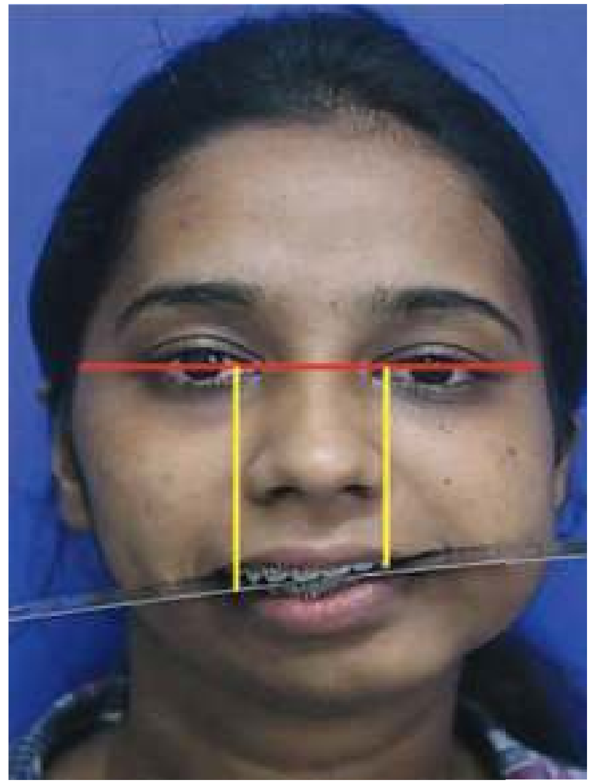

Fig. 70.2 Occlusal cant in relation to the pupillary plane and asymmetry marked from medial canthi to the oral commissure

Fig. 70.3 Submental (worm's-eye) view exhibiting asymmetry in the lower facial third and skeletal midline

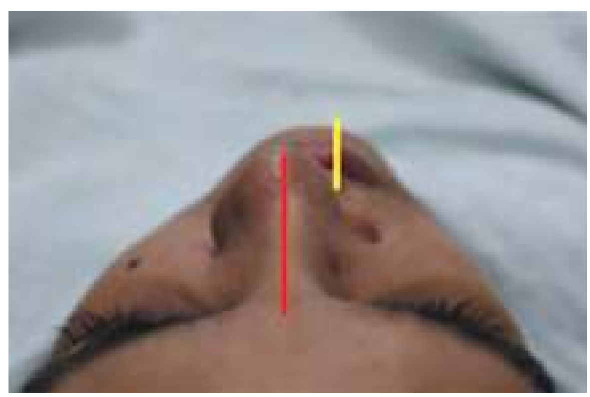

Fig. 70.4 Superior (bird's-eye) view exhibiting midline discrepancy and rotation of the face

and projection of the anterior cranial vault, orbital areas, nose, cheeks, malar eminences, and mandibular body contours.

Profile View

In order to avoid underestimating the severity of the facial asymmetry due to compensatory head postures, it is essential to position the head so that the clinical Frankfort horizontal plane (a line from the tragus of the ear through the palpable bony infraorbital rim) is parallel to the floor (Fig. 70.5). The patient should also be reminded to relax the peri-oral musculature to better assess the tooth to upper lip relation at rest. Evaluating the left and right sides from the profile view will allow assessment of discrepancies in the antero-posterior and vertical dimensions [e.g., maxilla, mandible, and chin] rather than asymmetry evaluation.

70.3.2 Oral Examination

Orthodontic study models mounted in centric relation by face-bow transfer onto a semi-adjustable anatomic articulator help in dento-alveolar and occlusal assessment with a further advantage of studying the occlusion from the lingual aspect. The dental arches are evaluated for overdevelopment, underdevelopment, presence of yaw, and asymmetry in the antero-posterior, transverse, and vertical planes. The dental examination should include the presence or absence of missing, deformed, carious, impacted, or ankylosed teeth; dental midline shift; dental crowding or spacing; congenital deformity [e.g., cleft alveolus in a case of cleft lip and palate]; habitual pattern [e.g., tongue thrusting or thumb sucking]; pathology; and size of tongue and trauma (Figs. 70.6, 70.7, and 70.8). These findings can be incorporated into the treatment planning.

Fig. 70.7 Crowding in both arches along with a reverse overjet

Fig. 70.8 Non co-incident dental midlines (blue-upper dental mid line, yellow-lower dental midline)

70.3.3 Photographic Examination

A dedicated photography room where extra-oral and intra-oral photographs are taken under standardized settings [e.g., lighting, background, focal length, and distance-to-subject] is ideal. Extra-oral photographs of the frontal [with and without smile, occlusal and mandibular inferior border cant], three-quarter, submental, and superior views are essential for the assessment of facial asymmetry. Intra-oral frontal, lateral, superior [45° to the occlusal plane from above], and inferior [45° to the occlusal plane from below] views with the teeth in occlusion are essential for dento-alveolar assessment [11, 23–26].

70.3.4 Radiographic Examination

The three primary radiographic examinations performed in the assessment of facial asymmetry are lateral cephalometry, postero-anterior cephalometry, and orthopantomography. They have been described briefly below. As a rule, serial cephalometric assessment every 6 months for a minimum duration of 1 year may be helpful in determining if the asymmetry is static and stable or if it is progressive [24, 25].

1. Lateral Cephalometry:
   It is used to assess hard tissue and soft tissue relationships in 2D, i.e., antero-posterior and vertical dimensions. This tool is less commonly used to assess facial asymmetry. The head is placed into a reproducible position within the cephalostat with the help of the nasal bridge indicator and ear roads which closely approximates the clinical Frankfort horizontal plane. The patient keep should also be instructed to keep the jaws in centric relation with the teeth lightly touching and the lips slightly parted or relaxed. The ability of the cephalostat to reproduce the near about the same position every time allows for comparative cephalometric analysis and super-imposition of tracings. Bilateral vertical discrepancies [e.g., increased vertical dimension of the body and ramus-condyle unit of the mandible in unilateral condylar hyperplasia type 2] can usually be assessed in a lateral cephalogram. The right and left sides are presented as two separate non-super-imposing lines, and this can be measured as a discrepancy between the two images of the occlusal plane and inferior borders of the mandible (Fig. 70.9).
2. Orthopantomograph [OPG]:
   The OPG is an excellent tool to evaluate mandibular asymmetry and dental status. The anatomy of the condyle—ramus unit, body, and inferior border of the mandible is readily discernible. Increase or decrease in dimensions or changes in mandibular morphology can be studied. In cases of unilateral asymmetry, the affected side can be compared to the normal side. The course of the inferior alveolar nerve can also be assessed and is of vital importance if an inferior border osteotomy is being performed [e.g., inferior border osteotomy in cases of unilateral condylar hyperplasia type 2 where the inferior alveolar nerve might be coursing near the lower border of the mandible] (Fig. 70.10). The OPG is also an excellent tool for the screening of maxillofacial pathology that may cause facial asymmetry, e.g., tumors and fibro-osseous lesions.

Fig. 70.9 Lateral cephalogram showing double images of the inferior border of the mandible (blue arrows) along with displaced IAN canal (yellow arrow) in a case of type 2 condylar hyperplasia

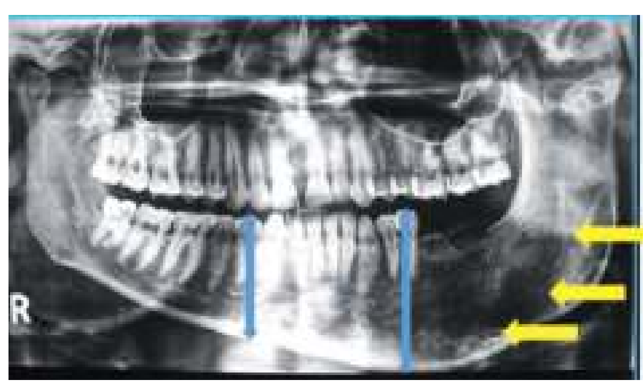

Fig. 70.10 OPG demonstrating the difference in height of the mandibular body (blue arrows), displacement of the IAN canal toward the inferior border (yellow arrows)

3. Postero-antero Cephalometry:
   The PA cephalogram allows a comparative study of the symmetry between the structures of the right and left sides. Projections can be obtained in both open mouth position and centric occlusion with head oriented in natural head position to identify the full extent of static and dynamic [functional] asymmetry. The horizontal reference plane is represented by a line passing through the bilateral zygomatico-frontal sutures. The vertical reference plane is a line perpendicular to the horizontal plane passing through crista galli. Transverse and vertical distances of various facial structures are measured by drawing perpendicular lines drawn from the structures in question to the vertical and horizontal reference planes. By comparing the distances measured bilaterally, the type and extent of the underlying asymmetry can be assessed. Additionally, a shift in the dental midlines can be assessed by comparing them to the skeletal midline. The Grummons and Ricketts analyses are commonly used PA cephalometric analyses for the evaluation of facial asymmetry (Fig. 70.11).
4. Computed Tomography/Cone Beam CT with 3D Reconstruction:
   The main advantage of the 3D CT scan is that it helps in visualization and treatment planning of complex facial asymmetry in cases like craniosynostosis, Treacher Collins syndrome, hemifacial microsomia (Figs. 78.4, 78.5 and 78.6), TMJ ankylosis, and unilateral condylar hyperplasia (Fig. 70.12a, b). Unlike cephalometric and panoramic radiographs, there is no superimposition of structures, the absolute position of anatomical landmarks can be defined, and viewing is possible from any angle. It is also an excellent tool for patient education. The CT scan data can be used for fabrication of stereolithographic

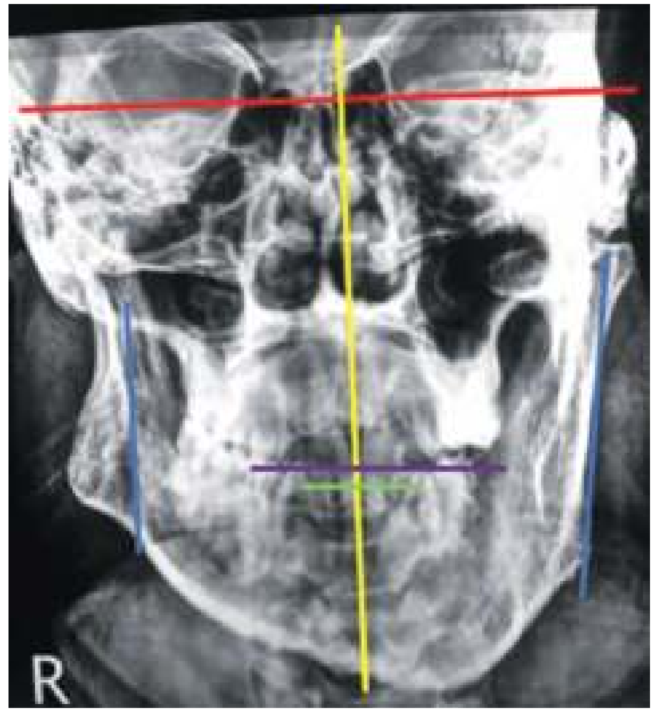

Fig. 70.11 Grummons and Ricketts analysis using PA Cephalogram for evaluating the facial asymmetry. Horizontal reference plane (red); vertical reference plane (yellow); ramal height (blue); intercuspid width (green); intermolar width (purple). Refer to additional reading

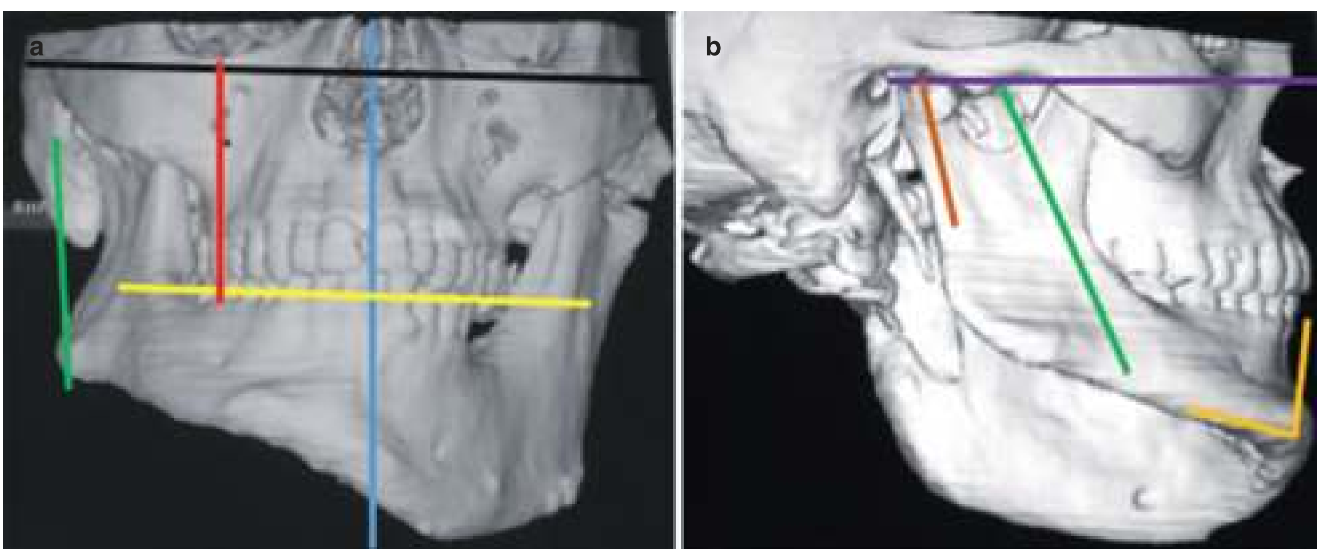

Fig. 70.12 (**a**, **b**) 3DCT face analysis for assessing the facial asymmetry. Various parameters include, Arbitrary horizontal reference plane assuming orbits are normal (black); FH plane (purple); mandibular height [canine to mandibular plane (orange)]; maxillary height (first molar to FH) (red); ramal length (Co superior to Go inferior) (green); occlusal plane (yellow); lateral ramal inclination (Co superior to Go posterior to FH) (brown); midsagittal plane (light blue)

medical models which help make surgical planning even easier. The disadvantage of the CT scan is the exposure to a high radiation dose; with the introduction of the CBCT, the amount of radiation exposure has been greatly reduced. 3D reconstruction, stereolithographic model printing and integration with 3D stereo photogrammetry data allows for treatment planning, treatment simulation, and assessment customized according to the patient [e.g., Dolphin 3D, IPS by KLS Martin]. Lastly, both CT and CBCT provide valuable information regarding the hard tissue status of the TMJ and aid in the diagnosis of reactive [inflammatory] arthritis of the TMJ, osteoarthritis of the TMJ, idiopathic condylar resorption, avascular necrosis, and degenerative remodeling of hard tissues of the TMJ in dentofacial asymmetries [24, 25].

5. Magnetic Resonance Imaging:
   MRI is primarily used to study the soft tissues of the TMJ [e.g., disc, capsule, ligaments] and combined with the CT/CBCT scan data is able to accurately diagnose reactive [inflammatory arthritis] of the TMJ, internal derangements, condylar resorption, and degenerative remodeling of soft tissue of the TMJ in dentofacial asymmetries (Fig. 70.13a, b) [e.g., thinning and displacement of the disc of the contralateral unaffected TMJ in cases of unilateral condylar hyperplasia] [24, 25].

70.3.5 Stereophotogrammetry

It is the construction of a three-dimensional model based on the positions of recognizable points or landmarks in several different photographs. It utilizes two or more cameras configured to capture a pair of stereo images of the surface of patient's face which are then used to generate a 3D image of the face by triangulation performed through sophisticated stereo algorithms. The technique is minimally invasive and has an expanded coverage of close to 360° of the structure being studied with quick capture speeds (often under 1 second). These advantages make it is particularly useful when working with young children [with craniofacial deformities] for whom quantification of facial features can be challenging [25, 26]. The ability to store images for subsequent use, accurate reproduction of the surface geometry of the face, and ability to map realistic color and texture data onto the recorded geometric shape make this technique the preferred facial surface imaging modality over older conventional imaging modalities like laser scanning [26].

70.3.6 Stereolithographic [SLA] Models

Medical modelling involves first acquiring a CT, CBCT, or MRI. This data consists of a series of cross-sectional images of the region being studied. The selected part is now created in a layer-by-layer fashion using photopolymerization ultimately forming a three-dimensional solid. The use of such models in maxillofacial surgery has significantly improved predictability of clinical outcomes in facial asymmetry cases when compared to similar treatments without its use. The models facilitate direct visualization of complex 3D facial asymmetry, decrease operating time due to better treatment planning, and can also be used as an educational tool for patients (Fig. 70.14) [27].

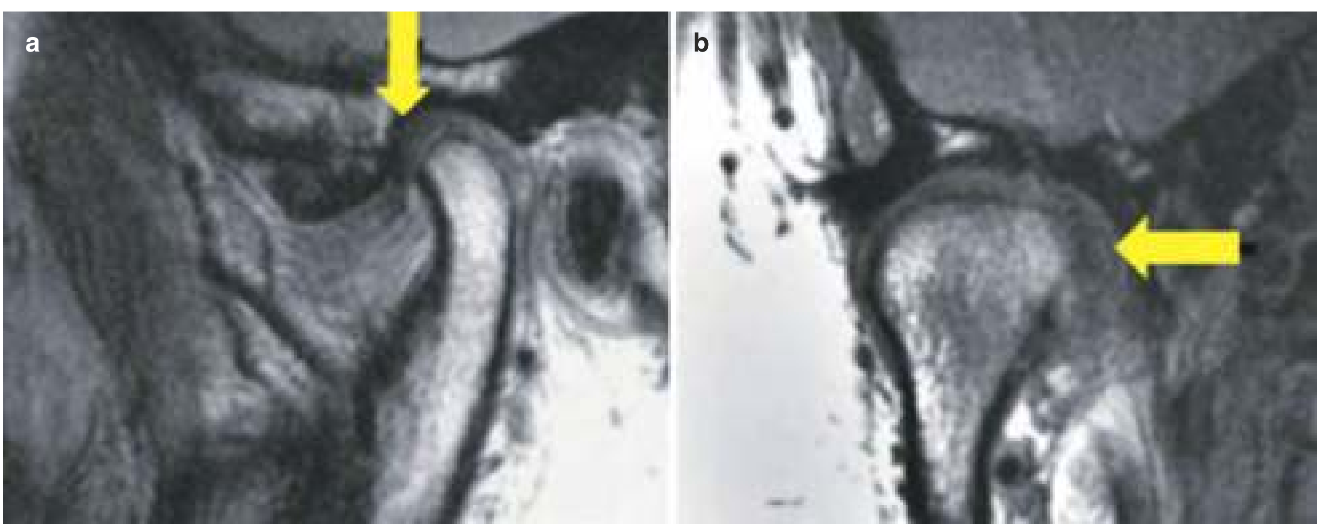

Fig. 70.13 (**a**, **b**) MRI of TMJ showing anteromedial disc displacement (yellow arrows)

Fig. 70.14 Facial asymmetry demonstrated on STL model involving both the midface and mandible with hyperplasia involving the right side

70.3.7 Virtual Surgical Planning [VSP]/ Computer-Aided Surgical Simulation [CASS]

VSP/CASS involves four key stages demonstrated in Box 70.1.

Figure 70.15 shows the sequence involved in VSP/ CASS. The advantages are an increased dental relationship accuracy, reduced OR time, increased patient satisfaction, and decreased costs. Simulating surgery preoperatively allows measurements to the 1/100th of a millimeter, and when combined with 3D-printed splints and customized pre-bent plates, the reconstructive and aesthetic outcome is supe-

Box 70.1 Four key stages in virtual surgical planning

- Data collection and pre-surgical workup
- Virtual treatment planning
- Splint fabrication
- Surgery and accuracy

Fig. 70.15 Flow chart outlining the steps involved in virtual surgical planning has been reproduced after permission from the article "Farrell BB, Franco PB, Tucker MR. Virtual surgical planning in orthognathic surgery. Oral Maxillofac Surg Clin North Am. 2014; 26(4):459–73" [28]

rior to traditional 2-dimensional (2D) modelling and cephalometric tracing [28].

70.3.8 TMJ Examination

TMJs must be healthy for predictable orthognathic surgery outcomes. The TMJ must be assessed before and after orthognathic surgery for joint noises (clicking and popping), localized tenderness, radiating facial [e.g., headaches] and neck pain, and limitation of mouth opening and jaw locking. The literature reports a higher incidence of TMD in patients with retrognathic mandibles and in those with steep occlusal planes [29, 30].

There is no conclusive evidence regarding the effect of orthognathic surgery on TMD with opinions split between improvement, no change, or worsening of signs and symptoms. However, high-angle, class II patients with pre-existing TMD undergoing counterclockwise rotation or large mandibular advancement procedures are known to experience worsening of symptoms. Figure 70.16 is the Boston University Protocol for the management of facial asymmetry requiring orthognathic surgery with pre-existing TMD [29].

70.3.9 Nuclear Medicine Imaging Modalities (Scintigraphy)

A bone scan is a nuclear imaging test that involves injecting a small amount radiotracer that into the bloodstream. The radiotracer travels through the area being examined and gives off radiation in the form of gamma rays which are detected by a special gamma camera and a computer to create images of your bones. Thus, skeletal scintigraphy offers the potential to identify disease in its earliest stages as it is able to identify any abnormal increases in metabolic activity [31].

Cisneros first used bone scintigraphy to study mandibular asymmetry in patients [31]. There are two types of bone scan techniques commonly used: skeletal scintigraphy [subtypes: planar bone scanning and single-photon emission-computed tomography] using technetium-99m methylene diphosphate and positron emission tomography [subtypes: with and without CT, full ring and half ring] using radiolabeled 18F-2-fluoro-2-deoxyglucose [glucose analog].

Planar [regular] scintigraphy is not very accurate as it is only a two-dimensional assessment of three-dimensional anatomy. On the other hand, SPECT [single-photon emission computed tomography] allows three-dimensional assessment as the isotope is dispersed in the subject's body thus allowing spatial localization of the pathology in the mapped body organ.

Dedicated/full-ring PET [as compared to half-ring PET] provides better spatial resolution than a planar bone scanning and SPECT (Refer Fig. 78.13) because of its narrower electronic collimation [full width half maximum (FWHM) central resolution for PET being 6 mm compared with 11 mm for SPECT] [21, 32, 33]. As the condylar growth plate is thin, PET gives an advantage to identify pathologies like condylar hyperplasia.

Important factors to be taken into account when assessing a bone scan:

- The efficacy of bone scan is reduced during the growing phase as condyles are growth centers and both will show increased metabolic activity.
- The efficacy of bone scan is increased after the growth phase is completed as only the affected condyles will show increased metabolic activity.
- The efficacy of bone scan is increased in unilateral cases and reduced in bilateral cases.
- *Condylar Hyperplasia Type 1*
  - The growth in type 1 condylar hyperplasia is only slightly faster than the normal condylar growth rate. Therefore, the difference in intensity of radiotracer uptake between a normal and affected condyle is negligible.
  - The cellular growth activity is confined to a narrow band at the normal growth center resulting in low uptake of the radiotracer.
  - Condylar hyperplasia type 1A cases: It is difficult to differentiate CH type 1A from normal growth as it a bilateral condition with both joints involved.
  - Condylar hyperplasia type 1B cases: As this is a unilateral condition, it is easy to identify clinically. There has to be a difference in activity of at least 10% between the affected side and the normal side for a diagnosis of asymmetric growth activity/unilateral condylar involvement to be made.
- *Condylar Hyperplasia Type 2*
  - It is easy to diagnose on the bone scan as it is usually a unilateral condition with a tumorous rate.
  - There is diffuse cellular activity throughout the tumor in the condylar head which makes it easier to diagnose on the bone scan.

70.4 Clinical Considerations

70.4.1 Occlusal and Orthodontic Considerations

Asymmetries with congenital and developmental etiology are commonly associated with dental compensations in all three dimensions as growth ensues. Rotations and crowding are

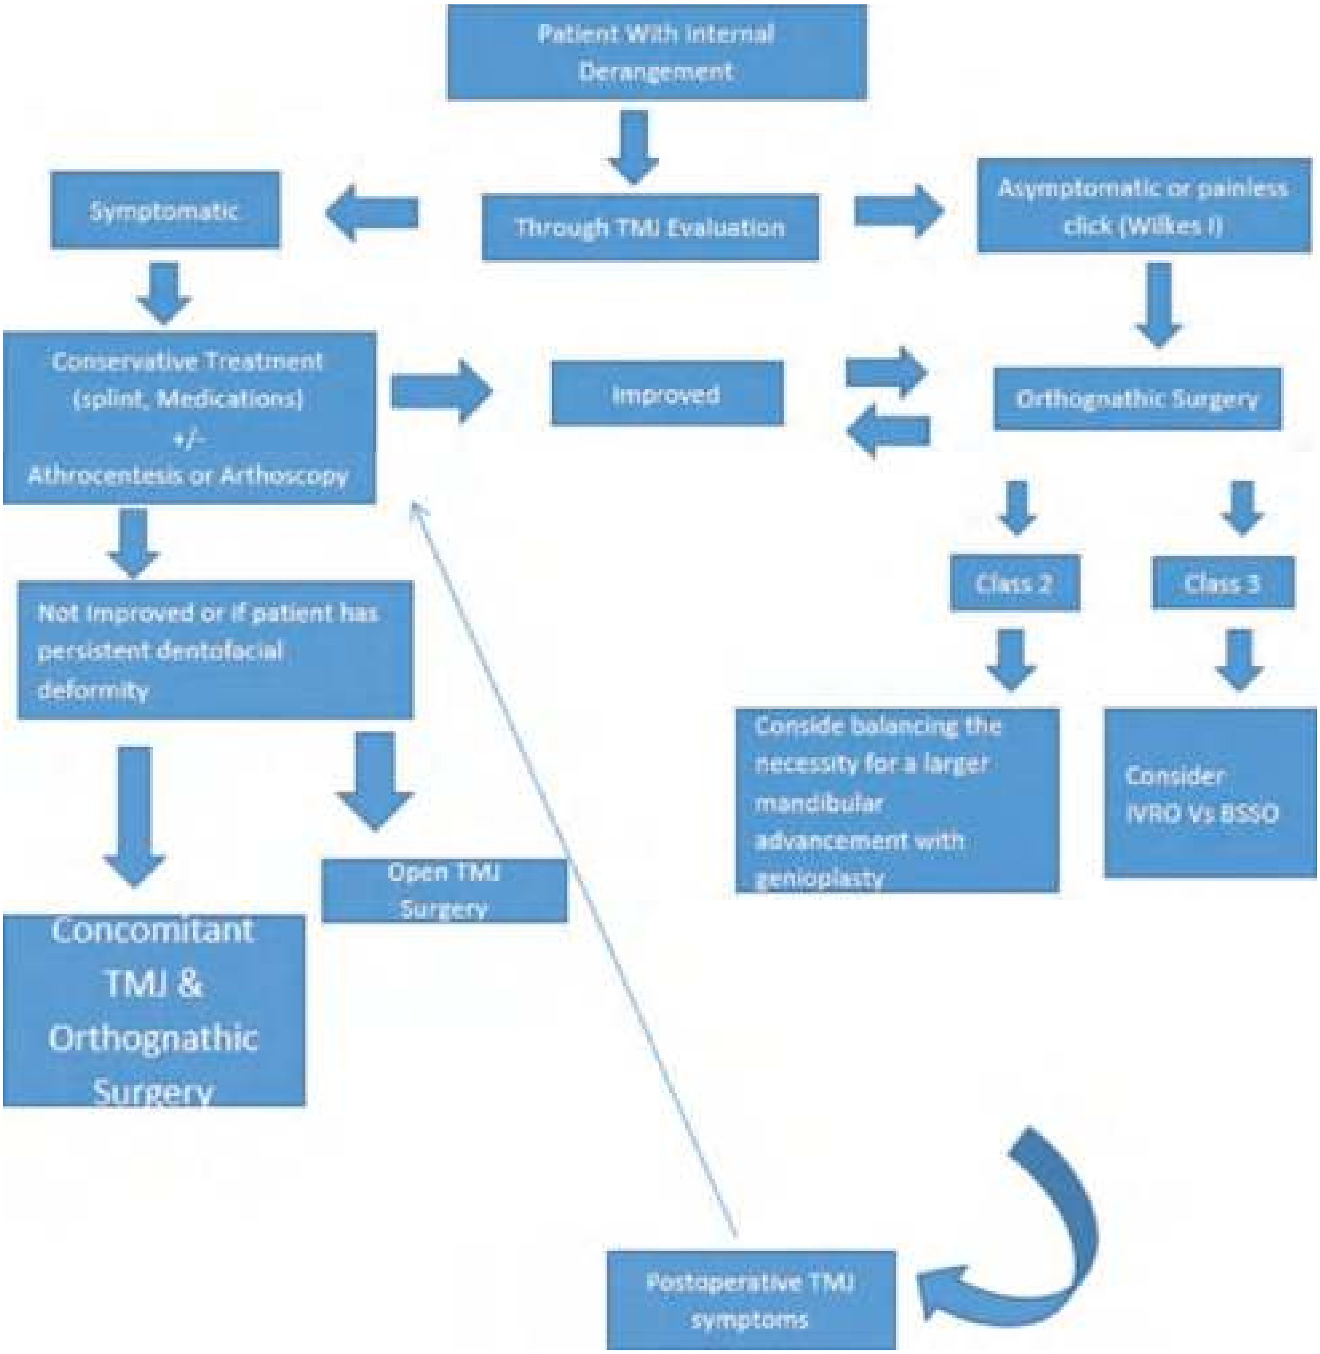

Fig. 70.16 The flow chart outlines the Boston University Protocol for the management of temporomandibular disorders in patients who present for orthognathic surgery and has been reproduced from the article "Nadershah M, Mehra P. Orthognathic Surgery in the Presence of Temporomandibular Dysfunction. What Happens Next? Oral Maxillofac Surg Clin North Am. 2015; 27(1):11–26" [29]

seen in hypoplasia cases such as hemifacial microsomia, and spacing and cross bites can be encountered in case of overdevelopment such as condylar hyperplasia. Transverse growth discrepancies also result in different arch shapes and Bolton discrepancy. Also, the extent of maxillary asymmetry should be accounted for, as maxilla tends to be ignored in obvious mandibular asymmetry. Thus, pitch, yaw, and roll need to be adjusted or decompensated keeping the surgical movement in mind [34]. Pre-surgical orthodontic treatment in patients with facial asymmetry must include the following:

(a) The presence of a dental and facial midline mismatch indicates a discrepancy in the yaw of the affected jaw[s]. Midline correction at the time of orthognathic surgery provides the best results.

(b) Any occlusal cant correction should not be attempted orthodontically. Cant is evidently skeletal in nature and should be corrected surgically.
(c) Levelling and alignment of the dental arches should be done.
(d) Post-operative position of the upper incisor and the upper lip-maxillary incisor relationship is the most important factor determining surgical result. This should be checked intra-operatively before fixation of the maxilla.
(e) Position of the symphysis similarly is another important determinant of a satisfactory postsurgical correction in cases of asymmetry; thus the anatomical position and surgical limits of symphysis correction should be determined pre-surgically.
(f) The facial midline reference should be taken from the unaffected jaw.
(g) In cases of hemifacial microsomia and temporomandibular joint ankylosis, a unilateral open bite is created after increasing the ramus height. This is done to correct the skeletal cant by allowing the vertical alveolar growth of maxilla.
(h) Cephalometric analyses are essential but seldom definitive in determining the amount of advancement in antero-posterior and vertical movements. Prediction tracings are helpful but not mandatory in planning postsurgical outcome. Specific norms available are not always applicable especially in asymmetry cases as the etiology is variable. The etiology and duration of asymmetry influence the extent and severity of the case.
(i) Based on the severity of crowding, the amount of retraction and uprighting needed; upper second bicuspid extraction [minimal decompensation] or upper first bicuspid extraction [greater decompensation] is indicated.

70.4.2 Growth and Development of the Craniofacial Skeleton

Importance of understanding growth of the maxillofacial skeleton in an individual presenting with asymmetry cannot be emphasized enough. Almost half of the asymmetries are either due to an underdevelopment or an overdevelopment of the TMJ resulting in a deviated mandible in the vertical or antero-posterior direction or both of the involved side or the contralateral side. If this development takes place in the growing period, the maxilla follows the deviation of the mandible. Interceptive orthodontics can be applied in growing areas to arrest or limit the extent of asymmetry of the maxilla and mandible [35]. However, surgical intervention is generally needed after completion of growth period for the final skeletal and dental correction. Surgical treatment performed before growth completion is unpredictable on account of the continual growth that the patient experiences till skeletal maturity and as such is reserved only for those cases suffering from extreme functional, aesthetic, and psychological problems. Additional surgery may be needed to correct the recurrent asymmetry. Thus, timing of surgery relies very much on the growth completion.

Serial cephalometric radiographs, scintigraphy, and SPECT scans are useful to assess growth potential. The absence of activity in the TMJ and other areas helps the surgeon to proceed for corrective orthognathic surgery. The second factor for determining the timing of treatment is the progression of the asymmetry. If the asymmetry is progressive like condylar hyperplasia, it is better to wait or perform high condylectomy to check any further asymmetric growth. On the contrary, non-progressive asymmetries such as hemifacial microsomia, treatment can be initiated in early years [36]. Comparably, early surgery has usually been performed for individuals with marked malformations such as plagiocephaly, cleft lip and palate, and/or severe functional burden (e.g., increased intracranial pressure, severe obstructive sleep apnea, etc.). Lastly, in few cases of acquired asymmetry such as tumor resection, “wait-and-watch” policy needs to be adopted to eliminate chances of recurrence before a definitive reconstruction can be planned.

70.4.3 Role of Functional Orthopedics and Interceptive Orthodontics

Functional orthopedics play a substantial role in congenital asymmetries, the greatest example being nasoalveolar molding in cleft lip and palate cases to bring the maxillary segments into a more desirable position prior to surgery. Growth modification with the use of functional appliances is directed toward eruption of the dentition in a more favorable position and prevents worsening of the skeletal asymmetry exacerbated during growth period. Functional therapy is also aimed at maintaining the condyle in a more anatomical position to allow further growth in a symmetrical pattern. Studies have shown that an asymmetric lateral force during the growth period results in growth modification by influencing the morphology of the mandibular bone and the overlying masseter muscle. Occlusal splints can be fabricated to allow for mandibular shifts toward midline, and open bite can be created to eliminate canting. This is especially helpful in hemifacial microsomia and TMJ ankylosis cases. Patient compliance is a prerequisite in functional therapy cases. Also, keeping in view the growth potential, long-term follow-up is always warranted.

70.4.4 Role of TMJ and Considerations for Treatment

TMJ is the driving force in the development of an asymmetry. Although the role of condylar cartilage has been proved to be secondary in mandibular growth and development, any pathological change leading to under- or overdevelopment can cause severe progressive asymmetry. As mentioned, TMJ-related asymmetries can be categorized as underdevelopment or overdevelopment of the condyle and in some cases both. Pseudo-asymmetry occurs due to lateral shifts on account of dental pre-maturities. Kaban and Pruzanksy have also graded hemifacial microsomia (Refer Chap. 78) based on the anatomy of the ramus condyle unit [RCU] and the glenoid fossa which make up the TMJ [36, 37]. Management of the TMJ pathology should be performed initially following which any skeletal correction should be attempted. Failure to do so has led to relapse due to the unpredictability of TMJ behavior and growth. Clinical and diagnostic imaging should be performed prior to any asymmetry correction to assess the status of TMJ. CT scans are a must for assessment in all three axes, as TMJ tumors like osteochondroma may not be discernible on 2D imaging. High or low condylectomy, ankylosis release, and RCU reconstruction should be done prior or simultaneously with orthognathic surgery. Distraction osteogenesis has also been used for neo-condyle formation. Alloplastic reconstruction of the TMJ is the most recent advancement with stable long-term results. The rationale for TMJ reconstruction is to provide a functional stable and reproducible movement which is harmonious with the stomatognathic system. Asymmetrical patients have also been found to have a higher incidence of condylar morphological changes and temporomandibular disorders on the affected side. Over time, due to the imbalance of masticatory loads and poor jaw function, the TMJ of the unaffected side also displays similar pathological changes [38].

70.5 Treatment Planning

Following issues need to be considered before planning orthognathic surgery (Box 70.2):

Box 70.2 Issues that need to be considered before planning orthognathic surgery

1. Single jaw versus bi-jaw surgery
2. Mandible first versus maxilla first approach
3. Surgery first approach
4. Traditional planning versus virtual planning
5. Modifications in surgical technique for asymmetry cases

70.5.1 Single Jaw Versus Bi-Jaw Surgery

Facial asymmetries are rarely corrected by single jaw surgery. When the amount of discrepancy is excessive, it is best treated by dividing the overjet as well as the cant between the two jaws to achieve optimal results. During growth in congenital and developmental cases, maxilla follows and is equally involved as the mandible. Thus, it is prudent to do a bi-jaw surgery. Also, in cleft maxillary hypoplasia cases, differential maxillary advancement with simultaneous setback is the treatment of choice. We have presented a case where simultaneous maxillary distraction was done with mandibular setback. Owing to the presence of a cleft, maxilla has severely deviated midline with an extreme reverse overjet. In such cases, maxillary distraction allows slowly advancing the maxilla and simultaneously correcting the midline by distracting more on the deficient side [39] (Fig. 70.17a–c). Segmental osteotomies or differential surgically assisted rapid palatal expansion (SARPE) might also be needed in some cases to correct transverse asymmetry (Fig. 70.18a–c). Additionally, bone contouring of the mandible and zygoma may be needed to reduce the hyperostotic bone to achieve a harmonious facial contour. This is true in case of hemifacial hypertrophy and hemi mandibular hyperplasia. Similarly, additional augmentation of paranasal areas, malar prominence, and angle of mandible augmentation are frequently indicated in hypoplasia cases.

70.5.2 Mandible First Versus Maxilla First Approach

Either of the surgical sequences can produce similar outcomes when properly planned and executed in the vast majority of bimaxillary cases. Mandible first approach is specially mentioned here as it is important in Class 3 asymmetries. Firstly, in cases where maxilla may be hypoplastic, especially in the syndromic cases of mandibular hyperplasia, rigid fixation of maxilla and down-grafting may not give stable results. Thus mandible should be fixed first, then maxilla. Secondly, because of differential load on the TMJ, CO-CR discrepancy exists, and it is difficult to achieve a stable centric. In such cases fixing the mandible first is beneficial [40]. Lastly, Class 3 asymmetries are associated with concomitant TMJ pathologies, hence TMJ surgeries such as high condylectomy may be needed to be performed simultaneously, in such cases, and mandible first approach is generally the preferred choice.

70.5.3 Surgery First Approach (Refer Chap. 67)

The surgery first approach [SFA] came about as there was a need for immediate aesthetic improvement with shortening of the overall duration of treatment. However, it should be known that not all cases fulfil the criteria for SFA [e.g., flat curve of Spee and minimal crowding and rotations]. The total treatment duration can be shorter than the conventional three-staged surgical orthodontic treatment owing to the lack of need of pre-operative orthodontics and the subsequent post-surgical "regional acceleratory phenomenon." However, reliability of SFA is still questionable, especially in more complex dentofacial deformities, like facial asymmetry.

Park et al. reported no significant differences in postoperative stability between SFA and OFA after bimaxillary surgery in skeletal class III malocclusion patients [41]. In SFA, vertical dimension in surgical occlusion can increase due to occlusal interference and lead to postoperative counter clockwise rotation of the mandible as occlusal settling progresses during the postoperative orthodontic period. This may contribute toward greater postoperative mandibular forward movement.

70.5.4 Modifications in Surgical Technique for Asymmetry Cases

The bilateral sagittal split osteotomy is the commonly used technique in asymmetry cases. It is highly flexible and adaptable in all movements. The three-dimensional anatomy of the mandible must be retained when planning a BSSO. According to Schwartz, three types of surgical move-

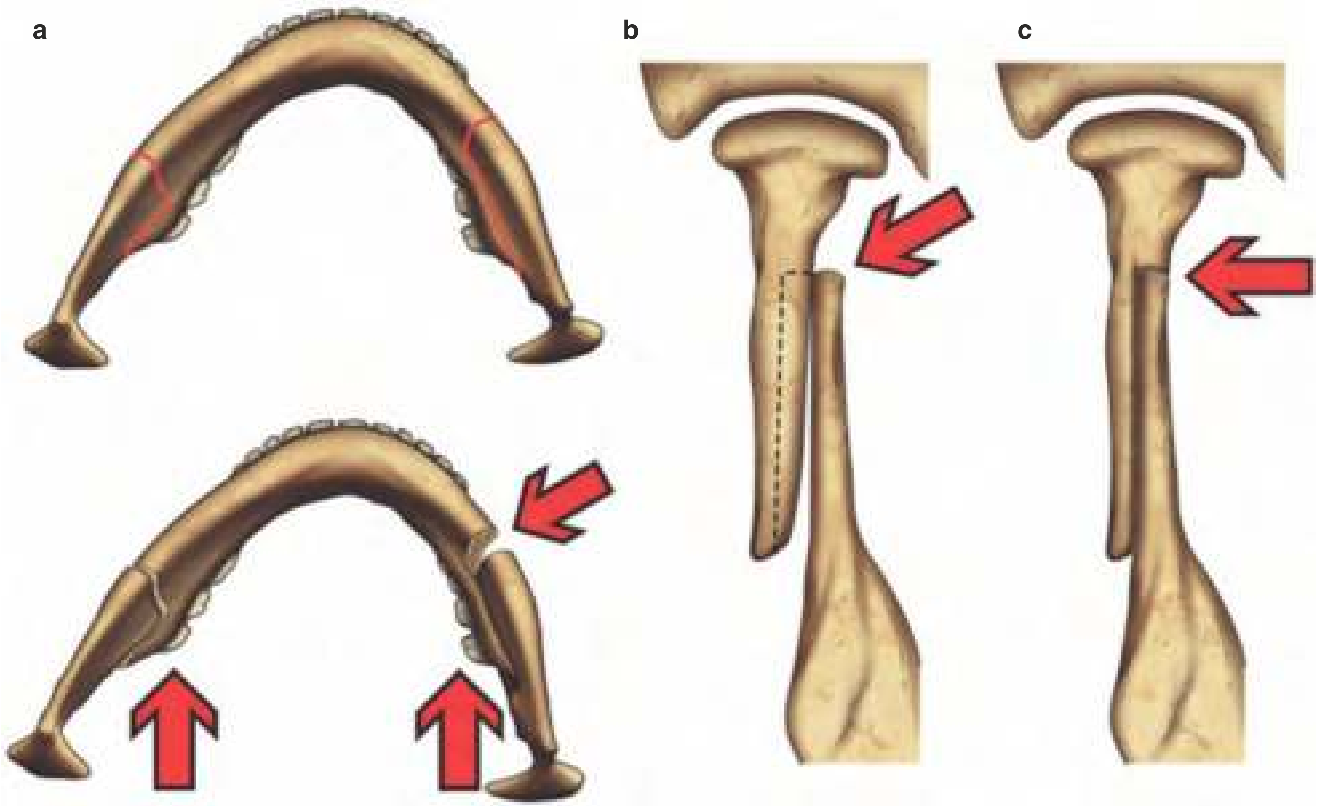

Fig. 70.19 (**a**) When an asymmetric case is viewed along the vertical axis, areas that require immediate bone removal become obvious. Heavy interferences will take place anteriorly on the long side and posteriorly on the short side; (**b**) After the condyle is seated, premature bone contact is noted posteriorly. The area proposed for additional bone removal is indicated by the dotted line; (**c**) Good bone contact has been achieved. Image Source: Schwartz HC. Efficient surgical management of mandibular asymmetry. J Oral Maxillofac Surg. 2011 Mar;69(3):645–54. doi: 10.1016/j.joms.2009.03.009. Epub 2010 Oct 8. PubMed PMID: 20934795 [42]

ments can be planned with BSSO in asymmetry cases: in case of a normal overjet and overbite, differential movements will be made that is setback on the long side and advancement on the short side. In Class II asymmetry, in order to achieve symmetrical advancement, there will be a longer advancement on the short side than on the long side and lastly in Class III cases, there will be a larger setback on the long side than on the short side. During surgery, the distal segment rotates from the short side to the long side as the midline is corrected (Fig. 70.19a). Selective bone removal from the area of interferences should be done before the distal segment has been passively repositioned. Bone is removed from the anterior and medial aspects of the proximal segment until there is broad contact along segments. On the short side, first contact will occur posteriorly [42]. Bone is removed from the medial aspect of the proximal segment posteriorly (Fig. 70.19b, c). This is done to reduce condylar torque during rigid internal fixation to ensure stability of the movement. Figures 70.20a–d and 70.21a, b show a case of unilateral condylar elongation treated with differential BSSO.

70.5.5 Soft Tissue Interventions

The asymmetrical growth of soft tissues may lead to residual soft tissue asymmetry even after correction of the underlying bony deformity. Furthermore, some asymmetrical craniofacial regions cannot be corrected by means of conventional surgical techniques. Adjunctive soft tissue procedures [e.g., dermis fat transplant, autologous fat transfer, microvascular adipose free flaps] might be indicated to achieve bulk in deficient soft tissue deformities such as Parry Romberg syndrome, TMJ ankylosis, etc. Alloplasts such as Medpore, silicone, nanogels, tissue expander, etc. have also been used with varying degrees of success (Sect. 70.7 “Case Scenarios”).

70.5.6 **Distraction Osteogenesis** (Also refer Chap. 87)

Distraction osteogenesis is the process of native bone formation via traction of osteotomized segments. On account of distraction histogenesis, simultaneous soft tissue and

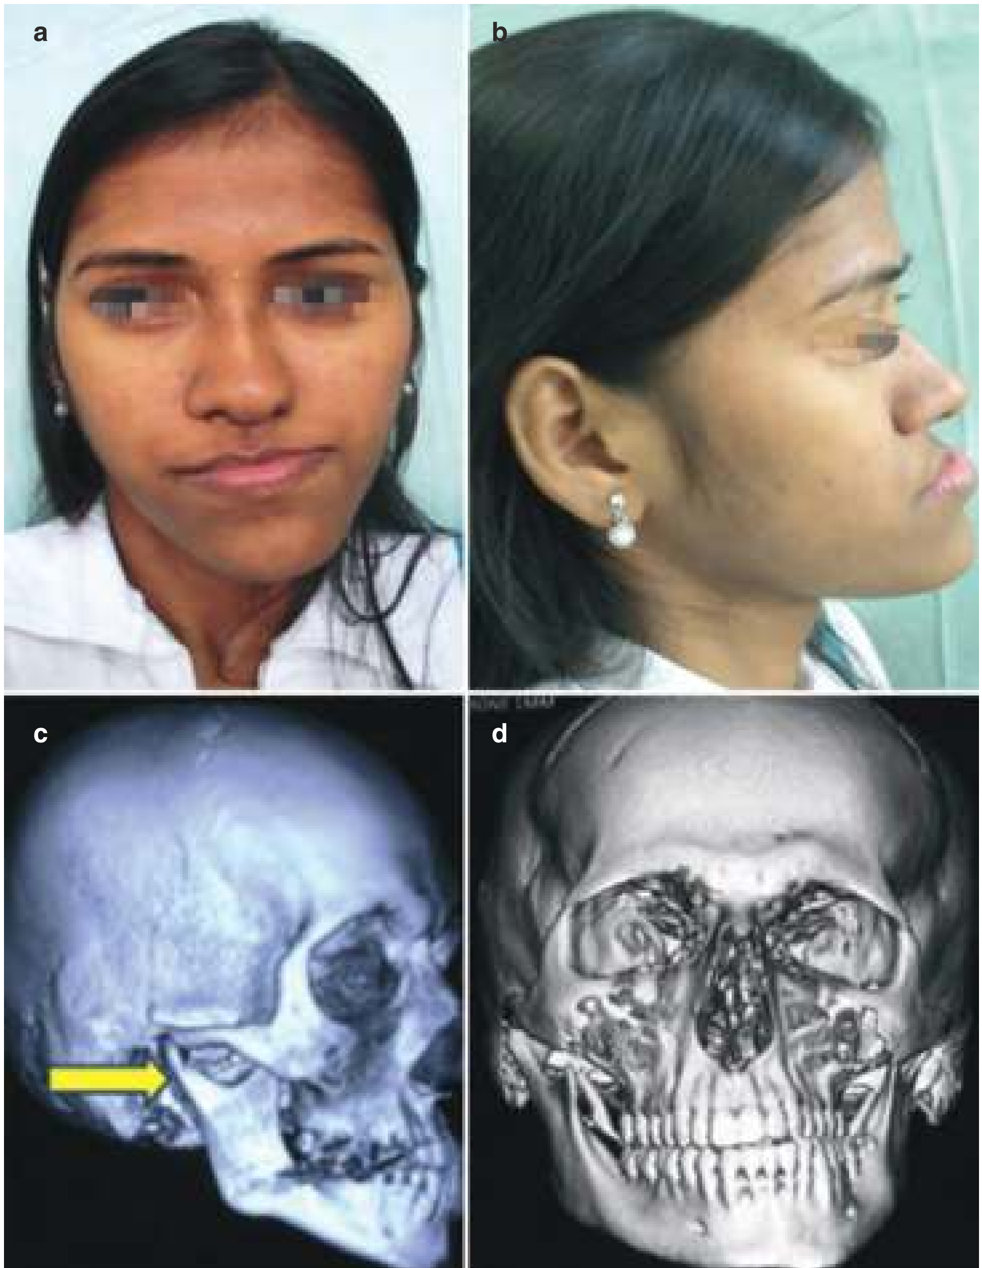

Fig. 70.20 (**a**–**d**) Clinical and radiographic images showing a case of image showing severe facial asymmetry with unilateral condylar elongation on the right side. (**a**) frontal photo, (**b**) profile photo, (**c, d**) lateral and frontal views on volume rendered 3D CT scan

hard tissue augmentation can be achieved. Adequate amounts of advancements can be achieved without any soft tissue limitations. Various cases have been treated successfully with DO that are presented in this chapter. DO has various advantages over conventional osteotomies in complex facial asymmetries. Pre-arthroplastic distraction in ankylosis-related asymmetries has been reported to have excellent results [43]. This is because simultaneous distraction of skin, muscle, and tissue takes place with bone regeneration. Thus, better esthetics are achieved without any need for additional soft tissue procedures. Distraction is often the only procedure of choice in large advancements, rate of relapse is significantly lower, and results are much stable. Figures 70.22a–e, 70.23a, b, 70.24a–d and 70.25a–g show a case of facial asymmetry secondary costochondral graft resorption in a case of TMJ ankylosis, treated with stage one distraction osteogenesis followed by definitive correction with BSSO.

70.6 Conclusion

Facial asymmetry is a three-dimensional facial deformity having multiple etiologies. Complete and thorough knowledge of the etiological factors, the progressive nature of the asymmetry plays a crucial role in formulating a treatment plan. Growth and development of the individual and timing of intervention is the single most important factor affecting the stability of results in any form of asymmetry. Severe relapses could occur if the exact cause of asymmetry is overlooked and treatment is attempted before completion of growth [44, 45].

70.7 Case Scenarios

Case 1: Condylar Hyperplasia with Concomitant Masseteric Hypertrophy (Figs. 70.26a, b, c, 70.27a, b, 70. 28a, b and 70. 29a, b)

A 27-year-old female patient reported with a complaint of a progressive facial asymmetry and an appearance of fullness over the left angle of the mandible.

On examination, the patient had a tapered, triangular shape of the face with an obvious facial asymmetry which was evident along with elongation of the right side of the face and fullness over the left angle region (Fig. 70.26a). The mandible revealed bowing on the right side with a mild symphysis kink. TMJ on palpation revealed mild clicking on the right side and otherwise equal movements along with unrestricted mouth opening was noted. On assessing the left angle region, an outward projection was noted due to the underlying hyper functioning of the masseter muscle. On clenching, significant enlargement of the involved muscle was seen as compared to the contralateral side (Fig. 70.26b).

Intraoral examination did not reveal any occlusal cant (Fig. 70.26c). There was an absence of cross bite/open bite, on either side, along with a stable occlusal relationship. The dental midlines were coincident with the skeletal midline and with each other too. No other dental abnormalities were evident on examination.

Imaging studies revealed mild degree of deflection of the chin and mandible toward the left side (Fig. 70.27a, b). Transverse mandibular asymmetry was reported. The condylar head appeared to be irregularly deformed, while the neck on the right side appeared broader as compared to the left side. The ascending ramus appeared elongated with a rounded gonial angle. The mandibular lower border was bowed downward and positioned lower on the right side as compared to the left side. The distance between the tooth

roots and mandibular canal was increased with displacement of the latter towards the lower border of the mandible on the right side. The right side vertical ramus appeared relatively increased height as compared to the left. Thickened trabecular pattern was also evident on the right side.

Management

Following preparation for the administration of GA and a scintigraphy report which did not reveal an active mandibular hyperplastic condyle on the right side, the patient was prepared to be taken up for the procedure of an intraoral inferior border osteotomy. An intraoral vestibular incision was taken from 33 regions up to the external oblique ridge on the right side. Complete degloving was done to expose the inferior border in the anterior, body, and angle region of the mandible on the right side. Care was taken to identify the mental foramen and salvage the nerve. Methylene blue ink was used to mark the osteotomy line extending from the right central incisor posteriorly up to the angle region (Fig. 70.28a). It was correlated with the position of the neu-

rovascular bundle, so as to prevent any damage to the same. The cut was initiated with a fine fissure bur under copious saline irrigation extending from buccal cortical plate to lingual cortical plate. With the help of an osteotome, the anterior cut was completed, and the lower inferior hyperplastic border was removed in one piece (Fig. 70.28b). The raw surface was smoothened with a vulcanite bur, and contouring was done to match the normal left side. The wound was closed in two layers with interrupted sutures using 3-0 vicryl. The surgical site was flushed with 2% povidone iodine solution.

For the masseteric hypertrophy on the left side, Botox [botulinum toxin Type A, Allergan™] powder was reconstituted with normal saline solution, pushed within the vial, and 30 units of it were administered using an insulin syringe and 30 gauge needle within the substance of the muscle, divided equally at three sites in a triangular fashion (Refer Chap. 33 and Fig. 33.10 for details on Botox injection to treat masseteric hypertrophy).

Complete correction of facial asymmetry with left side masseteric hypertrophy and right side condylar hyperplasia features was achieved with this surgical method (Fig. 70.29a, b).

Fig. 70.26 (**a**, **b**) Frontal and profile views showing facial asymmetry due to condylar hyperplasia of the right side. (**c**) Occlusal view showing dental cant on account of condylar hyperplasia

Case 2: Parry Romberg Syndrome (Figs. 70.30a, b, 70.31a, b, 70.32a, b, c, 70.33a–h and 70.34a–f)

An 18-year-old female patient reported with gradual disfigurement and shrinkage of the right side her face since last 8–9 years.

Clinical examination revealed an asymmetry of the face on the right side with a marked atrophy of facial soft tissue (Fig. 70.30a). Significant orbital dystopia along with a hypoplastic soft tissues in the right, evident on worm's view (Fig. 70.30b). Clinically, a deformed and hypoplastic upper lip was seen with an increased vermillion show of the lower lip, resulting in a slanting rima oris. The right commissure, right ala of the nose, and the right supraorbital ridge region revealed obvious depression.

Intraoral examination revealed a missing upper right permanent canine along with crowding in the premolar region. Alveolar height in the maxillary right premolar region was reduced which was a pathognomonic sign of Parry Romberg (Fig. 70.31a, b). The occlusion was deranged, with a shift of the dental midline to the right.

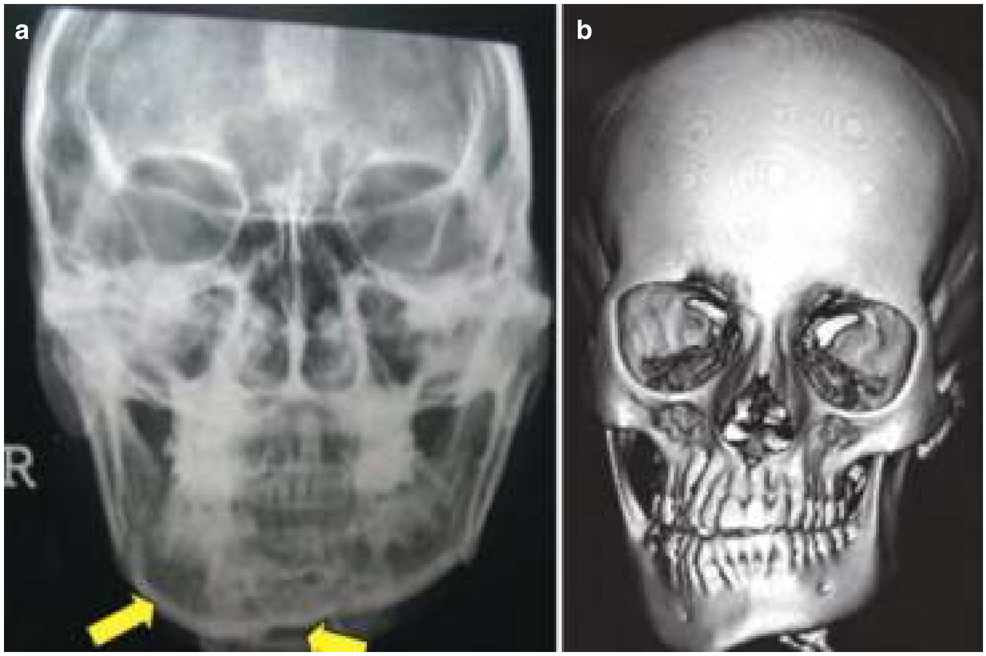

Fig. 70.27 (**a**) PA mandible showing inferior border bowing on the right side and kink in chin region (yellow arrows) which stops at the midline. (**b**) 3D CT shows mild degree of tilting of chin and mandible toward the left side

Fig. 70.29 (**a**) Pre- and (**b**) post-op correction in facial asymmetry. Reduction of fullness on left side and centralization of chin

Imaging studies revealed some degree of hypoplasia of mandible, zygoma, and maxilla on the right side. Presence of impacted permanent right maxillary canine was evident. The body-angle ramus, coronoid, and condylar process however appeared normal. Alveolar height was reduced in the right maxillary premolar region (Fig. 70.32a, b, c).

Management

The patient was prepared for GA administration for correction of facial asymmetry. A camouflage technique was planned wherein multiple Medpore© implants were used to fill up the deficient areas on the right side of her face in the right supraorbital, right maxillary alveolar region in the canine, and premolar areas right parasymphysis region of the body of mandible and right side chin along with autologous lipo transfer to increase the volume of the upper lip. Two separate small incisions were taken in the submandibular region anteriorly and posteriorly keeping the intervening skin and tissues intact. Layerwise dissection was done to reach the angle, body, and the anterior regions of the mandible. Tunnelling was done between the two incisions so as to receive the pre-shaped Medpore© implant, which was inserted from the anterior site and was pushed posteriorly to sit on the body, angle, and a portion of the ramus. The implant was notched in the superior aspect, in the region of the mental nerve to prevent impingement of the same. Four long titanium screws were used to fix the Medpore© implant on the body of the mandible on the right side (Fig. 70.33a). An additional half chin implant was placed to augment the deficient chin on the right side for achieving symmetry and was fixed with 2 long titanium screws (Fig. 70.33b). The incision sites were closed in two layers.

Another lateral eyebrow incision was taken on the right side (Fig. 70.33e). Dissection was done to expose the supraorbital rim. Supraorbital foramen and nerve were identified. An infra-orbital rim Medpore© implant for the right side was inverted and placed on the right supraorbital region to augment this deficient area. Two long titanium screws were used to stabilize the Medpore© implants.

Intra-orally a vestibular incision was taken in the right premolar and canine region. A full-thickness mucoperiosteal flap was raised. The infra-orbital nerve was identified and protected. A paranasal Medpore© implant was fixed with 1 long titanium screw to give fullness in this region. The wound was sutured in two layers with 3-0 vicryl.

Periumbilical and medial thigh regions were prepared to harvest fat cells. Manual aspiration of the fat cells was done. Following the simple method of sedimentation, the fat cells were separated from the blood components (Fig. 70.33f). 2 mm incisions were taken on either side of the oral commissure. A large 16 gauge epidural needle attached to 10cc syringe was used to push the fat within the substance of the upper lip from either side (more on right side than on the left) increasing the

71 Obstructive Sleep Apnea Syndrome

Suresh Menon

71.1 Introduction

Obstructive sleep apnea (OSA) is a condition that affects 2–4% of the adult population. This disease has reached a proportion of increasing importance due to its neurological and cardiological consequences. Abnormal pharyngeal anatomy and altered activity of the upper airway musculature dilator physiology are primarily responsible for the collapse of the pharyngeal walls during sleep.

71.2 Definition

OSA is defined by the occurrence of daytime sleepiness, loud snoring, witnessed breathing interruptions, or awakenings due to gasping or choking in the presence of at least five obstructive respiratory events (apneas, hypopneas, or respiratory effort-related arousals) per hour of sleep [1].

When OSA is accompanied by excessive daytime sleepiness, it is termed Obstructive Sleep Apnea Syndrome.

The common terms that are used in OSA are apnea, hypopnea, apnea hypopnea index (AHI), and respiratory distress index (RDI) [2].

1. *Apnea* is the cessation of airflow, exceeding 10 seconds.
2. A *hypopnea* is reduced airflow exceeding 10 seconds accompanied by a desaturation of 3% or more of oxygen and/or electroencephalographic evidence of arousal.
3. *The apnea hypopnea index* (AHI) is the number of apneas and hypopneas per hour of sleep. A value of 5–15 represents mild sleep apnea, 15–30 moderate, and greater than 30, severe.
4. *Respiratory distress index* (RDI) includes other parameters in addition to apnea and hypopnea like respiratory effort-related arousals (RERAs). This is characterized by increasing respiratory effort for 10 or more seconds leading to an arousal from sleep but not meeting the criteria of an apnea or hypopnea [3].

71.3 Etiopathogenesis

The upper airway is a flexible structure consisting of muscle and fat tissue and is usually only passively supported by bones. Therefore, it can be easily influenced by soft tissue factors like fat deposition in the parapharyngeal structures, edema/inflammation of the parapharyngeal region, hypertrophy of adenotonsillar tissues, or enlarged tongue.

The primary actor in the pathophysiology of OSA is the narrow, floppy upper airway. There is increased resistance of the upper airway due to anatomic factors that creates a negative airway pressure. This results in impaired function of airway-dilating muscles, thus increasing collapsibility. During sleep, the loss of skeletal muscle tone narrows the upper airway, making it floppier, especially during rapid eye movement (REM) sleep when muscle relaxation is intense. This results in two significant actions:

- The turbulent flow patterns that occur lead to vibration of structures causing snoring.
- The pharynx collapses due to the Bernoulli effect. This causes an obstruction which could be partial or complete. This tends to persist until sleep is interrupted and muscle tone is restored. These interruptions usually last less than 15 seconds, and the individual is unaware of them. Sometimes, the obstruction results in an awakening, and the individual complains of suddenly waking with a snort or a snore. Breathing is reestablished on arousal, and after a few breaths deeper sleep resumes with repetition of the cycle during muscle relaxation.

S. Menon (✉)

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_71

Additional factors that can increase the severity of upper airway resistance during sleep are mouth opening or a supine posture which allows the gravitational forces to push the tongue and soft palate back. Upper airway resistance can occur anywhere from the nasopharynx to the hypopharynx but primarily involves the oropharynx (Fig. 71.1).

71.4 Risk Factors for OSA

71.4.1 Age

The disease prevalence increases steadily with age and reaches a stable level after the age of 60 years. The probable explanations for the age-related increase in prevalence include increased fat deposition in the parapharyngeal area, soft palate lengthening, etc.

71.4.2 Excess Body Weight

Body weight is an important risk factor for OSA, and studies have endorsed the positive effects of dieting and surgical weight loss on reducing OSA. Body weight increase can affect normal upper airway mechanics during sleep through:

1. Reduction of upper airway by increased parapharyngeal fat deposition.
2. Changing neural compensatory mechanisms that maintain patency of airway.
3. Instability of respiratory control system.
4. Reduction in functional residual capacity.

71.4.3 Gender

It is an established fact that men are more vulnerable than women toward developing OSA. The differences exist not only in prevalence but also in polysomnographic characteristics of sleep and breathing patterns. Women were seen to have a lower AHI in non-rapid eye movement (non-REM) sleep. Disordered breathing events in women have a shorter duration and are associated with less oxyhemoglobin desaturation than in men.

71.4.4 Craniofacial Anatomy

The mechanical properties of the upper airway and the tendency to collapse during sleep can be influenced by both hard and soft tissues in the region. Findings in the craniofacial region like large tongue or soft palate, reduced mandibular size, or tonsillar hypertrophy in addition to inferiorly placed hyoid, maxillary, and mandibular retropositioning can narrow upper airway dimensions and leading to episodes of apneas and hypopneas during sleep.

71.4.5 Familial and Genetic Predisposition

Inheritance and familial factors also play a major role in OSA. First-degree relatives of OSA patients seem to be at risk more likely than others. The familial susceptibility tends to increase directly with the number of affected relatives.

Heredity and genetic factors also have been found to have a role in determining the volume of the lateral parapharyngeal

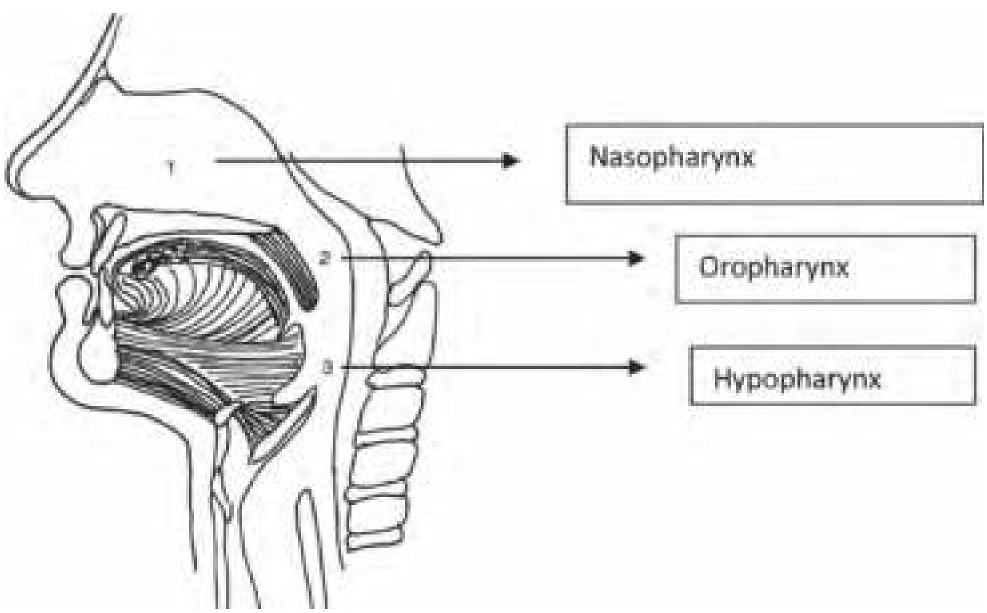

Fig. 71.1 Areas causing OSA

walls, tongue, and total soft tissue structures. A detailed family history can help in identifying those that have the disorder but remain undiagnosed.

71.4.6 Smoking and Alcohol Consumption

Cigarette smoking and alcohol are also possible risk factors for obstructive sleep apnea. Airway inflammation can occur due to cigarette smoke that could modify the properties of upper airway and increase its collapsibility during sleep. Alcohol consumption before sleep increases upper airway collapsibility and the precipitate apneic and hypopneic episodes during sleep. Another effect of alcohol is to inhibit respiratory motor output to the upper airway, causing hypotonia of the oropharyngeal muscles.

71.4.7 Medical Comorbidity

There is enough evidence to suggest that OSA can be a factor in the development of hypertension, coronary artery disease, congestive heart failure, and stroke [4].

OSA is also associated with diabetes mellitus, Therefore, diagnosing the condition and intervening early could directly or indirectly enhance glycemic control [5]. The role of positive airway pressure (PAP) therapy could result in reduced day time fatigue, better physical activity, resulting in improved metabolic control.

71.5 Clinical Sequelae [6]

71.5.1 Endocrine and Metabolic Effects

The central effects of sleep fragmentation and hypoxemia have been seen to induce a reversible neuroendocrine defect in growth hormone and testosterone secretion. This may explain impaired growth seen in children with upper airway obstruction which seems to get better after adenotonsillectomy.

71.5.2 Neuropsychological and Social Consequences

The classic feature of OSA prevalent as excessive daytime sleepiness may lead to both impaired work performance and driving. OSA patients seem to perform poorly on psychometric tests, and improvement has been seen after nasal CPAP therapy.

71.5.3 Cardiovascular Sequelae

There are two serious consequences of OSA involving the cardiovascular system. Initially acute cardiovascular changes occur during an apnea. This is followed by more chronic cardiovascular conditions like hypertension, myocardial infarction, stroke, and death.

71.6 Epidemiology [7, 8]

OSA has no specific age predilections, but a study by Young et al. estimated the prevalence in middle age to be 4% for men and 2% for women. Their study estimated that 1 of every 5 adults has at least mild OSA and 1 of every 15 has at least moderate OSA.

71.7 Diagnosis [1]

A detailed study of clinical signs and symptoms established during a comprehensive sleep evaluation and findings identified by sleep testing lead to the diagnosis of OSA.

71.7.1 History and Physical Examination

The diagnosis of OSA begins with a sleep history in one of three settings:

1. Part of routine health maintenance evaluation.
2. Part of an evaluation of symptoms of OSA.
3. Part of the comprehensive evaluation of patients at high risk for OSA.

Of the available, the Epworth sleepiness scale (ESS) (Table 71.1) is a popular subjective-based self-assessment of sleepiness that determines the degrees of sleepiness [9]. When scores are greater than 10, further investigations are recommended. However as about 10% of the population have a score of 11 or more, this score should be complemented by a narrative confirmation of intrusive somnolence.

71.7.2 Polysomnography (PSG)

This is an overnight sleep study monitored by a sleep technologist and is considered the "gold standard" in sleep medicine (Fig. 71.2). The physiologic parameters measured during PSG include simultaneous monitoring of

Table 71.1 Epworth sleepiness scale

Name:	Date:
Age:	Sex:
How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired?	
Use the following scale to choose the most appropriate number for each situation:	
0—Would never doze	
1—Slight chance of dozing	
2—Moderate chance of dozing	
3—High chance of dozing	
Situation	*Chance of dozing (0–3)*
1. Sitting and reading.	----------
2. Watching TV.	----------
3. Sitting inactive in a public place like theatre/meeting.	----------
4. As a passenger in a car for an hour without break.	----------
5. Lying down to rest in the afternoon when circumstances permit.	----------
6. Sitting and talking to someone.	----------
7. Sitting quietly after lunch without alcohol.	----------
8. In a car, while stopped for a few minutes in traffic.	----------

brain wave activity continuously, eye movements, muscle activity of the legs and mandible, body position, heart rate and rhythm, blood pressure, snoring, and respiratory activity including breathing patterns and oxygen saturation. A detailed analysis of these can reveal apneic, hypopneic activities, etc.

Presence of obesity or signs of upper airway narrowing should also be documented.

Patients at High Risk for OSA and Who all should be evaluated for OSA Symptoms [1]

1. Obesity (BMI > 35).
2. Congestive heart failure.
3. Atrial fibrillation.
4. Treatment refractory hypertension.
5. Type 2 diabetes.
6. Nocturnal dysrhythmias.
7. Stroke.
8. Pulmonary hypertension.
9. High-risk driving populations.
10. Alcohol consumption.
11. Preoperative for bariatric surgery.

OSA Symptoms That Should Be Evaluated During a Comprehensive Sleep Evaluation

1. Witnessed apneas.
2. Snoring.
3. Gasping/choking at night.
4. Excessive sleepiness not explained by other factors.
5. Non refreshing sleep.
6. Total sleep amount.
7. Sleep fragmentation/maintenance insomnia.
8. Nocturia.
9. Morning headaches.
10. Decreased concentration.
11. Memory loss.
12. Decreased libido.
13. Irritability.

71.7.3 Imaging Aids

71.7.3.1 Cephalometrics

There is a plethora of imaging aids to help diagnose and plan the management of OSA. Cephalometrics has been the oldest imaging modality in the diagnosis of OSA. However, its role in quantification of the pharyngeal volume is controversial as the image that is two-dimensional is used to evaluate a three-dimensional structure [3].

It is a known fact that the lateral pharyngeal wall collapse has a bigger influence on severe sleep apnea than retropalatal and retrolingual collapse as studied with dynamic MRI, and this would not appear evident on a lateral cephalogram [10]. Another shortcoming of lateral cephalograms is that they are taken with the patient upright and awake and therefore do not characterize the asleep or supine airway.

Cephalometric images however have other advantages that can be used to predict OSA. It can be used to measure the upper airway length (UAL) (Fig. 71.3). UAL is significantly longer in OSA patients due to the relation between UAL and airflow resistance. Since the part of the airway is primarily composed of the soft tissues compared to the more rigid, cartilaginous, subglottic airway, this region may predispose to collapse. Studies have proved that male patients with UAL ≥ 72 mm have an eightfold increase in the probability of OSA while females with UAL ≥ 62 mm have a fivefold increase in OSA probability [11].

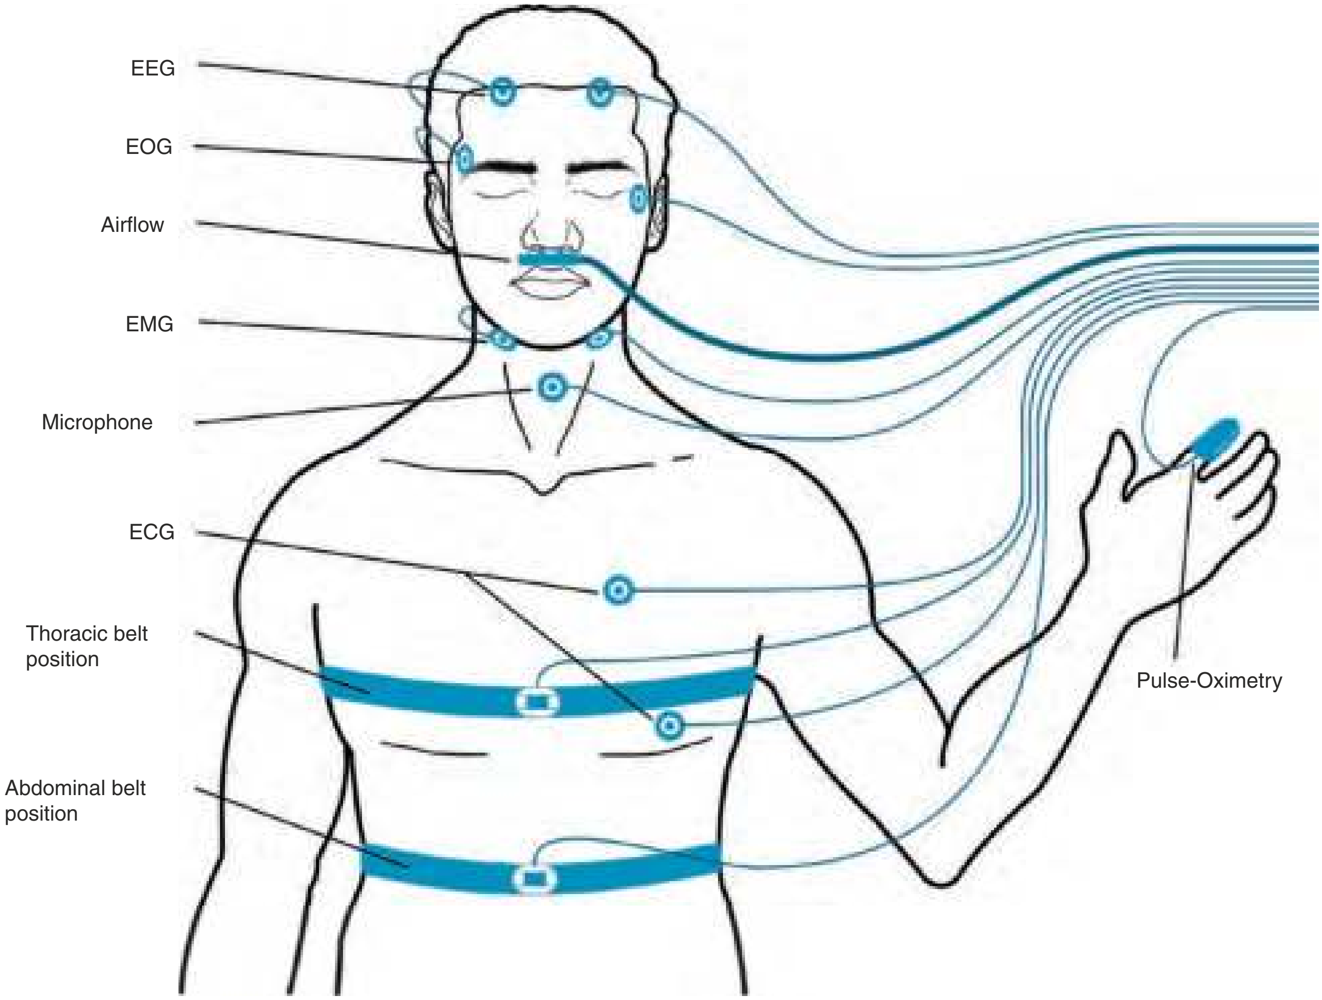

Fig. 71.2 Polysomnography leads and parameters. *EEG* Electroencephalogram, *EOG* Electrooculography, *EMG* Electromyography, *ECG* Electrocardiography

Cephalometrics can also be used to predict the success in multilevel phase I therapy for patients. Skeletal class II patients with a more retrognathic mandible are poor responders. Other patients who could be poor responders include those with hyperdivergent vertical pattern with a larger mandibular plane angle, longer lower facial height, and steeper occlusal plane [9].

71.7.3.2 Dynamic Upper Airway Imaging [12]

Dynamically assessment of the level of upper airway obstruction in OSA patients will allow targeted intervention and allow planning a specific surgical procedure by allowing a delineation of the site and specifying degree and pattern of obstruction. It can also be used to exclude pathology like tumors. Dynamic sleep MRI and drug-induced sleep CT scan characterize the airway in OSA with the advantage of ability to evaluate the airway in a multiplane fashion in the sleeping state or a simulated sleep state.

Drug-induced sleep endoscopy (DISE) is an alternative to conventional endoscopy with the goal of more accurately representing patterns of collapse during the sleeping state.

71.7.3.3 Acoustic Reflex Ion Test

In this test, sound waves are projected into the airway and are reflected into the tube to a computer which creates an image that determines the location of obstruction. This can also predict the effect of mandibular advancement and protrusion on upper airway.

Fig. 71.3 Narrowing of oropharynx and long upper airway length in OSA

Table 71.2 Symptoms of OSAS

Adult	Children
Heavy snoring	Snoring
Excessive daytime sleepiness	Restless sleeping
Apneas	Somnolence
Sudden awakenings with 'choking'	Aggression/behavioral problems
Accidents related to sleepiness	Hyperactivity
Poor memory/concentration	Odd sleeping postures
Delirium	Frequent coughs/colds
Gastroesophageal reflux

Central adiposity/increased neck circumference
Hypertension and other cardiovascular consequences

71.8 Clinical Features (Tables 71.2 and 71.3)

71.9 Treatment Modalities

OSA is a chronic condition that would require multidisciplinary management over a long period of time. There is a myriad of options to treat the condition ranging from behavioral to medical to surgical options. The success of treatment would have to ensure the voluntary active participation of the patient.

71.9.1 Positive Airway Pressure [13]

Continuous positive airway pressure (CPAP) is usually the first line of treatment for OSA. It works on the principle of binding the upper airway in an open position to improve patency during sleep (Fig. 71.4).

This was first described by Sullivan [14] in 1981. The pneumatic splinting action is effective in reducing the AHI. PAP may be delivered in either continuous (CPAP), bilevel (BPAP), or auto titrating (APAP) modes. CPAP is the first line of treatment for moderate to severe OSA and may be used occasionally in mild OSA. CPAP has also found to be effective as an adjunctive therapy to alter blood pressure in OSA patients having hypertension.

Some of these patients may elicit intolerance for CPAP therapy. In these cases, BPAP, pressure relief, or APAP can be considered as an alternative. In addition to its splinting action, CPAP increases vagal tone, cardiac output, and stroke volume and decreases systemic vascular resistance, and there is reduced risk of cardiovascular mortality.

Compliance with nasal CPAP (nCPAP) ranges from 50 to 89% [15]. Reasons for noncompliance are usually due to tolerance problems like dry mouth, conjunctivitis, rhinorrhea, skin irritation, pressure sores, nasal congestion, and epistaxis. Other less common causes of noncompliance include aerophagia, chest discomfort, and bed partner intolerance or psychological problems arising from lack of motivation, claustrophobia, and anxiety.

Though there is no established known lower limit of nightly use below which nCPAP therapy is ineffective, it is suggested that 3.4 h per night of nCPAP use may be adequate to improve cognitive function and quality of life.

71.9.2 Behavioral Strategies [16]

Behavioral strategies have also been used as treatment methods in OSA. These include weight loss, regular exercise, positional therapy, and sleep hygiene which involves alcohol abstinence and consumption of sedatives before sleep.

Sleep position while supine can decrease the lateral upper airway dimensions, particularly while in the supine position.

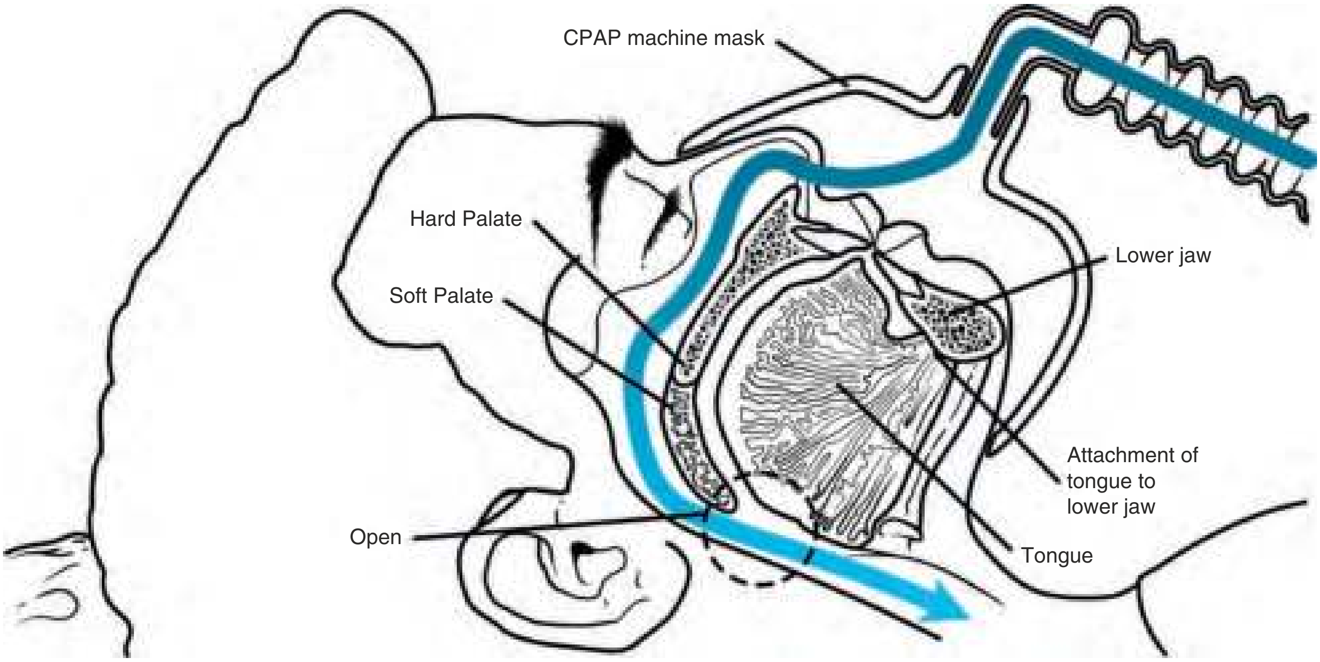

Fig. 71.4 CPAP usage

Therefore, in positional therapy, the patient is kept in a non-supine position.

71.9.3 Oral Appliances [17]

The primary role of oral appliances (OAs) is to enlarge the posterior oropharyngeal airway space, leading to reduction of chances of the upper airway collapsing during sleep. They are ideally indicated in mild and moderate cases of OSA who are noncompliant/poorly compliant to nasal CPAP. Oral appliances are of two types: tongue retaining or mandibular repositioning.

- *Tongue retaining devices* [18]: These appliances position the tongue anteriorly by means of negative pressure and are indicated for patients who have few teeth or are edentulous, have macroglossia, or who are unable to adequately advance their mandible. The result is increase of the volume of the upper airway.
- *Mandibular repositioning devices (MRD)* [19]: As the name suggests, they reposition the mandible and structures attached to it like the tongue and hyoid bone anteriorly, thus increasing the upper airway dimensions in both sagittal and transverse planes, especially at the level of the velopharynx (Fig. 71.5). The appliances completely cover the maxillary and mandibular dentition and hold the mandible forward with respect to the resting position. The amount of advancement is titrated depending on the symptoms not exceeding 80% of the patient's maximum protrusive capacity. This is followed by polysomnography to check the efficacy.

It is mandatory for patients using MRD to have adequate number of teeth to seat the appliance. There should not be any deleterious TMJ disorder, and the patients should have an adequate range of jaw motion and adequate manual dexterity and should be motivated to use the appliance.

The MRD device is customized and the material used is flexible polyamide.

In general, OAs are either titratable or non-titratable. Titratable OAs permit varying amounts of mandibular protrusion. Non-titratable OAs hold the mandible in a single protrusive position without any possibility to change the position during treatment. Some of the non-titratable devices are a simple splint, bionator, Karwatsky activator, or Herbst appliance [20].

71.9.4 Surgical Treatment of Obstructive Sleep Apnea [21] (Table 71.4)

Surgical procedures to correct or treat OSA essentially provide site-specific treatment to increase airway size and decrease airway resistance, thus reducing the effort required in breathing. The site of obstruction is specific to each patient and is as unique as fingerprints. Therefore, one needs to know which the most appropriate procedure is to guarantee success. Since no single factor is predictive of OSA, the significance of a thorough physical examination and imaging to

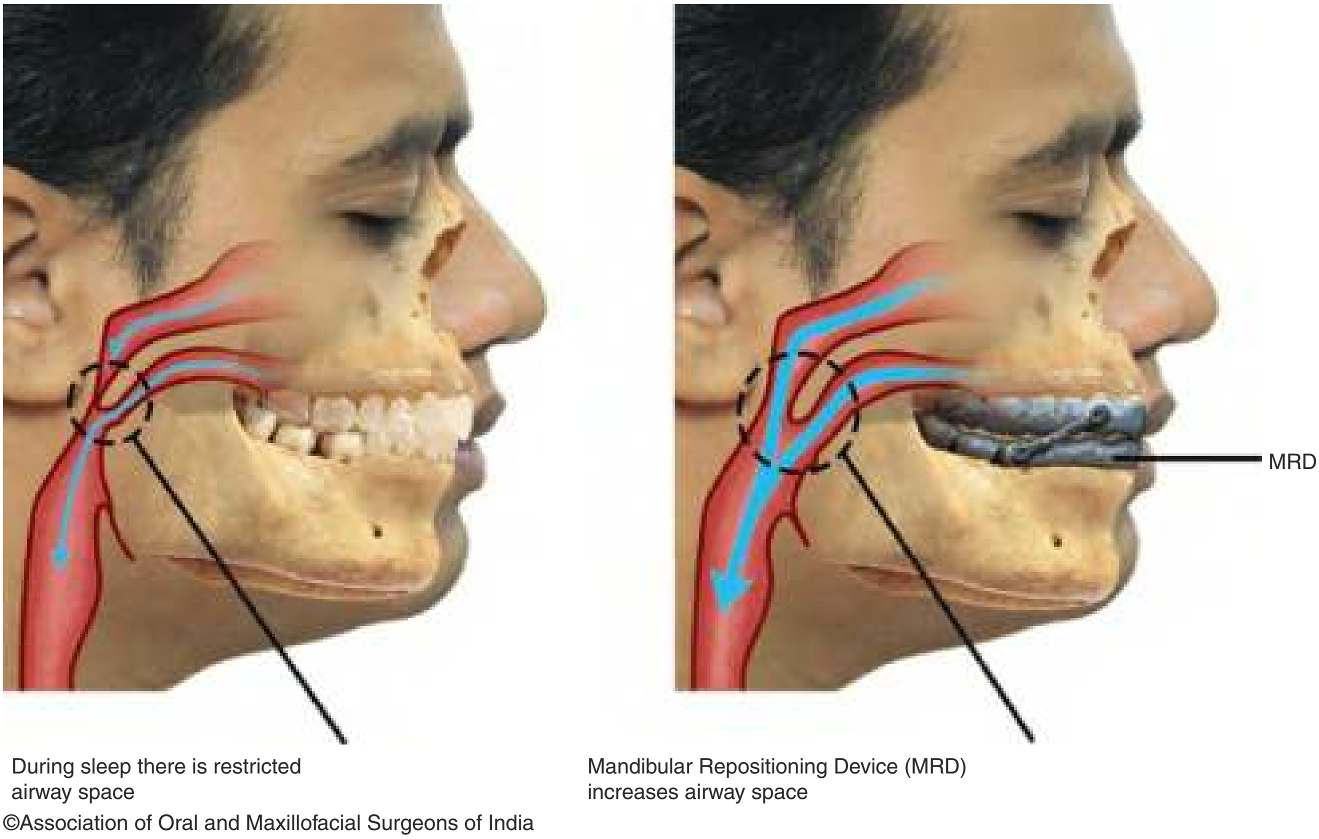

Fig. 71.5 Mandibular repositioning device

Table 71.4 Common surgical procedures for OSA by site

Procedures that bypass the upper airway	Tracheostomy
Nasal procedures	Septoplasty
	Functional rhinoplasty
	Nasal valve surgery
	Turbinate reduction
	Nasal polypectomy
	Endoscopic procedures
Oral, oropharyngeal, and nasopharyngeal procedures	uvulopalatopharyngoplasty
	Palatal advancement pharyngoplasty
	Tonsillectomy/adenoidectomy
	Tori mandibularis excision
Hypopharyngeal procedures	Tongue reduction
	Lingual tonsillectomy
	Genioglossus advancement
	Hyoid suspension
	Mandibular advancement
Laryngeal procedures	Epiglottoplasty
	Hyoid suspension
Global airway procedures	Maxillomandibular advancement
	Bariatric surgery

identify the target site of airway resistance cannot be over emphasized.

Tracheostomy has been used to bypasses the upper airway and is thus a successful modality in treatment, but the morbidity associated with it limits its application.

Factors in the nasal cavity may also play a role in influencing the pharyngeal stability through abnormalities like septal deviation and inferior turbinate. *Nasal surgery* to remove these abnormalities can improve nasal airflow, thus having a positive effect on OSA.

Multiple surgical procedures of the palate like uvulopalatopharyngoplasty (UPPP), which involves removal of the tonsils, uvula, and posterior velum in patients with large tonsils and relatively normal palatal position, are also good adjunctive procedures.

UPPP can also be done assisted by lasers allowing more precise incision and excision than conventional surgery. It also has the advantages of avoiding the need for general anesthesia and with minimal bleeding.

Tonsillectomy with adenoidectomy is the usually first line of surgery for children with OSA without significant craniofacial anomalies.

Fig. 71.6 Genioglossal advancement

Tongue reduction is also a part of the surgical option in enlarges tongue cases where partial glossectomy can reduce the tongue volume.

Surgical procedures of the genial segment of the mandible like *Genioglossal advancement* moves the genial tubercles forward along with the genioglossus muscle, resulting in a more forwardly positioned base of tongue. In addition, it also causes the forward movement of the hyoid bone. This shift increases the posterior airway space and avoids the collapse of its walls during the REM phase of sleep. There are a lot of modifications of the genial advancement procedures.

The standard procedure moves the whole genial segment including the chin. A modified technique allows the surgeon to advance the genial tubercle without altering the normal anatomic position or shape of a patient's chin by only moving the rectangular bony component involving the tubercle (Fig. 71.6).

Hyoid myotomy involves the detachment of infrahyoid muscles and moving the hyoid forward and upward and fixing it with sutures. Another procedure moves the hyoid forward and downward with excision of the lesser cornu and fixing the hyoid anterior to the thyroid cartilage by sutures.

Surgical procedures can also be performed at different levels either concomitantly or in a staged manner. This is done when patients have more than one site of obstruction.

Hypoglossal nerve stimulators (HGNS) are a new addition to the armamentarium for treatment of OSA. It was approved by the FDA for treatment of moderate to severe OSA in 2014 [22].

The device which acts like a pacemaker monitors the breathing patterns and gets activated during sleep to stimulate the hypoglossal nerve, thus controlling upper airway muscles.

Maxillomandibular advancement (MMA) is undoubtedly the most successful surgical technique in OSA. This advantage of this procedure is the effect in correcting airway obstruction at multiple levels. The surgical advancement of the maxillomandibular skeletal framework corrects the airway collapsibility at the nasopharyngeal and oropharyngeal levels and is ideal in patients with moderate and severe OSA who exhibit multilevel obstruction.

The Le Fort I osteotomy of the maxilla along with mandibular sagittal split osteotomy is performed for advancing maxilla and mandible, thus increasing the airway space as it draws the base of the tongue and soft palate forwards (Fig. 71.7).

Achieving *MMA by distraction* is another alternative technique, especially in cases of TMJ ankylosis (Figs. 71.8 and 71.9) where a deficient mandible in the sagittal plane is primarily responsible for the obstructed airway.

The dimensions of maxilla and mandible can also be increased in the transverse plane by distraction resulting in increase in the dimensions of nasopharynx, oropharynx, and the nasal cavity along with movement of tonsillar pillars and the musculature of the velum. Maxillomandibular transverse distraction osteogenesis can be concomitantly be performed with their sagittal advancement for a more effective form of treatment MMA alone.

71.10 Adjunctive Therapies

71.10.1 Bariatric Surgery [23]

Weight loss procedures through bariatric surgery is indicated in patients with a body mass index (BMI) ≥ 40 kg/m^2 or those with a BMI ≥ 35 kg/m^2 with important comorbidities especially when dietary attempts are ineffective.

71.10.2 Medications [23]

Pharmacologic agents can on occasion be used with some degree of success in treating OSA by increasing glossopharyngeal neurologic activity or decreasing REM sleep.

Protriptyline, a tricyclic antidepressant reduces the frequency of apnea and desaturation in non-REM sleep and suppressing REM activity. It also increases the tone of the upper airway muscles. The anticholinergic activity of the drug however limits its use.

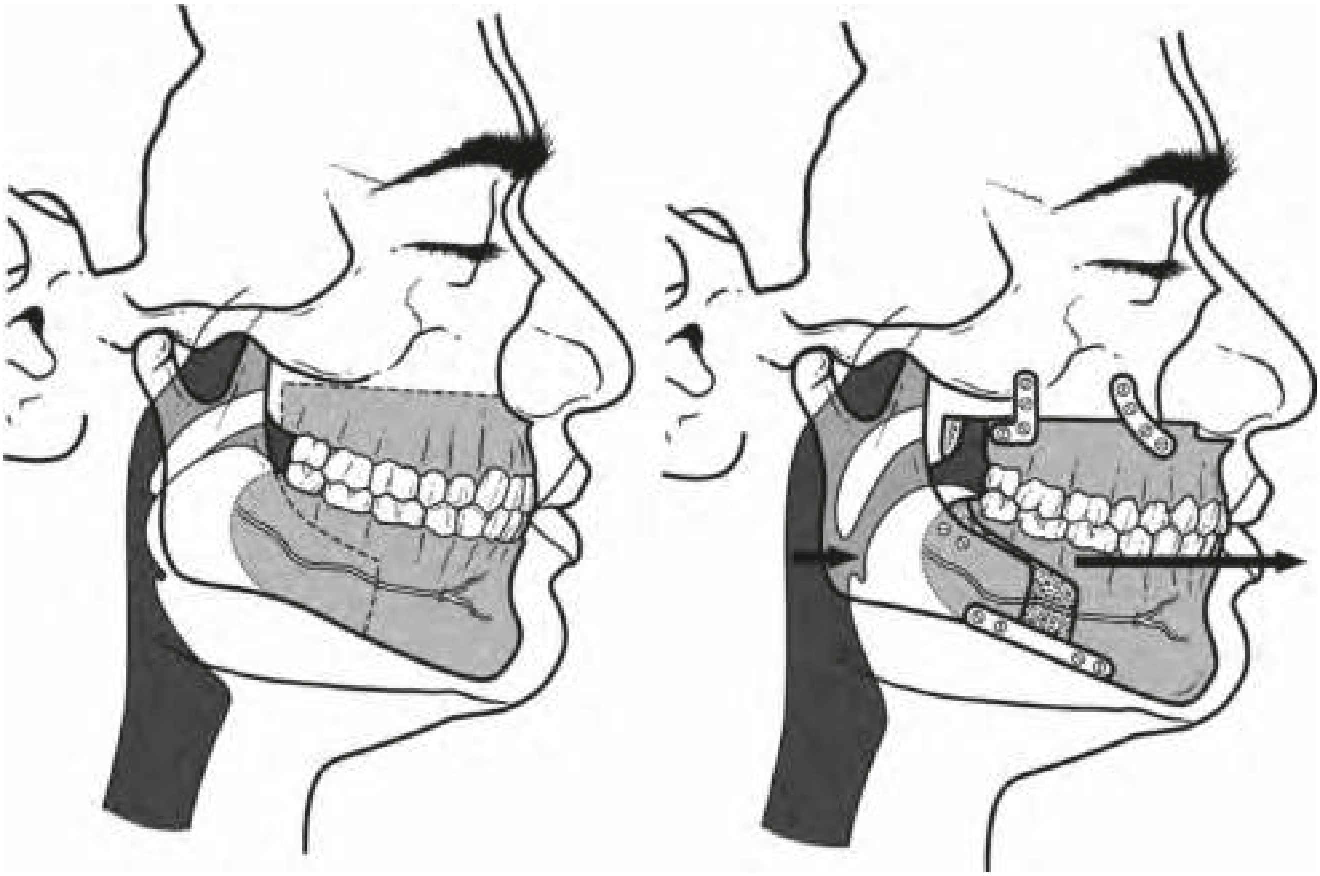

Fig. 71.7 Maxillomandibular advancement and its effect on the airway

Fig. 71.8 Compromised airway in ankylosis

Fig. 71.9 Improved airway after mandibular distraction in a TMJ ankylosis case

Theophylline reduces the episodes of apneas and hypopneas, but the quality of sleep deteriorates.

Modafinil is a wake-promoting medication that can improve residual daytime sleepiness in OSA patients despite regular use of CPAP. It is however avoided in patients who are noncompliant with CPAP. The adverse effects of these drugs are headache and nervousness.

Topical nasal corticosteroids have also been recommended in patients suffering from concurrent rhinitis.

71.11 Conclusion

Obstructive sleep apnea is a multi-factorial and multi-level condition whose management needs to be customized for every patient after a correct diagnosis. Treatment is regulated starting with the non-surgical options and moving to specific site surgical procedures depending on the area of involvement.

71.12 Case Scenario

A 12-year-old female patient with history of sleeping difficulty due to airway obstruction.

Clinical features: Retruded chin, incompetent lips, dry mouth, short chin throat distance (Fig. 71.10).

Preoperative radiographic findings: Deficient mandible, posteriorly placed menton, narrowed oropharynx (Fig. 71.11).

Fig. 71.10 Patients profile

PSG report: Episodes of 33 apneas and 76 hypopneas confirming OSA (Box 71.1).

Treatment plan: Mandibular advancement of 10 mm by distraction (Fig. 71.12).

Post op findings: Improved profile, no episodes of apneas hypopneas (Figs. 71.13, 71.14 and Box 71.2).

Part XIX

Developmental Deformities of the Oral and Maxillofacial Region

Cleft Lip

72

Pritham N. Shetty, Jaideep Singh Chauhan, Mamatha Patil, Neha Aggarwal, and Dipesh Rao

72.1 Introduction

A cleft lip [CL] is defined as a congenital defect in lip continuity due to an embryological malformation. Cleft lip and palate [CLP] have an overall incidence of 1 in 1000 live births [1]. For different ethnicities, the incidence varies. Like other facial deformities, cleft lip and palate produce a considerable degree of disfigurement and functional impairment. A comprehensive treatment involving a cleft surgeon, otolaryngologist, geneticist, speech pathologist, orthodontist and others are required at multiple stages right from infancy to adulthood. A successful lip repair requires careful consideration of presentation of the cleft, the availability of tissues or the lack thereof and effect of intervention on growth and function. We have tried to simplify this concept, keeping certain key points in mind necessary for comprehension of the subject. In this chapter, we have discussed embryology, anatomy and clinical presentation of cleft as an integrated phenomenon for better understanding of cleft lip. The author's technique of cleft lip is discussed in a stepwise manner.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_72) contains supplementary material, which is available to authorized users.

72.1.1 History of Cleft Lip Repair

The enigma of cleft lip and the historic journey to repair the defect has been well described in the narrative book by Millard [2].The excerpts from it illustrates the documentation of the first cleft lip repair in the year 390 AD where an unidentified Chinese physician cut the edges of the cleft and stitched it together with a postoperative order of limited lip movements for the next 100 days. The need to identify an ideal technique was derived on the basis of the anatomical outcome of the repair and also the postoperative scarring. The concepts of cleft lip repair have evolved from straight line repairs to a variety of techniques using various cutbacks, triangles, z-plasties and other flaps.

The techniques for cleft lip can be broadly classified into:

- Straight line repairs.
- Geometric designed techniques.
- Rotational advancement techniques.

We will discuss certain techniques to explain the evolution from a historical point of view. The rotation-advancement technique with its modifications will be discussed later in this chapter.

72.2 Embryology

72.2.1 Development of the External Face

The face is derived from two sources: the frontonasal process that covers the forebrain (neural crest origin) and the tissues of first pharyngeal arch (mixed mesoderm and neural crest origin). These tissues surround the oropharyngeal membrane. From the frontonasal process, two medial nasal processes and lateral nasal processes arise [3]. The first pharyngeal arch gives

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_72

rise to a pair of mandibular processes and a pair of maxillary processes from which palatal processes arise [3]. The maxillary prominences continue to grow medially, compressing the medial nasal prominences towards the midline, subsequently meeting the lateral nasal processes and then the lower part of the medial nasal processes (Figs. 72.1, 77.1). This lower part is known as the globular or premaxillary process. The components derived from various parts are given in Table 72.1.

Abnormalities throughout this complicated developmental process occur in the most severe congenital forms if they develop early in facial embryogenesis (4–8 weeks) to the relatively minor problems developing later (8–12 weeks). Cleft lip varies from a notch in lips red border to extending into the floor of nostril and the alveolar ridge. It may be unilateral or bilateral (Fig. 72.2). Some other forms of facial clefts have also been described in a pictorial form as a result of failure of fusion of the same processes but in a different trajectory and various permutations and combinations (Fig. 72.3).

1. Unilateral cleft lip—due to the failure of the maxillary prominence to join with the merged median nasal prominences which results in a cleft.
2. Bilateral cleft lip—due to failure of fusion of the maxillary prominences with merged nasal prominences bilaterally. The extent of clefting may or may not be similar on both sides.

Table 72.1 Components of face derived from various prominences

Prominence	External face derivatives
Frontonasal	The forehead, the bridge of nose, median and lateral nasal processes
Medial nasal	The philtrum of the upper lip, crest and tip of the nose
Lateral nasal	Alae of the nose
Maxillary process (first pharyngeal arch)	Lateral portion of the upper lip
Mandibular process (first pharyngeal arch)	The lower lip

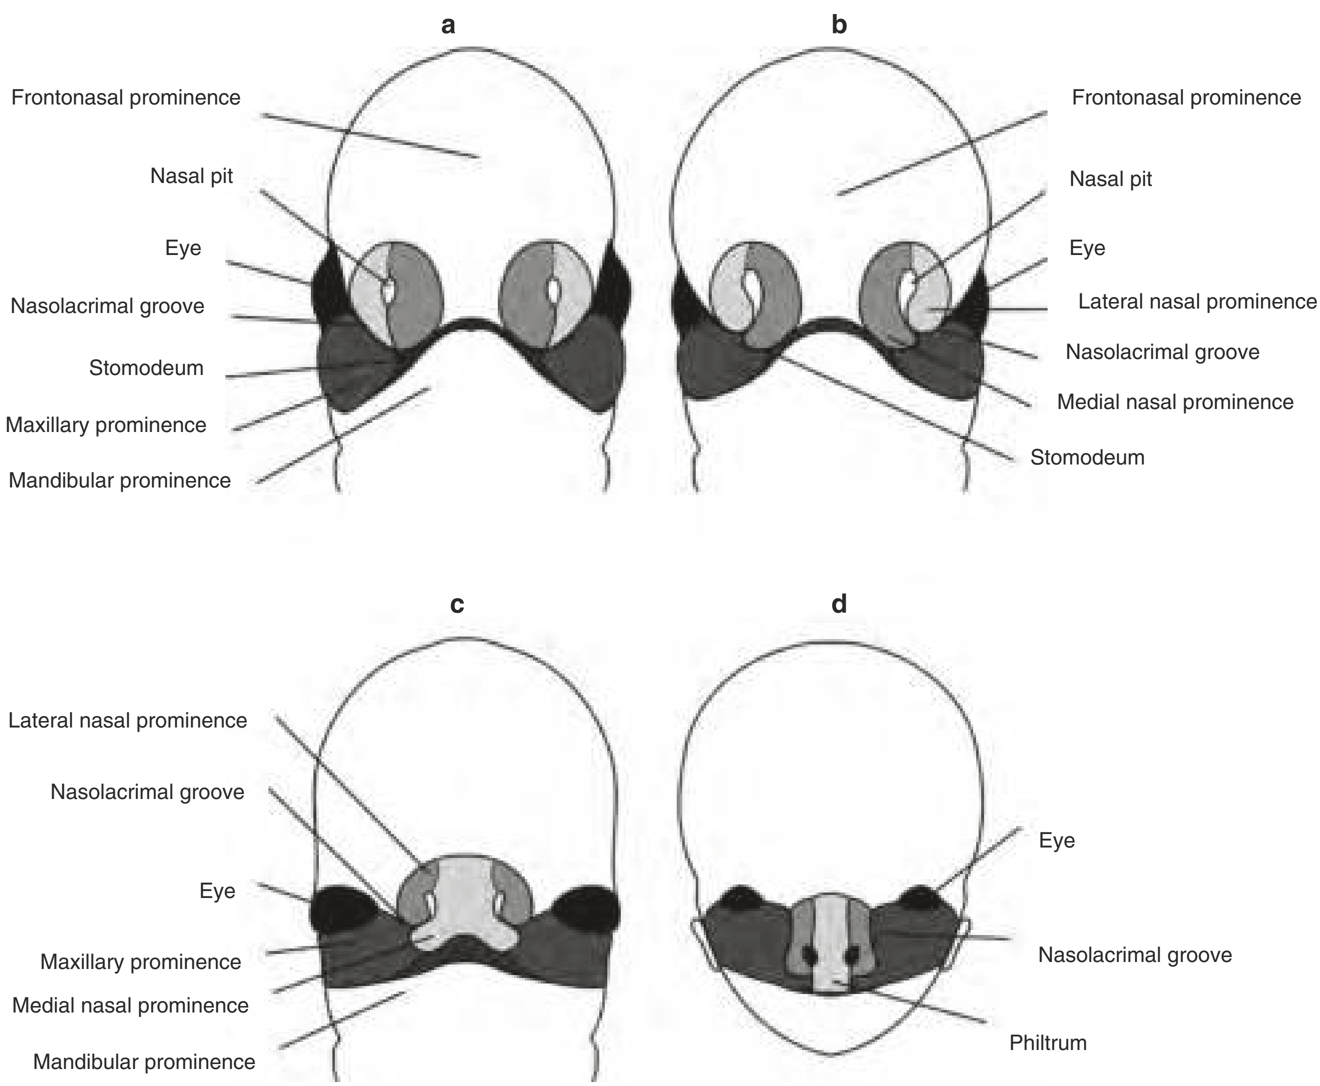

Fig. 72.1 (**a**–**d**) Development of the face. (**a**) Lateral nasal and medial nasal swellings that surround the nasal placodes appear on the frontonasal process (**b**) Paired maxillary processes grow medially, compressing the medial nasal prominences towards the midline. (**c**) Medial nasal processes fuse with each other, lateral nasal processes and the maxillary processes. (**d**) Complete development of the nose and upper lip

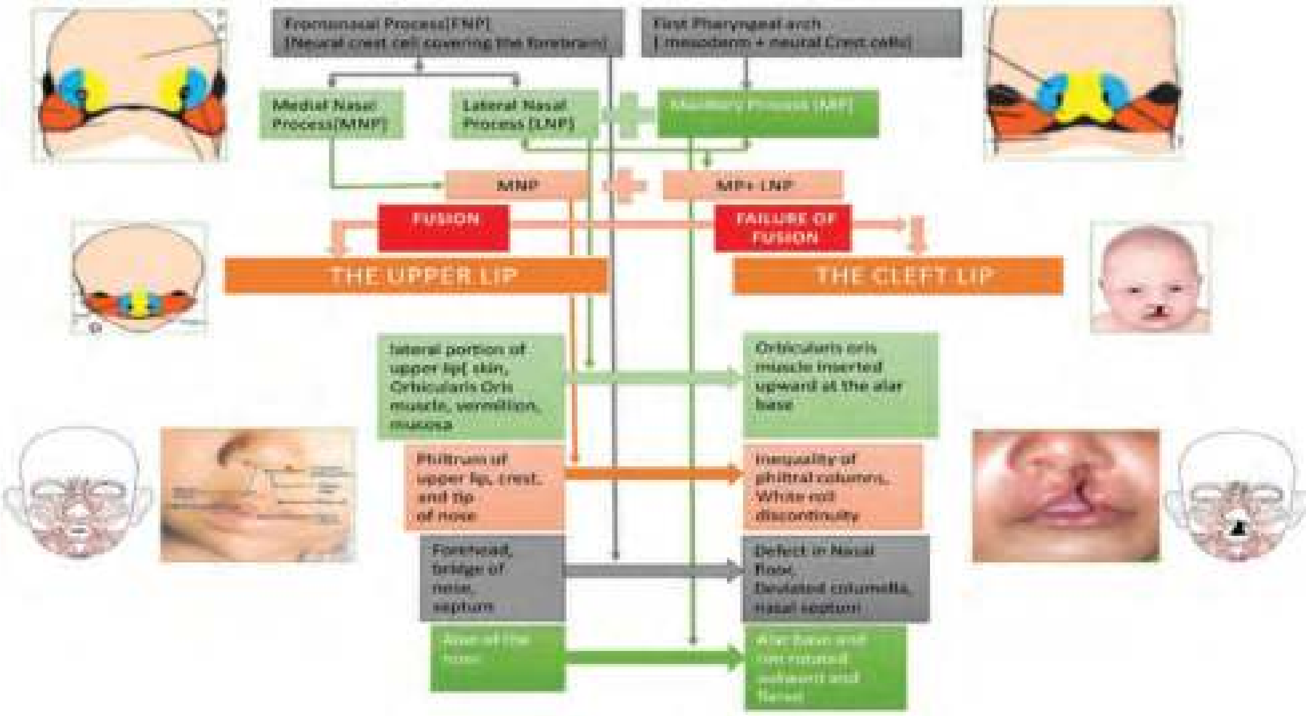

Fig. 72.2 Relation of embryological derivative to the anatomical and clinical description of cleft lip

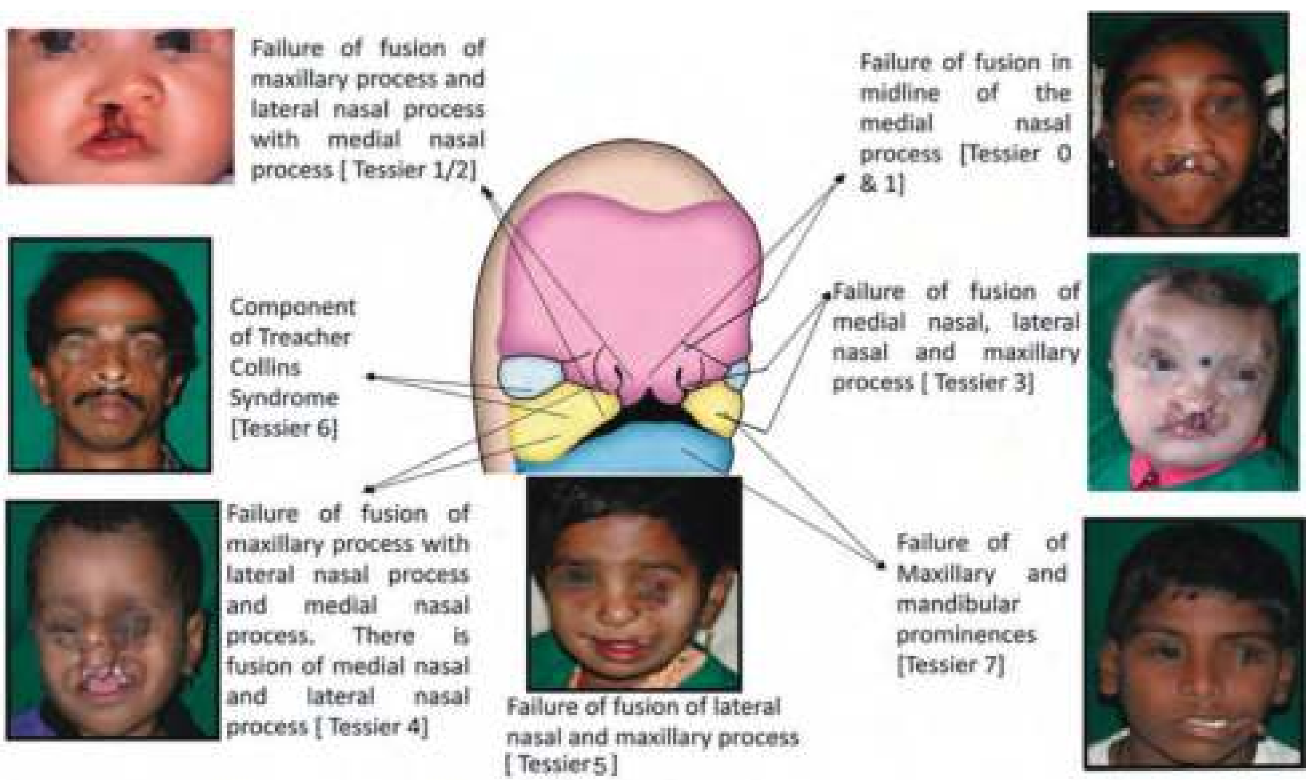

Fig. 72.3 Embryology of various facial clefts

3. Median cleft lip—a very rare condition. Occurs due to the partial or complete failure of fusion of the two medial nasal prominences to form the intermaxillary segment. It is the characteristic feature of Mohr's syndrome.

72.2.2 Embryology of Cleft and its Surgical Implications

1. Mesodermal Migration: There are various theories to describe how a cleft occurs. These theories explain that cleft rises as a result of failure of fusion of the five processes. These processes are formed as a result of mesodermal migration resulting in heaping under the ectodermal layer. Insufficient or late migration of mesoderm leads to partial or total cleft as a result of epithelial breakdown.

   Mesoderm gives rise to the fibromuscular layer of the lip. The importance of mesodermal migration carries in itself an important principle of cleft repair, i.e. muscle approximation. The author's technique presented later in this chapter describes this step as an important step in functional cleft repair. Also the mesoderm has chondrogenic potential which explains the accompanying deficit in the development of nasal capsule [4].
2. Vascular Supply: The philtrum and premaxilla derive their blood supply from the posterior septal artery and terminal branches of the ethmoidal artery (Fig. 72.4). Knowledge of this embryological vascular supply is important while designing the incision on the prolabium in a bilateral cleft lip repair. As the prolabium derives its blood supply solely from the frontonasal process, no back cuts are given during dissection of prolabial flap (Fig. 72.4). This is discussed again in surgical technique.
3. Premaxilla: In complete bilateral cleft lips, the labial artery fails to unite with its counterpart on the other side. In addition the arcade made by anastomosis of the posterior septal branch with the greater palatine artery through the incisive foramen is absent. Thus the blood supply of the premaxilla is derived from three sources: periosteal supply from the vomer, branches of the sphenopalatine and ethmoidal artery. This principle is used in anterior palate repair with concomitant lip repair in bilateral clefts. It is postulated that anterior palate repair using the vomerine flap can lead to premaxillary necrosis due to cutoff of blood supply from the posterior septal arteries. However, in author's opinion and experience, the premaxilla has a robust blood supply even after using vomerine flaps for anterior palate repair [5].
4. The maxillary process carries within itself the superior labial artery which supplies the orbicularis oris muscle. During muscle dissection, the artery is encountered within the muscle going upward. This vessel should be identified throughout the length of incision and muscle dissection and should be carefully cauterised.

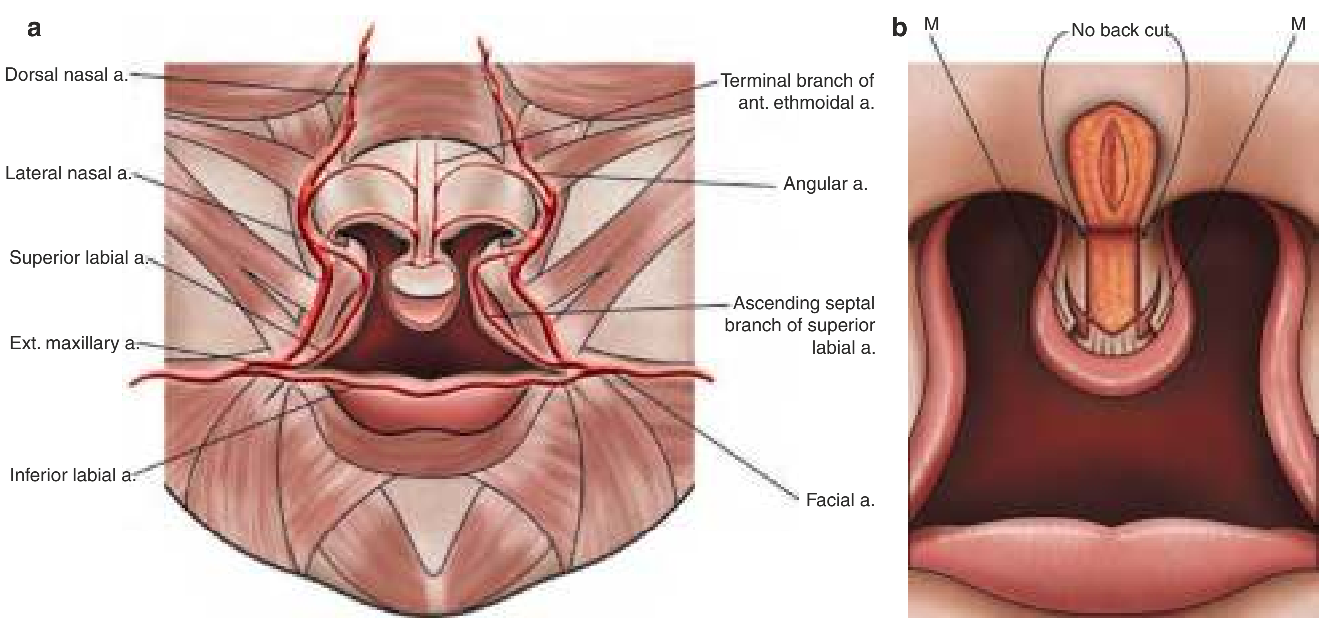

Fig. 72.4 (**a**, **b**) As the philtrum and premaxilla are derived from the frontonasal process, their blood supply is from the posterior septal artery and terminal branches of the ethmoidal artery (**a**). As the prolabium derives its blood supply solely from the frontonasal process, no back cuts are given during dissection of prolabial flap (**b**)

72.2.3 Prenatal Diagnosis in Cleft Lip

Cleft lip can be diagnosed in the intrauterine stage with the help of routine ultrasound scanning at different intervals of gestation. The prenatal diagnosis is usually established during the second and third trimester [6]. Recent data suggests that during the 11–13 gestational weeks, a midsagittal view of the fetal head, face and brain, in addition to certain measurable abnormalities, such as a smaller palatino-maxillary diameter, can make grounds for an underlying CLP. 3D sonography can construct a computerized volumetric rendering of the foetus, similar to 3D CT volumetric reconstructions. Detection rates of up to 75% have been described by specialist maternal-fetal medicine [MFM] physicians and radiologists. Thus, prenatal counselling continues to be important with evolving diagnostic procedures. Although there is currently no intrauterine treatment of cleft lip and palate, research has indicated that both mother and child benefit from early diagnosis and counselling. Prenatal counselling has positive psychological implications on the parents of a child with cleft as they are better prepared and motivated for treatment.

72.3 Surgical Anatomy

Anatomy of the cleft lip patient includes two major components: the lip and the nose. Both the structures vary greatly in a unilateral and bilateral cleft lip deformity and are discussed individually here.

The upper lip is attached above to the nose and blends laterally into the cheek, curving into the lower lip at the commissures. It is formed of muscles and glands covered superficially with skin and lined internally with mucous membrane. These layers are tightly adherent to the muscles and are sealed along the free margin (Box 72.1).

Box 72.1 Components of an Upper Lip

Normal upper lip anatomy

1. Skin, mucous membranes and vermillion with lbial mucosal glands.
2. Muscles: orbicularis oris insertion is displaced in unilateral and bilateral cleft patients.
3. Vascular supply: superior labial artery, inferior labial artery and septal arteries are the major blood supplies of the lips and the nose.

72.3.1 Surface Anatomy

The following anatomical surface components of the upper lip are to be kept in mind when assessing a patient with cleft lip (Fig. 72.5). Anatomical equal repositioning of these features is essential for an aesthetic and functional outcome (Box 72.2).

Box 72.2 Anatomic Landmarks

Philtral columns: They are paired bilateral vertical lip bulges created by the dermal insertion of orbicularis oris fibres into the skin of the upper lip.

Philtral dimple: It's a concavity between the philtral columns created by relative deficiency of muscle fibres.

White roll: The white roll is a prominent ridge just above cutaneous-vermillion border. It appears very distinct and white/light in colour due to reflection of light off the skin. This is due to insertion of pars maginalis of orbicularis muscle and absence of hair in this region.

Vermillion: It's the red mucosal portion of lip divided into dry (keratinized) and wet (nonkeratinized) mucosa.

Red line: It's the junction between wet and dry vermillion mucosa.

Cupid's bow: A curvature of central white roll, formed by the two lateral peaks as the philtral columns extend inferiorly.

Tubercle: Vermillion fullness at central inferior apex of Cupid's bow.

In the normal lip, the columella is a central straight column reaching up to the nasal tip. At its base the columella blends into the nostril sill in front of the nasal floors laterally towards the alar bases. The arches of the alae are symmetrical with equal bulges of the alar cartilages. The eversion of the upper lip places it slightly out in front of the lower lip at the mucocutaneous junction of the upper lip. There is a continuous 1–2 mm rounded roll from commissure to commissure which tops the vermilion and picks up white light it coincides in its curves with the peaks of the Cupid's bow of the vermilion which has central tubercle flanked by, each arch of the bow. The abundance of eleidin in the epithelial cell layers increases the translucency, and the numerous rich capillaries of the papillae create the red colour of this area [5].

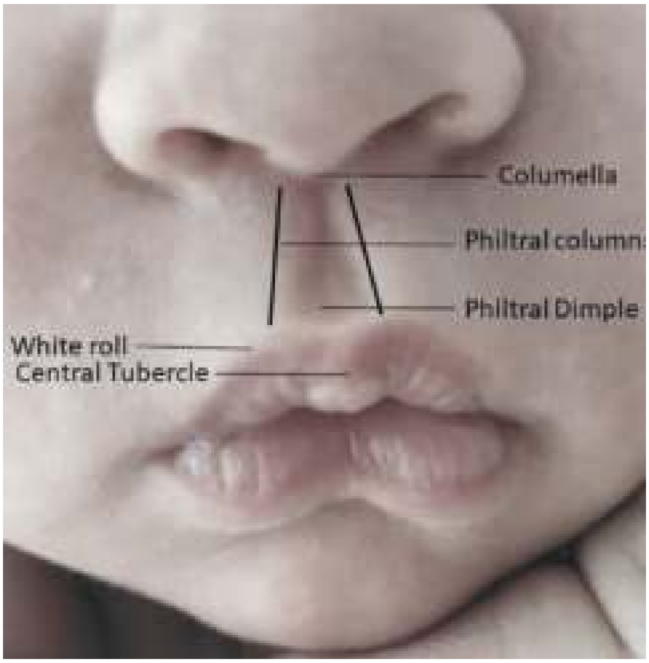

Fig. 72.5 Surface landmarks of a normal lip and nose

72.3.2 Muscles

The *orbicularis oris* consists of numerous layers of muscle fibres surrounding the rima oris traversing in different directions. It is partly derived from muscle fibres of the other facial muscles which are inserted into the lips and partly fibres of its own inserted into the skin near the midline. The main fibres of the lips are oblique and pass from the skin to the mucous membrane, throughout the lip thickness. In the upper lip, these fibres group into two bands bilaterally, lateral and medial [total of four bands]: the *lateral band* originating from the alveolus of the lateral incisor tooth and the *medial band* connecting the upper lip to the septum of the nose. The area between the two medial bands forms the *philtrum*, below the septum of the nose. The additional fibres for the lower lip arise on either side of the midline lateral to the mentalis and merge with the other muscles at the commissure [7].

Orbicularis oris derives from eight muscle components with their origins in the modiolus at each angle of the mouth. Orbicularis fibres of one side end by decussating in the median line with fibres from the opposite side. The orbicularis is composed of four pars peripheralis extending from the rima oris on the right and left side. Intimately associated with the pars peripheralis is the pars marginalis with its two right and left components lying in a plane superficial to the pars peripheralis and confined to the area beneath the vermillion. Pars marginalis is responsible for fine movement (speech) and pars peripheralis for gross movement of the lips (Fig. 72.6a–c). In the presence of cleft, the orbicularis oris muscle fibres do not decussate transversely across the midline but tend to go parallel to the cleft edges towards the base of the nose with their integrity divided. In addition, the transverse nasalis muscle, levator labii superioris and depressor septi do not insert and are prolapsed laterally. They often contract abnormally which has a ripple effect of the lip and the nose. Muscles make the most of their advantage exerting unnatural lateral lifting and distortion of the lip elements in both incomplete and complete clefts. They play a role in displacement of alar base to the side of cleft and the nasal septum on non-cleft healthy side.

72.3.3 Vascular Supply

The major vascular supply to the lip and nose area is derived from the facial artery, branch of the external carotid artery. Other additional sources are from the ophthalmic and the infraorbital arteries. The facial artery gives off inferior and superior labial branches which arise near the corner of the mouth and course as the coronary vessels beneath the free border of the lips deep to the muscle and close to the mucous membrane. The right and left labial arteries freely anastomose to form a circle surrounding the oral aperture. The facial artery then proceeds upwards along the nasolabial fold and gives off the lateral nasal branch and then becomes the angular artery proceeding up to anastomose with the dorsal nasal branch of the ophthalmic artery. The posterior septal artery arising from the sphenopalatine artery in the roof of the nasal cavity courses down the vomerine groove to the incisive foramen anastomosing with the major palatine and ascending septal branches of the superior labial arteries (Fig. 72.7a, b).

Near the inferior lateral attachment of the ala, the lateral nasal artery divides to run one branch along the lower border and another along the superior margin of the lower lateral cartilage. These branches anastomose in the midline with the terminal branches of the anterior ethmoidal artery. It enters the nose and passes along the undersurface of the nasal bone continuing distally over the upper lateral cartilages to the tip of the nose. It joins the lateral nasal branches to continue into the columella anastomosing with the ascending septal branches of the superior labial artery [5].

Vascular anatomy in a cleft lip has been described pictographically in Fig. 72.8. There is an interruption in the usual arcade in the upper lip in unilateral clefts. However, there is sufficient blood supply to both lip elements and the nose to ensure adequate healing.

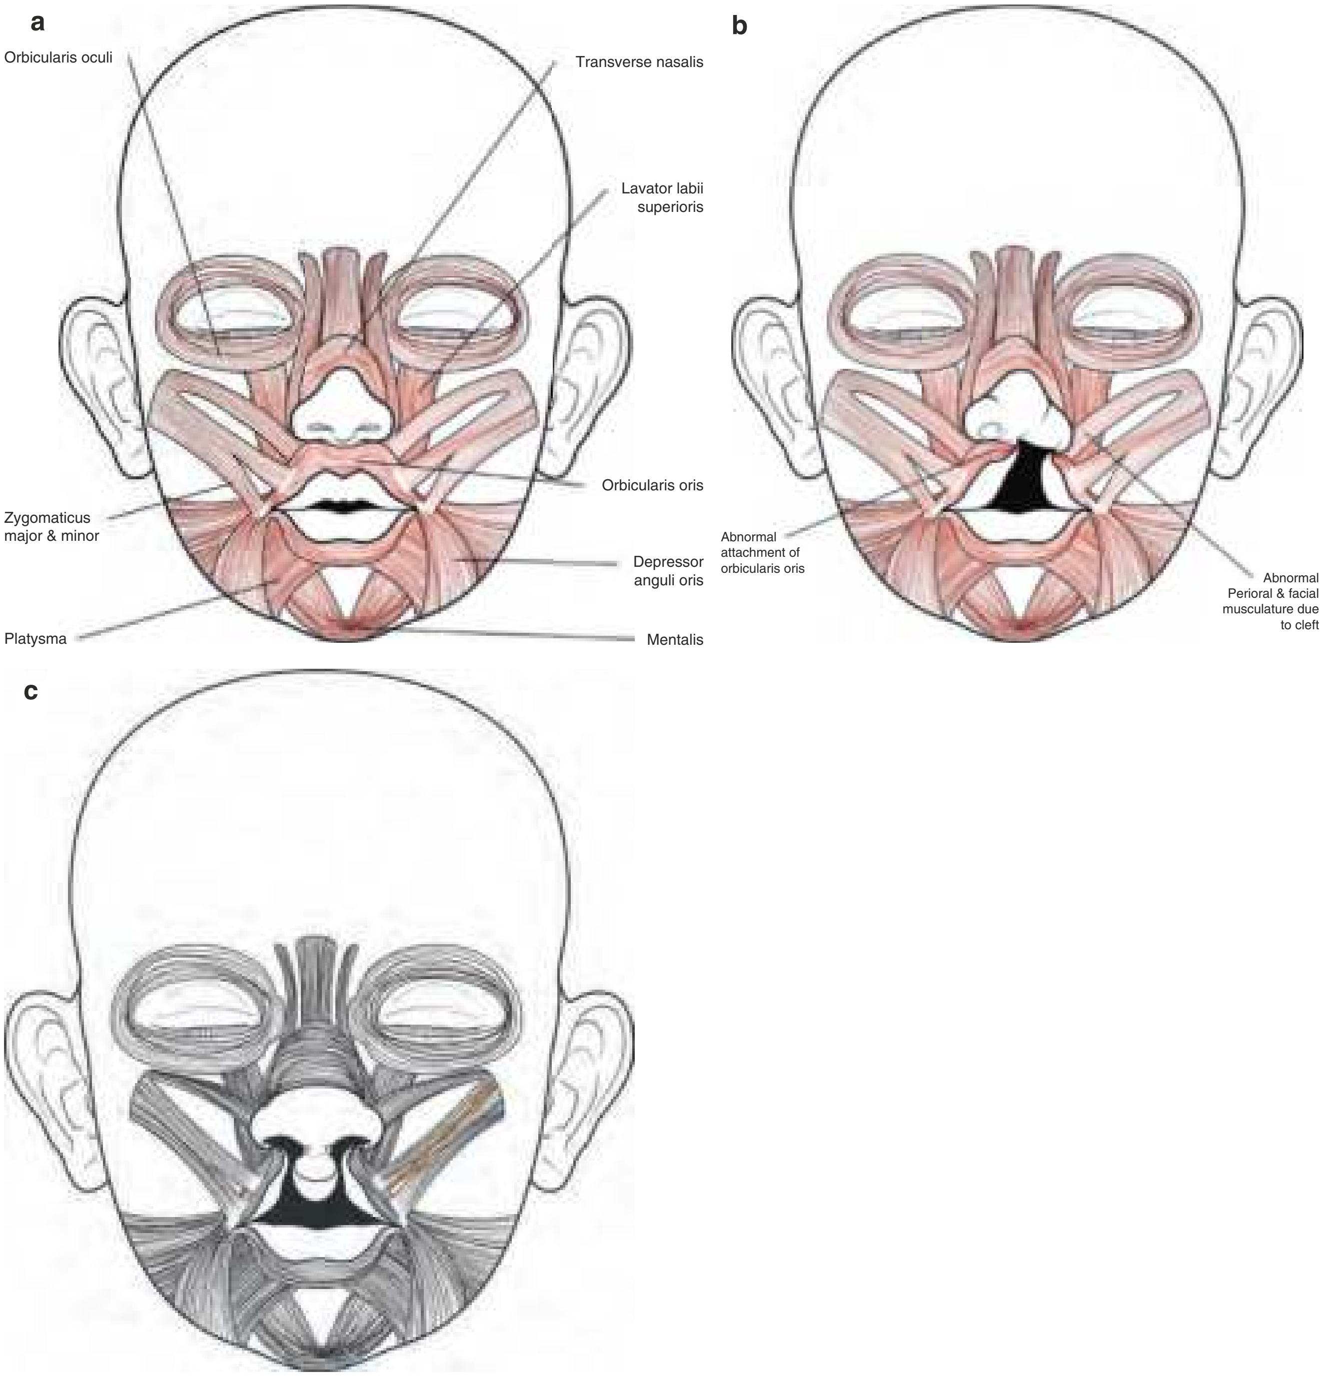

Fig. 72.6 (**a**–**c**) Concentric band of orbicularis oris forming oral sphincter. Upper and lower fibres arise from each modiolus and decussate in the midline. Superficial fibres upper lip criss-cross at midline to attach to the dermis of the overlying skin at the philtrum. Deeper fibres attach to the anterior nasal spine [left]. Note the abnormal attachments in unilateral and bilateral clefts [middle and right]

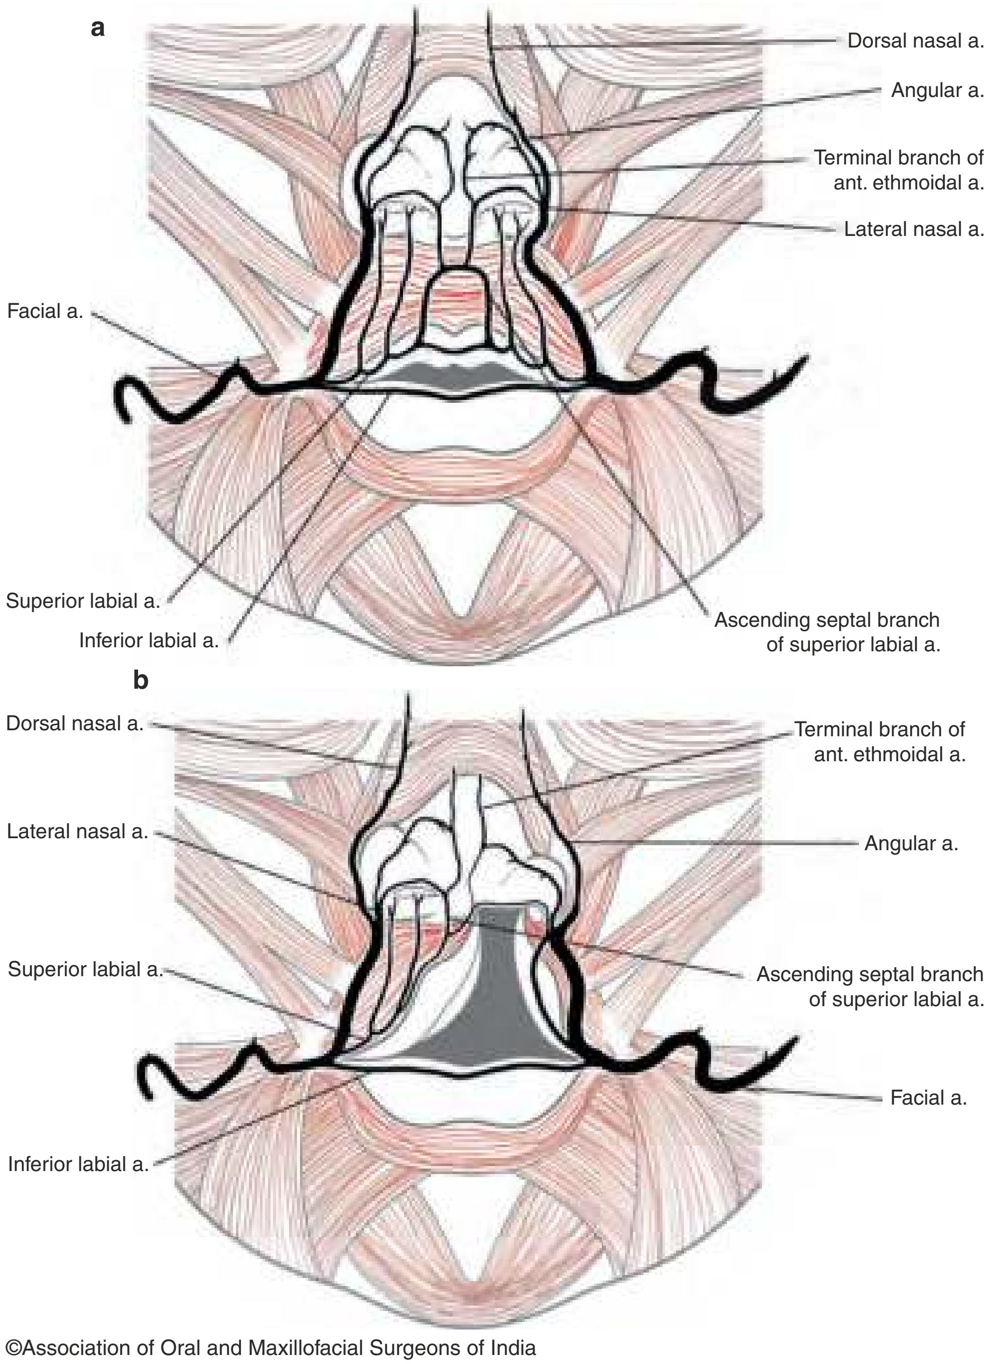

Fig. 72.7 (**a**, **b**) Vascular anatomy of a complete lip (**a**) and a unilateral cleft lip (**b**)

72.3.4 Nerve Supply

The sensory nerve supply to the involved areas of the lips and nose comes from branches of the fifth cranial nerve, trigeminal nerve surfacing through the infraorbital foramen as the infraorbital nerve and through the mental foramen as the mental nerve The motor nerve supply to the muscles of the lips and nose comes from the seventh or facial nerve through its zygomatic, buccal and mandibular branches.

72.3.5 Anatomy of the Unilateral Cleft Lip

A thorough knowledge of the normal lip anatomy can help us understand the abnormal anatomy in cleft. Displacement of muscle insertions and deformation and functional hypotrophy leading to paucity of tissues result in a distorted anatomy of labial clefts (Fig. 72.9). The following are the characteristics of the cleft lip and nose deformity (Table 72.2):

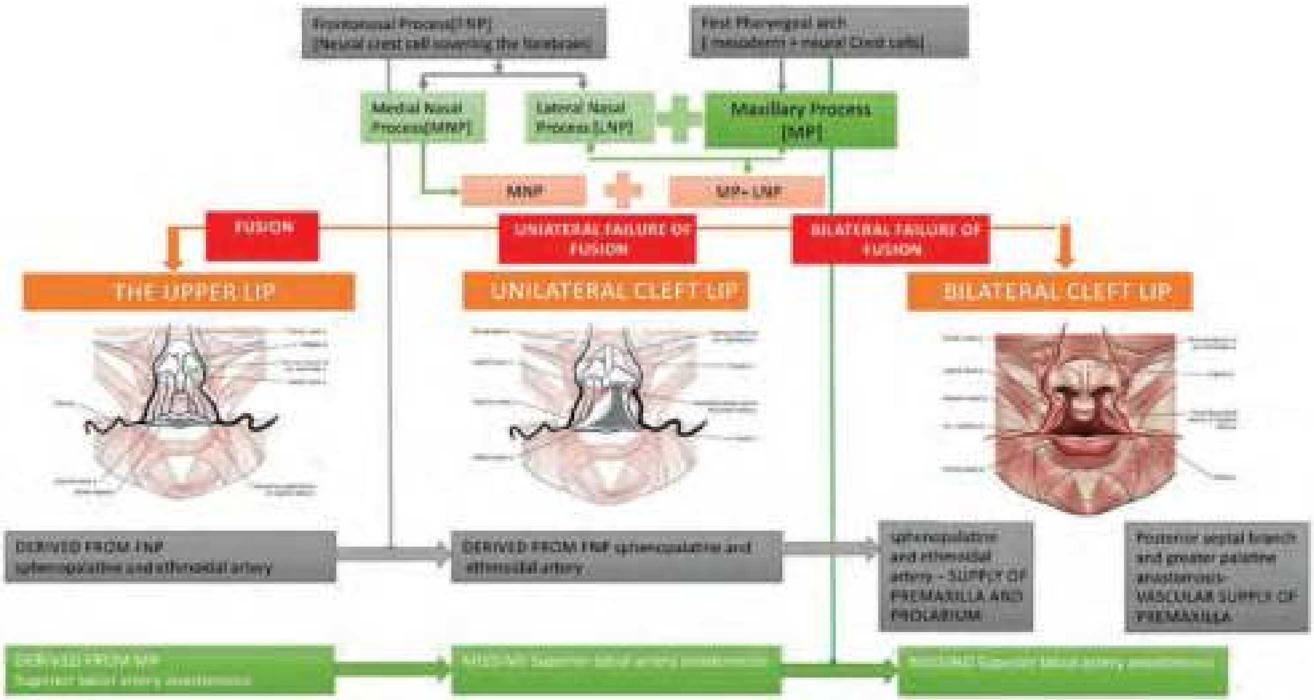

Fig. 72.8 Embryological basis of vascular anatomy in unilateral and bilateral cleft lip

Fig. 72.9 Presentation of a unilateral cleft lip. Note the abnormal anatomy of the lip and nose compared to the non-cleft side

Table 72.2 Comparison of normal and cleft anatomy

Normal anatomy	Unilateral cleft anatomy	Bilateral cleft anatomy
Labial skin	Non-fusion of the lip, the skin on both sides of the lip is less projected or drawn out	One prolabium and bilateral lip elements. The prolabium is the central lip element that has severe paucity of tissues
Philtral columns	Philtral columns are on the non-cleft side, obliquity and discrepancy in their length	No philtral columns present on any element
White roll	Lateral side, the white roll gradually diminishes to about 2–3 mm before it disappears. On the medial side, the demarcation of the white roll is less clear	The white roll on the prolabium is rounded and indistinct
Mucosa	Absence of a labial glandular bed, paucity of compressor muscles, thinner and finer mucosa	Absence of a labial glandular bed, paucity of compressor muscles, thinner and finer mucosa
Orbicularis oris	No muscle decussating in the midline. Abnormal attachment at alar base	Muscle runs bilaterally up into the alar bases, no muscle on the median lip element

1. Labial skin: Apart from the non-fusion of the lip, the skin on both sides of the lip is less projected or drawn out. This leads to a hypoplastic or decreased cutaneous length of the skin. However, the skin is thicker than in normal individuals. The lip consists of the skin, orbicularis oris muscle, minor salivary glands and the labial mucosa. These anatomical planes are important to identify while dissecting the muscle layer. Only 1–2 mm of subdermal dissection should be done, whereas on the mucosal side, the plane of dissection is between the muscle on one side and minor salivary glands and mucosa as a single layer.
2. Unequal philtral columns: The philtral columns are on the non-cleft side, with an obliquity due to discrepancy in their length leaning towards the contralateral sides.

   Matching of the philtral columns of both sides is central to a successful lip repair. The philtral columns are the paired elevated soft tissue structures of the face which make an important aesthetic subunit. Various surgical manoeuvres have been used to achieve symmetry of the philtral columns. The surgical design of rotation-advancement technique is also based on making the philtral columns of the same height.
3. White roll abnormality: From the lateral side, the white roll gradually diminishes to about 2–3 mm before it disappears. On the medial side, the demarcation of the white roll is less clear. Identifying the white roll is pivotal in making incision markings during surgery. A practical tip is to identify maximum width of the dark/dry mucosa; it is generally the most pertinent area to mark the point where the white roll starts diminishing. This is discussed again in the surgical technique.
4. Mucosa: In cleft lip, due to absence of a labial glandular bed and the paucity of compressor muscles, the mucosa of the cleft side is thinner and finer. Also, the mucosa merges with the skin closer to the nose and rolls inward. This mucosa of the cleft region is considered redundant and excised frequently. However, in author's clinical judgement, this tissue can be converted into a flap to close the nasal floor, thus precluding the need for any vestibular releasing incision.
5. Nostril skin on the lip: The skin of the lateral alar part, the columella and part of nasal vestibule intrudes onto the lip in the upper part. Distinction can be made between nostril skin and labial skin as the former is finely stippled while the latter is finely striated and has hair.

72.3.5.1 Nose

1. Platform: The base, i.e. the premaxilla, is projected and rotated outwards, whereas the lateral maxillary segment is retropositioned. Consequently, there is nasal asymmetry at the base.
2. Septum: Lower border of the septum is dislocated out from the vomerine grove, thus twisting the nasal tip and columella.
3. Columella: Unilateral shortness in vertical dimension is seen with deflection towards the non-cleft side.
4. Nasal floor: Has a defect in the skin, muscle and bone.
5. Lower lateral cartilage: The cleft alar cartilage is flattened and more horizontal in its long axis and stretched at an obtuse angle.
6. Alar crease: Due to the absence of alar cartilage bulge, alar crease continues across the tip to produce a disjointed effect.
7. Alar base: Rotated outwardly in a flare.
8. Alar rim: There is a skin curtain of ala that is without cartilage further reducing the apparent length of the columella on the cleft side (Fig. 72.9).

72.3.6 Anatomy of the Bilateral Cleft

The following are the salient anatomical features of a bilateral cleft:

- Prolabium and premaxilla: The prolabium and premaxilla isolated from lateral segments (lip and maxilla). The premaxilla is not found in the alveolar arch and either protruded or deviated or rotated. This is probably because of the excessive forward growth of the premaxillary-vomerine suture and uninhibited forward growth of the cartilaginous nasal septum (Fig. 72.10).
- The prolabium is the central lip element that has paucity of tissues. The prolabium has no muscle, is non-mobile and has a limited blood supply. The white roll on the prolabium is rounded and indistinct.
- Nasal deformity depends on the premaxilla and size and position of the prolabium. The columella is very short or absent. The base of the ala is positioned laterally and posteroinferiorly. There is a wide nasal base. The deformity in LLC is presented by the elongated lateral crus and shorter medial crus. The nasal tip is flat with increased distance between alar domes. Only in cases of asymmetric bilateral clefts, the septum is deviated.
- The orbicularis oris muscle runs bilaterally up into the alar bases. There is no muscle on the median lip element (Fig. 72.4).
- In complete bilateral cleft lips, the labial artery fails to unite with its counterpart on the other side. In addition the arcade made by anastomosis of the posterior septal branch with the greater palatine artery through the incisive foramen is absent. The philtrum and premaxilla therefore derive their blood supply from the posterior septal artery and terminal branches of the ethmoidal artery.

Fig. 72.10 Presentation of a bilateral cleft lip

72.4 Classification and Presentations of Cleft

As we discussed in embryology, insufficient or late migration of mesoderm leads to epithelial breakdown resulting in a cleft. Thus, a cleft lip presents in various forms, and the management differs slightly for all forms of cleft. The basic classification is based on the side of presentation, i.e. left and right and complete and incomplete (Figs. 72.11 and 72.12). The incomplete cleft lip can be further classified into various types (Box 72.3).

Box 72.3 Presentation of Incomplete Clefts

Incomplete clefts can be further divided on the basis of extent of involvement of the mucosa, skin and nasal floor.

1. Incomplete cleft lip with mucosal notch not extending into the skin.
2. Incomplete cleft lip with mucosal and skin notching.
3. Incomplete cleft lip involving the mucosa and skin extending upwards but not up to the nasal floor.
4. Incomplete cleft lip with Simonart's band. Simonart's band is a bridge of tissue between the premaxilla and the lateral lip element. Its prevalence is approximately 20%.

Similarly, bilateral cleft lip can be divided into complete and incomplete clefts. Complete clefts can be further divided on the basis of status of the premaxilla. The premaxilla can be severely, moderately or mildly protruded. However, this is a clinical classification and helps in deciding treatment of a bilateral cleft lip.

72.4.1 Classification

Throughout history, many surgeons have attempted to classify cleft lip and palate in their own ways. Classifications made have been on three bases: laterality, severity and morphology of the cleft. At the least any classification system should be able to specify the laterality, extent and severity of

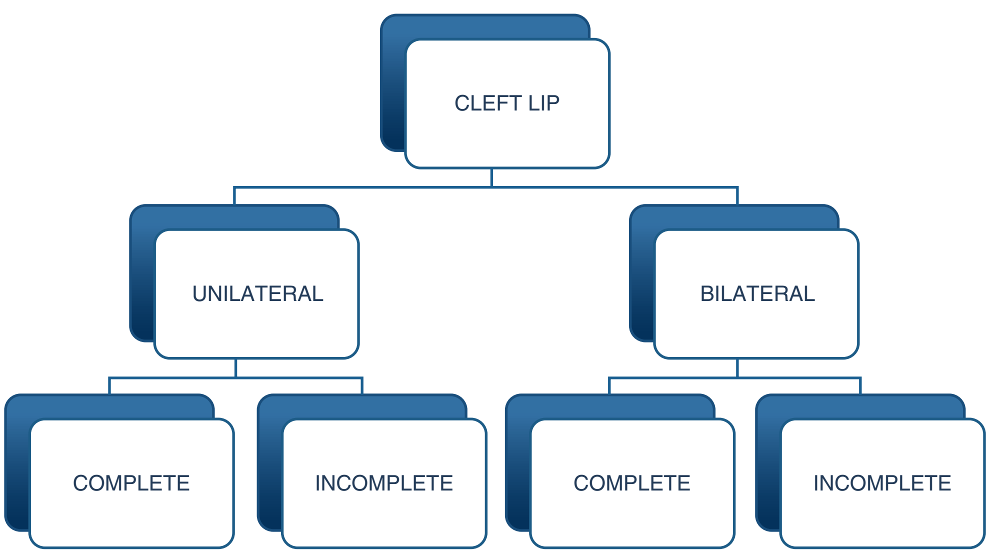

Fig. 72.11 Basic classification of cleft lip

Fig. 72.12 Incomplete cleft lip with mucosal notch not extending into the skin. (**a**) Incomplete cleft lip with mucosal and skin notching. (**b**) Incomplete cleft lip involving the mucosa and skin extending upwards but not up to the nasal floor. (**c**) Incomplete cleft lip with Simonart's band

the labial cleft and the palatal cleft necessary for treatment planning or outcome assessment (Tables 72.3 and 72.4).

Apart from the above-mentioned classifications, there are various reports of individual classifications by many international and Indian surgeons based on their experience and perspective. An ideal classification should be simple, clear and universally acceptable for purpose of communication and documentation.

72.5 Treatment of Cleft Lip

72.5.1 Timing of Intervention

Cleft lip repair constitutes the first surgical step in cleft lip and palate. Each cleft protocol team advocates different timings for lip reconstruction, with slight variations from the neonatal period to 6 months and later. Timing of intervention can be broadly categorised based on chronological age of the cleft patient or based on certain dental age milestones and status of dentition (Tables 72.5 and 72.6). There are a number of protocols adopted by various centres around the world. Proponents of traditional repair at the chronological age of 10–12 weeks argue that it poses a decreased risk of anaesthesia-related complications and provides improved aesthetic outcomes and positive psychological assurance to the parents. Surgery was traditionally delayed for several weeks based on the "rule of tens", i.e. infant weighing a minimum of 10 pounds, having a haemoglobin level of 10 g/mL and reaching an age of 10 weeks. This rule was based on the fact that the musculature of the lip is more evolved by this age and thus allows for proper reconstruction [23]. Another important milestone is the neck holding capacity of the baby. It is generally present at 3–4 months of age. It is prudent to wait till this milestone is achieved. This is crucial in cautious transfer of the infant as he/she is transferred to the operating room, recovery or intensive care unit and is handled by various healthcare personnel.

72.5.2 Basic Treatment Algorithm

We have devised a basic treatment algorithm for unilateral and bilateral cleft lip repair that we follow at our centre. Due to lack of awareness, prenatal and postnatal counselling and the social taboo, many patients in India do not report at the correct age for surgery. As a result, the treatment methods have been modified based on the age of presentation of the cleft patient to provide the optimal outcome (Figs. 72.13 and 72.14).

72.5.3 Presurgical Nasoalveolar Moulding

Wider, extensive clefts and bilateral clefts are associated with significant deformities of nasolabial complex, presenting a greater surgical challenge in approximating anatomic struc-

Table 72.3 Summary of all classifications given so far

Year	Author		Foundation point
1922	Davis and Ritchie [8]	Group I: Prealveolar process cleft (clefts affecting the Lip) 1. Unilateral (right/left: Complete/incomplete) 2. Bilateral (right, complete/incomplete; left, complete/incomplete) 3. Median (complete/incomplete) Group II: Postalveolar process cleft (clefts affecting the palate) 1. Soft palate 2. Hard palate Group III: Alveolar process cleft (any cleft involving the alveolar process) 1. Unilateral (right/left: Complete/incomplete) 2. Bilateral (right, complete/incomplete; left, complete/incomplete) 3. Median (complete/incomplete)	Alveolus
1921–1923	Brophy [9]	16 categories of distinct morphological forms of cleft palate with/without cleft lip	Based on morphology
1931	Veau [10]	I. Clefts of the soft palate II. Clefts of the soft and hard palate, up to the incisive foramen III. Clefts of the soft and hard palate extending unilaterally through the alveolus IV. Clefts of the soft and hard palate extending bilaterally through the alveolus	Extent, laterality and morphology
1958	Kernahan and Stark [11]	1. Clefts of structures anterior to the incisive foramen 2. Clefts of structures posterior to the incisive foramen 3. Clefts affecting structures anterior and posterior to the incisive foramen	Incisive foramen
1962	American Cleft Palate-Craniofacial Association Classification [12]	1. Clefts of the prepalate (cleft of lip and embryologic primary palate) (a) Cleft lip (cheiloschisis) (b) Cleft alveolus (alveoloschisis) (c) Cleft lip, alveolus and primary palate (cheiloalveoloschisis) 2. Clefts of the palate (cleft of the embryologic secondary palate) (a) Cleft of the hard palate (uranoschisis) (b) Cleft of the soft palate (staphyloschisis or veloschisis) (c) Cleft of the hard and soft palate (uranostaphyloschisis) 3. Clefts of the prepalate and palate (alveolocheilopalatoschisis) 4. Facial clefts other than prepalatal and palatal (a) Cleft of the mandibular process (b) Naso-ocular clefts (c) Oro-ocular clefts	Two principal anatomical landmarks: The "prepalate", anterior to the incisive foramen and the "palate", posterior to the incisive foramen
1969	International Classification (Broadbent et al., 1969)	1. Clefts of the anterior (primary) palate 2. Clefts of the anterior (primary) and posterior (secondary) palates 3. Clefts of the posterior (secondary) palate	Categorization of clefts of the lip, alveolus and palate based on embryologic origin and rare facial clefts based on topographic findings

Table 72.4 Incomplete cleft lip can be further divided into minor-form, microform and mini-microform [22]

Minor-form	Microform	Mini-microform
1. Notched vermilion-cutaneous junction extending 3 mm or more above the normal Cupid's bow peak 2. Deficient vermilion on the medial cleft side 3. Cutaneous groove and muscular depression that is evident on puckering 4. Hypoplastic median tubercle 5. Nasal deformity	1. Medial vermilion-cutaneous point less than 3 mm above the normal Cupid's bow peak 2. Deficient vermilion on the medial cleft side 3. Lower cutaneous lip shows a variable glabrous strip 4. Philtral line shows muscular depression, with a prominent medial component of the philtral ridge 5. Nearly normal length of the hemicolumella, the sill shows a small depression, slight slump of the alar genu and 1 to 2 mm lateral displacement and outward flare of the alar base	1. Discontinuous vermilion-cutaneous junction 2. Level Cupid's bow peaks 3. Notched free mucosal margin 4. Variable muscular depression 5. Variable nasal deformity; mostly a depressed sill

Table 72.5 Timing of intervention based on chronological age

Timing	Procedure
After 16 weeks of pregnancy	Cleft lip diagnosis by USG images
Prenatal	Discussion with surgeon Consultation with a geneticist
Neonatal	Presurgical orthopaedics Feeding instructions
12 weeks of age	Cleft lip surgery
6–12 months of age	Cleft palate repair with intravelar veloplasty
14 years or later	Orthognathic surgery
Adulthood	Secondary rhinoplasty

Table 72.6 Timing of intervention based on status of dentition

Timing	Procedure
Prior to cleft lip repair	Presurgical orthopaedics [NAM]
Primary dentition	Orthodontic maxillary expansion
Mixed dentition	Orthodontic maxillary expansion and protraction
Before eruption of permanent dentition	Secondary alveolar bone graft using iliac crest particulate cancellous bone marrow
Permanent dentition	Orthodontic treatment for dental arch alignment
After full eruption of permanent dentition	Dental arch alignment and levelling
Orthognathic surgery for maxillary advancement	After orthognathic alignment
Postsurgical orthodontics	For space closure and final settling of occlusion Prosthetic rehabilitation

tures, thus obtaining an optimum functional and aesthetic result. The basic goal of any surgical technique is to restore normal anatomy and function. Thus in such cases, where it is difficult to achieve goals of primary repair due to wide discrepancies, presurgical maxillofacial orthopaedic appliances mould the nasolabial structures through specifically directed forces, thus reducing the deformity before surgery for an easy repair.

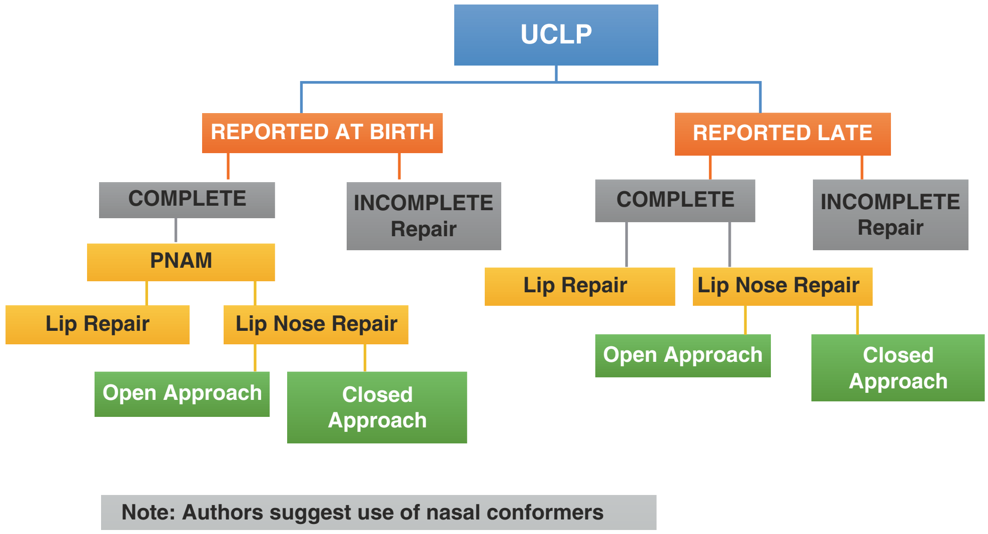
Currently, presurgical nasal alveolar moulding (PNAM) is a widely used orthopaedic technique for presurgical cleft deformity correction [23, 24]. PNAM theory is based on the theory that increased hyaluronic acid content is present in the infant cartilage, which makes the cartilaginous structure more pliable and plastic. By the age of 3 months, the cartilage becomes more rigid with less plasticity. PNAM can significantly improve the nasal symmetry, by elongating the columella, bolstering the alae, narrowing the cleft and restoring the alveolar arch form, thus demonstrating favourable immediate and long-term outcomes.

PNAM is based on the principles of negative sculpting and passive moulding of the alveolus, lip and nasal tissues. An initial impression is obtained, and custom-made plates are fabricated. A series of modifications are made to the surface of the appliances with the addition and deletion of materials in certain areas. This process is called negative sculpting [25]. The purpose of this is achieving approximation and symmetry of the two maxillary alveolar segments and addressing the nasal deformity by moulding the cartilage in anatomical position [26, 27] (Fig. 72.15). The process should be explained to the parents; insertion of the appliance should be carefully taught and made to practice. Parents should be explained the importance of this exercise through videos and photos of previous patients.

Impression Making A heavy-bodied polyvinyl siloxane impression material should be used for the first impression. The infant is held in prone position to keep the tongue forward and to allow any material or saliva to drain out of the oral cavity and prevent aspiration. This should be done in a hospital setting to manage any airway emergency in the presence of an anaesthetist available if needed. Once impression is made, the mouth should be examined for any residual material.

Device Fabrication The moulding plate is made with clear methyl methacrylate lined with a soft denture material on the dental stone model. The borders should be trimmed and smoothened to prevent any ulceration. The oral surface should be smooth and polished with good retention and no extensions into the cleft area.

Insertion and Moulding The moulding plate is to be worn full-time by the patient. It should be removed for cleaning and routine hygiene practices to prevent infection and check for any ulceration. Suckling should be checked with the plate in position and to check gagging. The plate is secured to the



©Association of Oral and Maxillofacial Surgeons of India

Fig. 72.14 Basic treatment algorithm for bilateral cleft lip

cheek bilaterally using orthodontic elastics going to the opposite side and secured with surgical tapes. The elastic loop extends from the retention arm approximately in a 40–45 degree angle, thus pulling the anterior flange of the plate posterosuperior vector for activation. 2 ounces of traction force is given by stretching the elastic to twice its original. The surgical tape is applied to a layer of wound dressing material like micropore tape and not the skin directly. The tape is to be changed once a day. The tape should be applied to the non-cleft side first and then pulled over to the cleft side. Weekly follow-ups should be made to evaluate the moulding plate for retention and changes in the alveolar segments.

Moulding Plate Modification Selective grinding of acrylic material is done from the region into which the alveolar segments are to move. At the same time, soft denture lining material is selectively added to the plate to direct the alveolar segments to the midline, as desired. In a patient with bilateral cleft, the premaxilla is retracted and derotated, to bring to a normal maxillary arch alignment. An ideal surgical result may be obtained when 1–2 mm gap remains between alveolar segments.

Nasal Stent When the maxillary alveolar segment approximation has been achieved, the nasal moulding should begin. The nasal stent is added to the existing moulding plate in the form of a stainless steel wire projecting out of the plate outwards going into the nose like a “swan neck”. A small wire loop can be made on which a bilobed intranasal acrylic component is made with a layer of soft denture liner. Nasal stent is placed 3–4 mm inside the ala and gently lifted towards dome until slight blanching is noted.

Fig. 72.15 PNAM treatment in a case of bilateral lip. (**a** and **b**) Pre- and postoperative PNAM. Note the changes in the nasal tip, alar cartilages and position of the premaxilla. (**c** and **d**) PNAM device with the nasal stent and lip taping

Blanching of the nasal tip as the baby suckles activates the appliance. Lip taping is continued after the nasal stent appliance is added.

In a follow-up study over 6–9 years, Bennum et al. observed that patients treated with PNAM within 15 days after birth maintained satisfactory nasal symmetry [28]. Ezzat et al. compared 12 unilateral cleft lip and palate patients with PNAM treatment and found narrowing of the alveolar cleft, increased posterior width of the dental arch, uprighting of the columella and improved nasal symmetry [29]. Yang et al. reported similar results from 45 unilateral complete cleft lip and palate patients [30]. In a large multicentre study sample, Ross argued that orthopaedic correction of the premaxilla failed to stimulate maxillary growth and thus was not necessary [31].

The authors conducted a study to evaluate the nasolabial aesthetics on two-dimensional photographs at 6 months post cheiloplasty. Cupid's bow, vermilion symmetry, vermilion notching, premaxillary show at rest, scar aesthetics, columella height and bialar width were all significantly better in the PNAM group [32].

72.5.4 Protocols

There is no universal protocol for management of cleft lip, and there is a striking diversity of clinical practice. There is a paucity of higher-level evidence (i.e. systematic reviews and randomized controlled trials) on cleft lip and palate. There have been few RCTs comparing individual treatment steps. The Eurocleft study showed that among the 201 European centres, 194 different treatment protocols existed for unilateral clefts [33]. Listed below are some standard protocols followed worldwide.

- Rule of tens.
- IOWA Protocol [34].
- Dallas Protocol [35].
- Warsaw Protocol [36].
- Oslo Protocol [37].
- Malek Protocol [38].
- American Cleft Protocol [39].
- Australian Cleft Craniofacial Society Protocol [40].
- European Studies and results [41, 42].

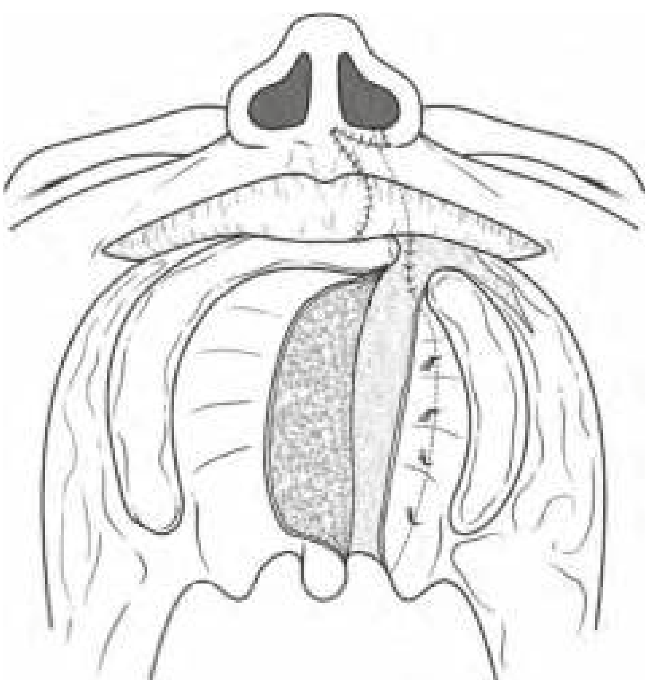
Discussion of each protocol is beyond the scope of this chapter. However, we have tried to compare and discuss in detail few protocols for a comprehensive understanding of cleft lip and palate repair

The basic protocols of cleft lip repair can also be classified as follows:

1. Primary cleft lip repair.
2. Primary cleft lip and anterior palate repair.
3. Primary cleft lip and soft palate repair.
4. Primary cleft lip and palate repair.

Primary Cleft Lip Repair Only: This protocol of early lip repair at 3–4 months of age following the rule of tens is followed popularly at various centres. The author's centre also follows the same protocol. The timing of intervention has been discussed previously in the chapter.

Primary lip and anterior palate repair: was proposed by Abyholm in Oslo protocol [37]. In the first operation, cleft



©Association of Oral and Maxillofacial Surgeons of India

Fig. 72.16 Cleft lip and anterior palate repair: Veau's vomer flap (Veau. 1931). An incision was made on the medial side of the cleft along the border line between oral and nasal mucosae or in bilateral clefts, along the free edge of the vomer. A mucoperiosteal flap is raised from the vomer and turned across the cleft. The lateral edge of the cleft is incised, and the palatal mucoperiosteum is elevated, allowing the vomer flap to be put under the mucoperiosteum and fixed with mattress sutures. In the alveolar area, and in continuity with the vomer flap plasty, the nasal mucoperiosteum is mobilised on both sides and joined across the cleft to complete the nasal floor anterior to the vomer flap. Towards the oral cavity, the raw surfaces of the vomer and of the flap are left uncovered

lip repair using Millard technique with simultaneous anterior hard palate closure using a single layer vomer flap. The mean age for first surgery was 3.3 months. The soft palate was closed at a mean age of 17.2 months (Fig. 72.16).

Primary lip and soft palate repair: It is a well-established early palatal closure which causes maxillary hypoplasia. Because of this reason, many surgeons used to perform palate repair in two stages, i.e. soft palate first followed by hard palate. At the time of introduction of this protocol, the soft palate was repaired along with the lip at around 4–6 months of age, and the hard palate was repaired at the age of 10–12 years. This was later reduced to 4–5 years.

Complete Lip and Palate Repair: one-stage simultaneous repair of the entire cleft is a simple and economic treatment of complete unilateral cleft lip and palate [43]. The concept of one-stage repair was first introduced in 1958, when Farina (1958) described the surgical technique. A decreased risk associated with general anaesthesia, better healing, lower incidence of fistulae and reduced hospitalization costs has been the rationale for performing such repair. This repair performed in children above 10 months of age has been claimed by surgeons with extremely good results without any complications. Overall, the cleft teams from Brussels, Belgium; Konya and Zonguldak, Turkey; and Warsaw, Poland, found that their protocols employing one-stage closure of UCLP produced favourable morphological results [36, 37, 44, 45].

72.6 Unilateral Cleft Lip Repair

72.6.1 Techniques of Cleft Lip Repair

The evolution of cleft repair was bound to happen mainly due to the nature of the aesthetics that had to consider the anatomical parameters, namely:

(a) Cupid's bow.
(b) White roll continuity.
(c) Vermillion continuity.
(d) Muscle continuity.
(e) Philtral columns and equality of length on both cleft and non-cleft sides.
(f) Minimizing scarring on the anatomical unit of the lip, i.e. philtral column, philtral dimple and nasal base.

Broadly over the period of cleft history, lip repair can be divided into three basic types depending on the design of flap used (Fig. 72.17). These are straight line repairs (Box 72.4), geometric flap repairs (Box 72.5) and rotation-advancement flap.

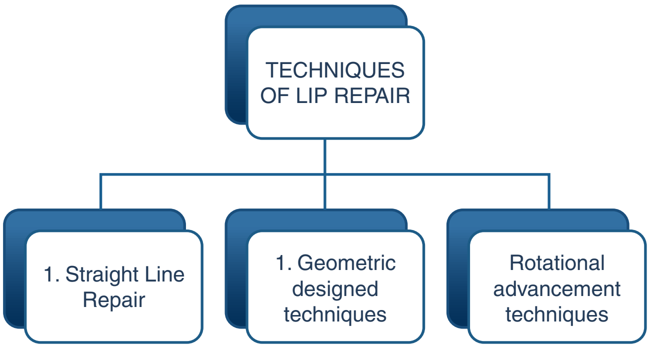


Fig. 72.17 Basic techniques of lip repair

Millard's Rotation-Advancement Flap.

Ralph Millard (1957) [2] revolutionized the cleft repair technique with most of its principles applicable and widely used in current day practice. His innovation was in designing the incisions without disrupting the aesthetic subunits. The cut as you go technique was simplified further by understanding the anatomy of the lip. He realized that two thirds of the Cupid's bow, complete with tubercle, white roll of the mucocutaneous junction, one column and the dimple of the philtrum, were all present in the non-cleft side but askew and thus had to be rotated down to normal position [60].

72.6.1.1 Basic Components of Millard's Repair (Video 72.1)

Labelling of the Flaps

A—Non-cleft side (with Cupid's bow and dimple—rotation). In Millard's original description, the incision for the rotation flap begins at the peak of the Cupid's bow [cleft side], marked along the cleft edge up to the junction with the columella, and curves under the base, crossing the midline, but doesn't cross the contralateral philtral column. Millard later added a back cut at the end of the incision, to allow for adequate rotation of the medial lip element and less tension on the repair [61, 62].

B—Cleft side (advancement).

The incision on the lateral lip element of cleft forms the advancement flap. It is made along the cleft edge, extending up to the nasal floor. This incision should match the length of the incision on the medial side of the cleft.

C—A small triangular flap attached to the columella from the non-cleft side left after the incision.

72.6.1.2 Points Marked: The Following Points are Marked in a Classic Millard's Technique (Fig. 72.18a, b)

1. Deepest point on the Cupid's bow.
2. Bow peak on the non-cleft side (distance usually 4 mm).
3. Bow peak on the cleft side (equal to distance between point 1 and 2 from point 1).
4. The alar base on normal side.
5. Final extent of the incision following a rotational curve, skirting the columella-lip junction and extending past the midline of columella base almost as far as the philtrum column on the normal side but no farther.
6. Commissure of the lip on the non-cleft side.
7. Commissure of the lip on the cleft side.
8. Equidistant point from 6 to 2 marked on the mucocutaneous junction (usually 20 mm), and distance between 10 and 8 is equal to 4 and 2.

   The vertical distance from the alar base on the normal side 4 to the height of the non-cleft peak of the bow 2 gives the distance that must be matched ultimately on the cleft side from its alar base 10 to its peak 8 (usually around 10 mm).
9. Most medial point or leading point of the advancement flap.
10. The alar base on the cleft side.

Despite being seemingly complicated, a simple exercise of carrying out the points over an illustration of complete cleft lip shall allow the reader to completely understand the simplicity of the description (Fig. 72.19). Complete surgical technique of Millard's cleft lip repair with the author's modification is discussed later in this chapter.

Once the markings are made, the rotation and advancement flaps are designed. The basic aim is to achieve symmetry of the philtral columns. This can be achieved by the following methods in a Millard's repair:

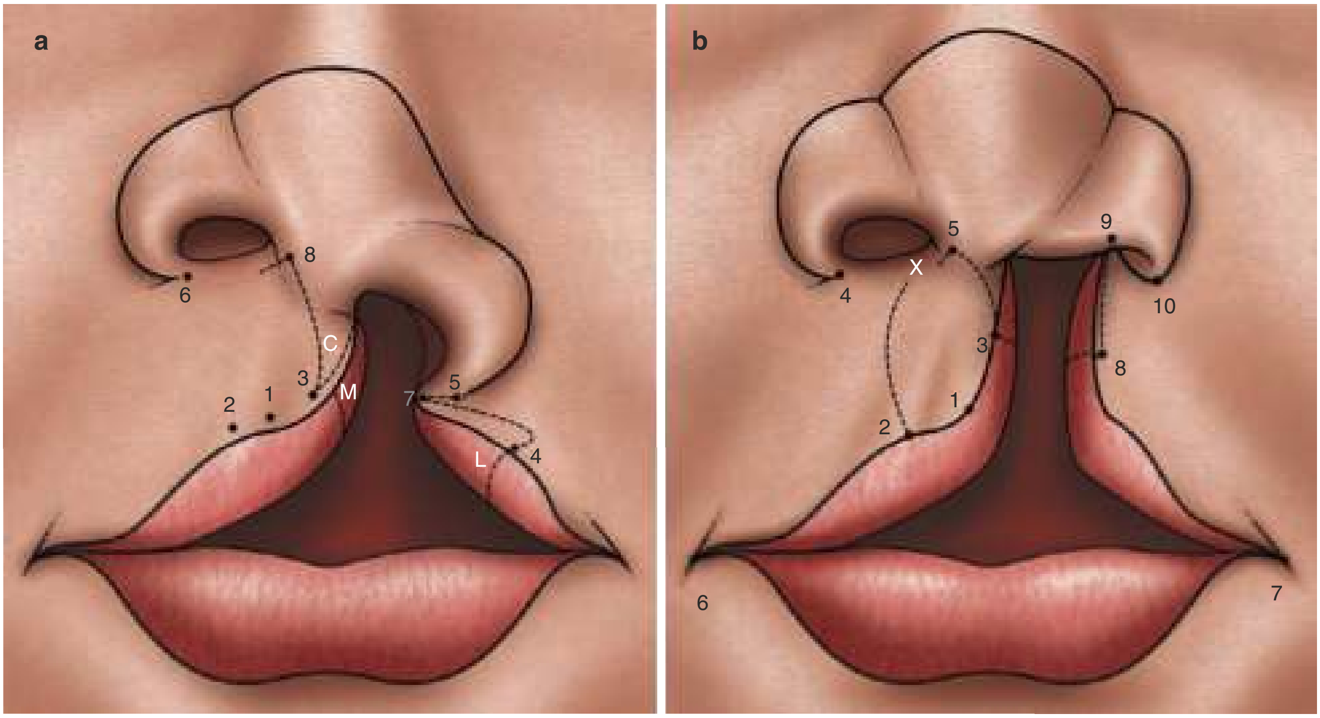

Fig. 72.18 (**a**, **b**) Basic design of Millard's technique

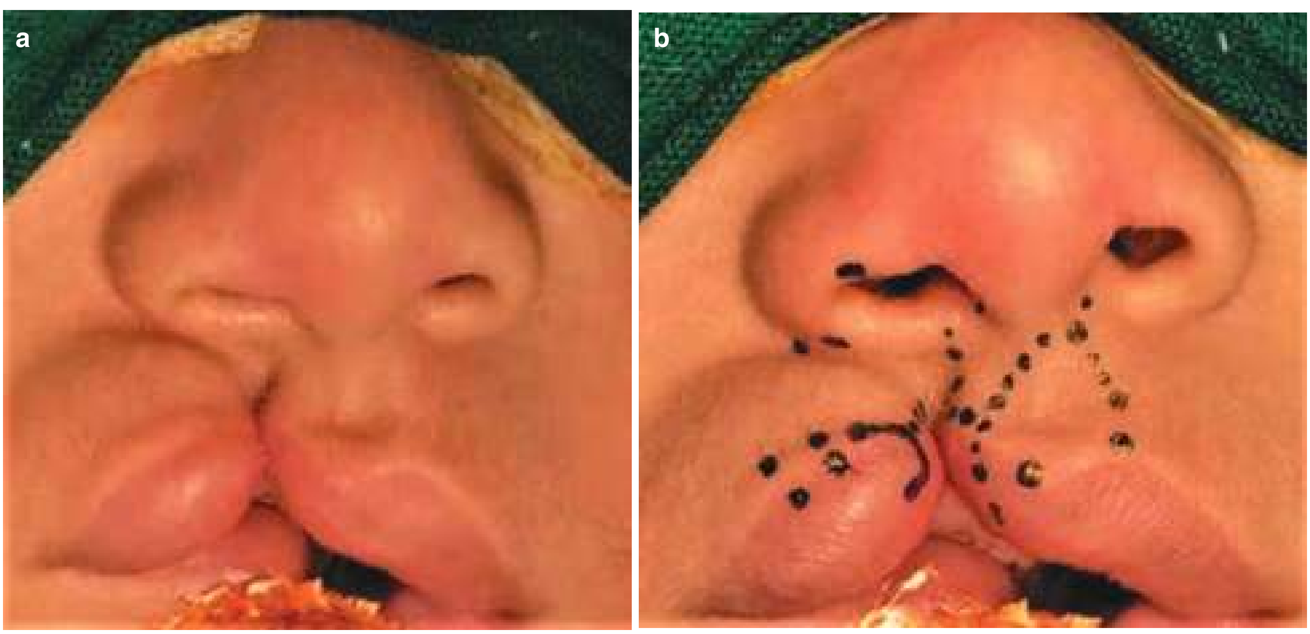

Fig. 72.19 (**a**, **b**) Marking of incisions

1. Curve the incision on the rotation side; this helps in gaining length on the cleft side philtral column.
2. Back cut: The role of the back cut comes into force when the rotation is not adequate to provide enough length to match the normal philtral column. It can be made to cross the midline or made parallel to the normal side philtral column as in Mohler's modification.
3. Role of "C" flap: The "C" flap can be designed to accomplish either of the following goals: closure of nasal sill, columellar lengthening or back into the defect created by rotation of the flap [63].

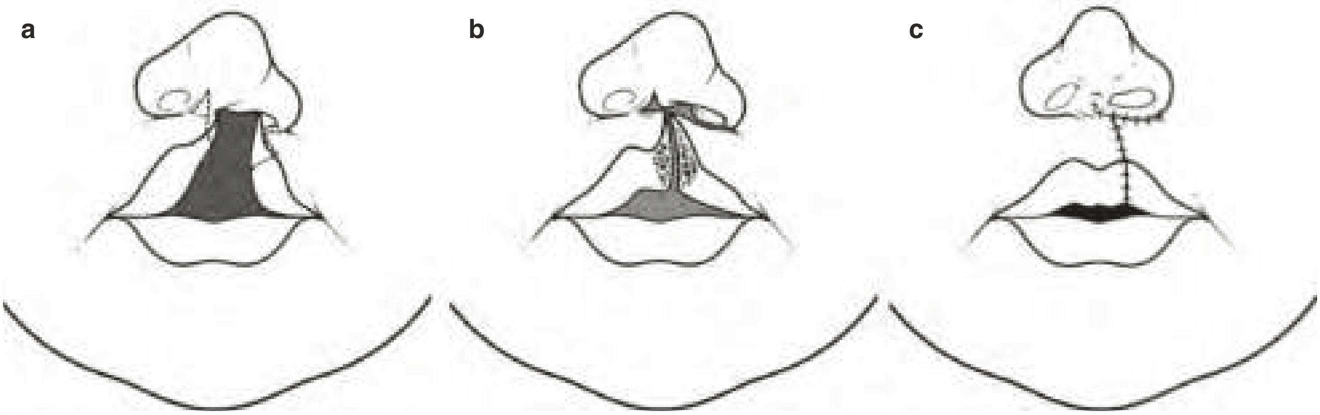

Fig. 72.20 (**a**–**c**) Mohler's modification of Millard's technique

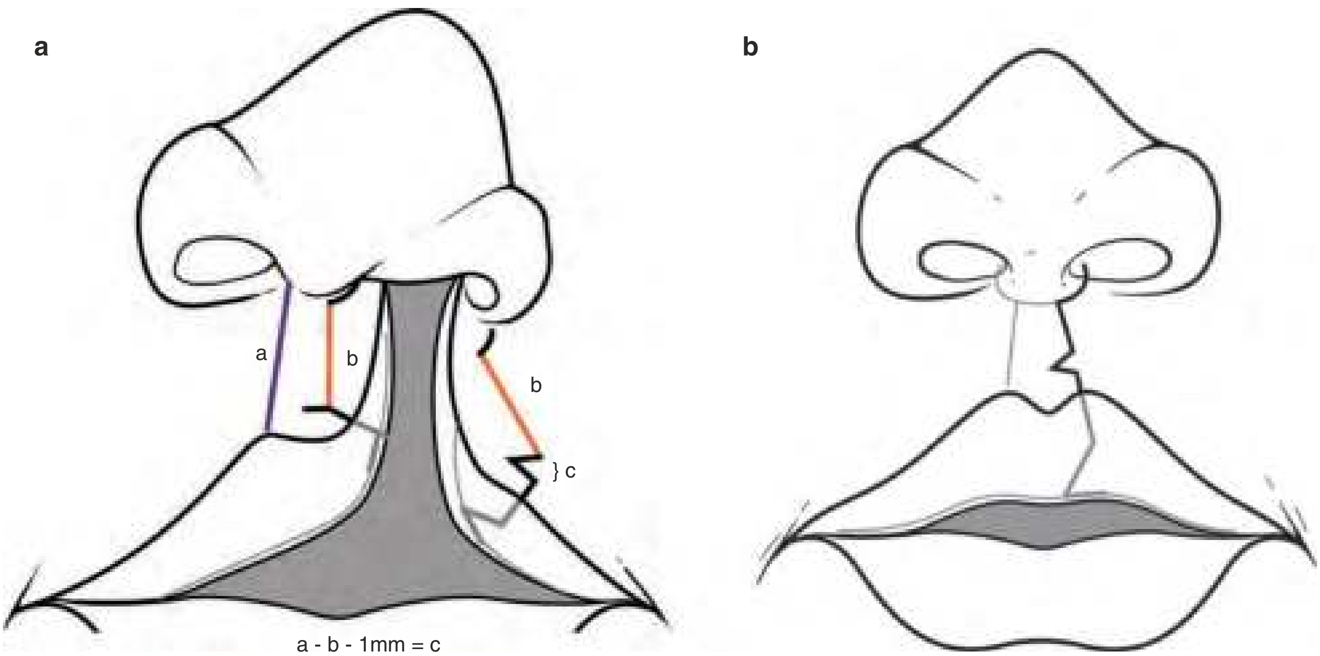

Fig. 72.21 (**a**, **b**) Fischer's modification

72.6.1.3 Modifications to Millard's Technique

In the original Millard's technique, the advancement flap often disrupts the upper third of the cleft side philtral column. Also, in wider clefts the advancement flap results in an unaesthetic scar around the alar base. This led to a series of modifications to the conventional Millard's rotational advancement technique:

External Scar Placement

1. *Mohler (1987)* [64]: The medial lip rotation incision was modified to extend onto the columella. The back cut was added which was confined to the columella. The C flap is used to fill the defect created by rotating the medial lip element at the base of the columella. Thus it is used for lengthening the shortened columella (Fig. 72.20).
2. *Fisher (2005)* [65] merged techniques of the Tennison triangle repair and rotation-advancement from Millard. It uses a small triangle above the white roll at the outset and avoids the use of rotation incision allowing most scar to be placed along the ideal philtral column (Fig. 72.21a, b).
3. *Vermilion Repair/Noordhoff's* [66] technique:

   In Noordhoff's words the essential features of this technique are as follows:

   (a) No dissection over the maxillary base.
   (b) No "back cuts" in rotation flap.

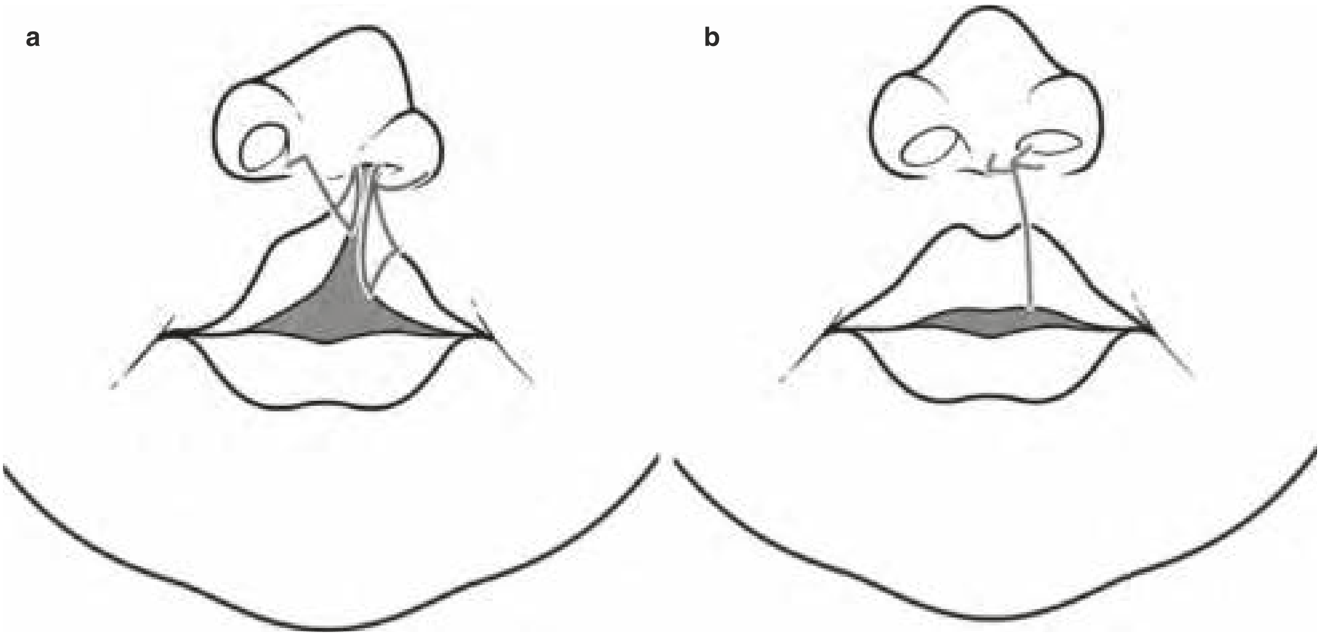

Fig. 72.22 (**a**, **b**) Cutting's modification

   (c) In cases where the rotation is inadequate, the use of a small triangular flap of the skin above the "white roll" will be used to achieve adequate rotation without distorting the philtral column. These flaps heal well and are aesthetic.
   (d) A lateral vermilion flap used for reconstruction of deficient vermilion on the cleft side Cupid's bow.
   (e) Muscle reconstruction.
   (f) Complete closure of mucosa of all areas using inferior turbinate mucosal flap that allows for repositioning of the lower lateral cartilage and adds mucosa wherever there is a deficiency.
   (g) Fixation of the lower lateral cartilage to the upper lateral cartilage at its base and to the skin with alar transfixion sutures.
   (h) Delayed upper limb rotation-advancement incisions limiting scars around the ala and nostril floor.
   (i) The alar groove should be defined well.
   (j) Postoperative splinting with a nasal silicone conformer to limit wound contracture.
4. *Columella Flap/Cutting* Repair: Cutting uses a technique that does not curve the incision towards the cleft and extends up onto the columella 1.5 to 2.0 mm slightly to the non-cleft side [67]. This yields a wider C flap thus filling the entire medial defect, allowing for a straight line closure (Fig. 72.22a, b).
5. *Muscle Repair*:
   The following modifications have been made in muscle repair:
   (a) *Cutting* [67]: Interposition orbicularis muscle repair.
   (b) *Mulliken* [68]: Vertical mattress sutures for end-to-end muscle repair to evert the orbicularis.
   (c) *Fischer* [65]: On both medial and lateral cleft elements, dissection of the overlying skin from the orbicularis. Dissection on the medial lip is limited to 1 mm from cut edge whereas of the lateral lip extends to the alar base to eliminate orbicularis bulge.

72.6.2 Step-by-Step Technique of Unilateral Cleft Lip Repair: Author's Technique (Figs. 72.23, 72.24, 72.25, 72.26, 72.27, 72.28, 72.29, 72.30, 72.31, 72.32, 72.33 and 72.34)

Lip Repair:

The authors have presented their technique of lip repair in a stepwise manner.

The following steps have been described:

- Markings: The most important principle of cleft lip repair is to identify the normal and abnormal structures. This includes the length of the philtral columns and the width of wet and dry mucosa. All the soft tissues should be kept in mind while designing the flap. No soft tissue should be discarded or considered redundant.

  Non-Cleft Side.

  Deepest point on cupid's bow, peak on non-cleft side and normal philtral column. (To make the philtral column prominent, one may use a two-pronged nasal hook to pull and retract the columella.)

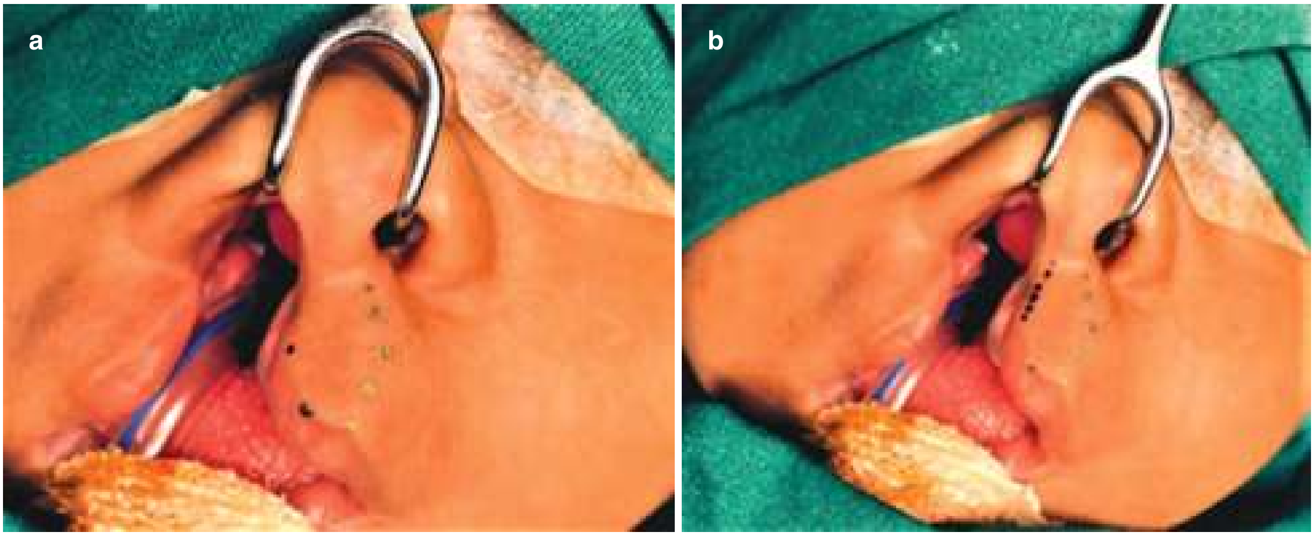

Fig. 72.23 (**a**) Mark the highest point on the Cupid's bow (cleft side), and also notice the philtral dimple. (**b**) Mark the future philtral column, and continue it up to the columella without cutting across the columella

Fig. 72.24 From the peak of Cupid's bow on the cleft side, mark the incision on the dry mucosa till the junction of wet and dry mucosa

Fig. 72.25 *Marking of C flap*: A triangular flap between the mucosa and the future philtral column

- Mark the highest point on the Cupid's bow (cleft side), and also notice the philtral dimple (Fig. 72.23a).
- Mark the future philtral column, and continue it up to the columella without cutting across the columella (Fig. 72.23b).
- At this point the surgeon should compare the mark with the philtral column on the normal side. It might appear shorter; however, it will increase in length once the muscle is dissected from the abnormal attachment. The back cut discussed previously is used for adequate rotation of the cleft side philtral column. The back cut should be made after the muscle closure.
- From the peak of Cupid's bow on the cleft side, mark the incision on the dry mucosa till the junction of wet and dry mucosa (Fig. 72.24).
- Marking of C Flap: A triangular flap between the mucosa and the future philtral column. Continue between the skin

Fig. 72.26 M flap: The mucosal element on the non-cleft segment after raising the C flap becomes the M flap and is raised to expose the underlying muscle

Fig. 72.27 On the side of the cleft, mark the point B. From the B point, extend the incision along the mucocutaneous junction till point D. From point D, marking goes into the nose to separate the nasal mucosa and the skin [D1]

and mucosa junction down to the mucosa to keep enough mucosa for nasal layer closure (Fig. 72.25).

- C flap originally described by Millard was used to augment the lateral lip at the insertion of alar base. We use the C flap either to create the nasal sill or if a back cut is given; it can be used to reconstruct the columella-lip junction.
- M Flap: The mucosal element on the non-cleft segment after raising the C flap becomes the M flap and is raised to expose the underlying muscle (Fig. 72.26).
- Rotational Flap: The muscle is now exposed, and the preparation of the lateral element can be divided into three easy steps:
- Oral mucosal layer: Separation of this layer from the muscle bulk can be identified with the plane where the minor salivary glands exist. Bleeding is generally encountered in this plane and should be managed early to reduce blood loss and keep a good plane of dissection.
- Skin-muscle dissection: The incision between this plane is to ensure just adequate separation to provide room for suturing the muscle bulk. Overexposing the muscle not only leads to excessive swelling postoperatively but also distorts the natural anatomical curves of the non-cleft element. On the cleft side, only 1–2 mm of subdermal dissection should be done. Closure of the skin later reinforced by the underlying muscle gives better elevation of the future philtral column as compared to overzealous separation of the muscle from the overlying skin.
- Release of abnormal muscle attachment: The abnormal attachments are usually near the alveolus and the base of the columella. At this point blunt dissection can be done to straighten out the septum.

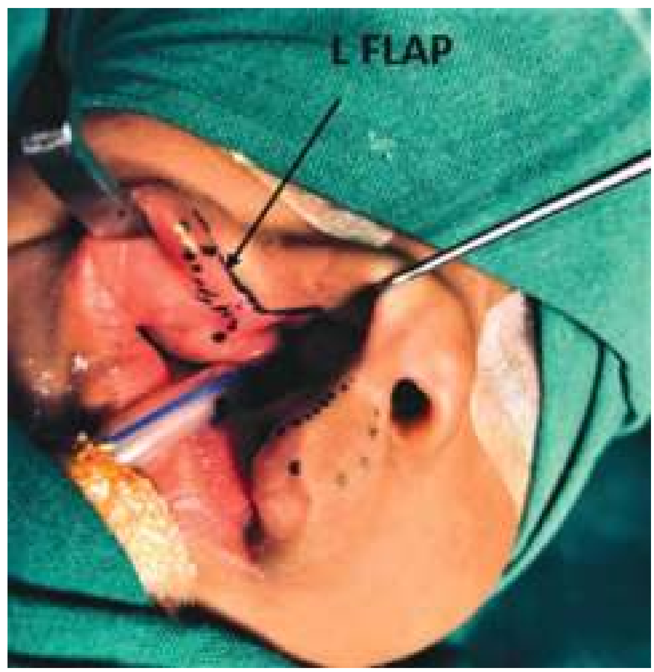

Fig. 72.28 Marking of L flap

Cleft Side:

- On the side of the cleft, mark the point B. First identify the white roll, and look for the point where the white roll starts to diminish; that is the exact point to join the Cupid's bow. Drop an imaginary line from this point to the junction of dry and wet mucosa. The maximum mucosal width is present at this point.

Fig. 72.29 Incision starts from the deepest point of the Cupid's bow till the columella base. The plane of dissection is just above the muscle

Fig. 72.30 Nasal layers are now sutured from both the cleft and non-cleft sides and sutured using a 4.0 Vicryl

- From the B point, extend the incision along the mucocutaneous junction till point D. Point D is a point at the edge of the lip at the junction of the skin and mucosa. From point D, marking goes into the nose to separate the nasal mucosa and the skin (Fig. 72.27).
- After marking the L flap, the incision is continued down to the alveolus, to free the abnormal muscle attachment at the base of the alveolus. In a classic Millard's technique, additional incision is given into the vestibule on the cleft side to get adequate mobilization of the advancement flap and medicalization of the cleft side alar base for nasal sill closure. Few surgeons also advocate subperiosteal or supraperiosteal dissection, through the intraoral incision at the pyriform region. However, in the author's experience, the need for this vestibular incision is not always necessary. An "L" flap can be designed from the mucosa of the cleft side as shown in the figure. This flap is continued upwards into the nasal mucosa and not towards the alveolar mucosa. The importance of this lies in the fact that, once harvested, the flap is retracted upwards into the nasal base and is thus used for closure of nasal sill. Moreover, due to this upward pull, the abnormal alar base attachment that leads to flattening of the alar rim is corrected. Thus, it helps in reducing the nasal symmetry (Fig. 72.28).
- Incision starts from the deepest point of the Cupid's bow till the columella base. The plane of dissection is just above the muscle. On the mucosa the incision continues till the junction of the dry and wet mucosa to expose the muscle. Insert a skin hook which will stretch the lip and aid in further dissection. *Note*: The superior labial artery can be encountered at this point and may need cauterization (Fig. 72.29).
- Begin the incision from the point where the white roll diminishes, and carry it along the marking between the skin and mucosa to reach the junction between the nasal skin and mucosa.
- A small mucosal triangle containing the dark mucosa is maintained, and incision is then carried out to raise the L flap.
- Once the L flap is raised, the muscle of the cleft side element is exposed.
- Incision is made between the mucosa and muscle similar to the non-cleft side in the plane of existing minor salivary glands.
- The incision between the skin and muscle is similar to the lateral element.
- The abnormal muscle attachments on this side are at the base of the alar and the pyriform region that would require subperiosteal dissection to release the attachment.
- *Insertion of Flaps and Suturing*.
- The final step of closing the flaps into desired position begins with insetting the L and M flaps.
- *Step 1*
- Using the M flap is optional. The author generally discards the M flap but occasional uses it to reduce tension while doing the nasal floor repair in very wide clefts.
- The L flap is used to create the nasal layer on the cleft side by lining it between the nasal skin and the nasal floor.
- *Step 2*
- *Creating the Nasal Floor*: Nasal layers are now sutured from both the cleft and non-cleft sides and sutured using a 4.0 Vicryl (Fig. 72.30).
- At this point of time, the septum is exposed. When the nasal layer is being raised, if required the septum can be straightened.
- *Step 3*

- *Suturing the Oral Mucosa*: Begin at the point where the wet and dry mucosae meet. The alignment of these two points from both elements is crucial for good mucosal repair. The rest is completed till the alveolar base. The suture material used here is 4.0 Vicryl. The dry mucosa will be closed last (Fig. 72.31).
- *Muscle Suturing*: The preference is to suture the muscle at the junction of white roll and Cupid's bow. The suture allows reassessment of adequate rotation of the flap to create equal length of the philtral columns. A back cut can now be placed to accommodate for discrepancies. The back cut is made parallel to the existing philtral column at the base of the columella.
- Muscle layer suturing is then completed carefully reorienting the fibres at equal height and bites from both elements. At this stage the lip anatomy should correspond to final anatomy, and the skin should be passively seated over the muscle layer. The suturing is completed using 4.0 Vicryl, and the knots are cut flush to prevent any extrusion of sutures on the skin surface (Fig. 72.32).
- *Skin Suturing*: The first step in suturing the skin is to evaluate the area where the C flap is going to be utilized and also the dimension of the flap needed. The excess flap can be trimmed or in some instances completely discarded (Fig. 72.33a).
- The preference of the C flap is to use it as a hemi-columella or nasal sil. Using the C flap into the back cut defect creates an unnatural scar across the cutaneous lip and columella junction.
- Once the C flap is tucked beneath the skin, excess skin tissue if any is trimmed, and suturing begins from the base of the columella down to the vermilion. The suture

Fig. 72.31 Suturing of the oral mucosa

Fig. 72.32 Muscle suturing

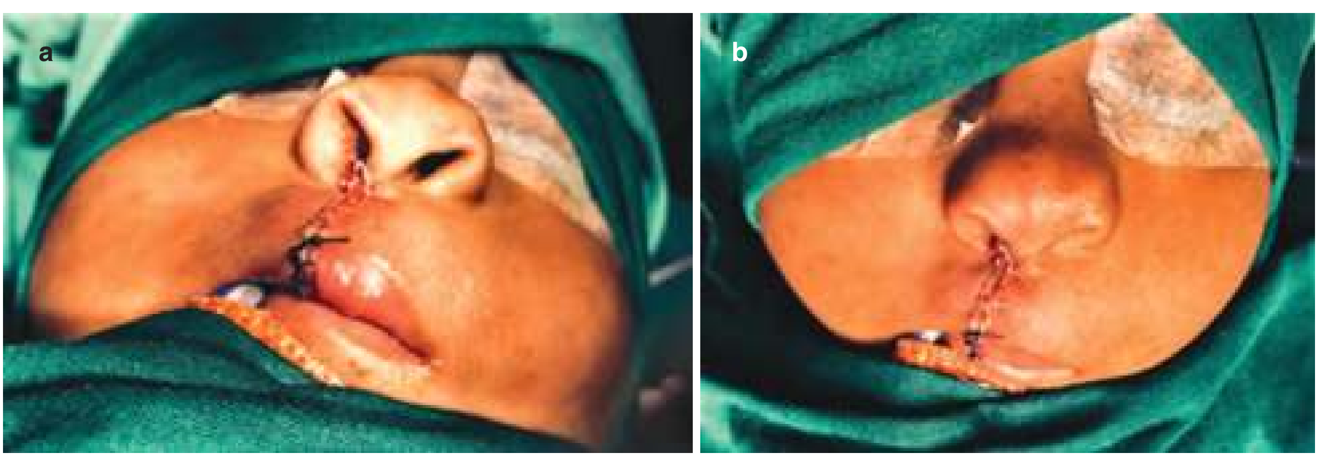

Fig. 72.33 (**a**) Skin suturing. (**b**) Note the matching of the white roll

Fig. 72.34 Dry mucosa suturing

used here is 5.0 Vicryl Rapide or 6.0 Vicryl Rapide (Fig. 72.33b).

- *Dry Mucosa Suturing*: At the end of skin suturing, the vermilion continuity is established by using the V-shaped mucosal flap established from the cleft segment tucked into the non-cleft mucosa. At this stage care should be taken to secure a suture beneath the vermilion for muscle repair, and the mucosal stitch should be passive to reduce necrosis of the mucosal tip (Fig. 72.34).
- A good repair depends upon minimal handling of the tissues and a tension-free closure of all layers especially the skin as the muscle bears the stress of tension forces.

72.7 Bilateral Lip Repair

James Barrett Brown said "Bilateral clefts are twice as hard as unilateral clefts, and the results are less than half as good" [69]. Bilateral cleft lip repair can be one-stage or two-stage. Proponents of one-stage repair stress on creating a symmetric, balanced lip. This is indicated in cases of complete or incomplete symmetric bilateral clefts or where the premaxilla is within the arch. Two-stage repair is indicated in the presence of a small prolabium, an asymmetric cleft or a protruded premaxilla. Proponents of two-stage repair advocate this technique for conversion of a bilateral into unilateral cleft, to encourage the growth of prolabium and to avoid excessive lip tension. In earlier techniques of bilateral lip repair, excision of the prolabium was made mistakenly assuming it to be a displaced columella. This was because surgeons failed to recognize the potential of the prolabium to grow in width and height when attached to the dynamic lateral lip elements.

Principles of Bilateral Cleft Lip Repair: Certain key points and landmarks need to be kept in mind while considering a bilateral cleft lip repair. The following principles of bilateral cleft lip repair should be adhered to:

1. Symmetry must be established. In case of staged repairs, this is hindered which lead to asymmetrical results.
2. The surgeon should anticipate a fourth dimensional changes that occur with growth. Failure to account for this may result in a widened philtrum. This is attributable to slower-growing areas such as the lengthening columella and projection of the nasal tip, compared with faster-growing areas such as the philtral width [70] Thus, there is a need to undercorrect fast-growing areas and overcorrect the slow-growing structures.
3. Prolabium: No matter how small it is, the prolabium is always sufficient for reconstruction. It should always be used for reconstruction of the midportion and not used for partial reconstruction of the philtrum and columella. When white line is present in the prolabium, it must be used, however, a short prolabium pulls down nasal tip creating a secondary nasal deformity.
4. Premaxilla: Presurgical orthopaedic treatment should be done only to expand the maxillary segments. Closure and joining the muscle at the midline create enough pressure to retroposition the protruding premaxilla. Sometimes, resection of the vomer behind the vomerine-premaxillary suture can be done, and the premaxilla can be repositioned using plating or K-wire with or without bone graft.
5. Vermillion: There is a very narrow strip of vermillion present in a bilateral cleft lip. A vermillion flap from lateral lip elements should be taken for fullness and protrusion of the lip.
6. Muscle repair: As the prolabium is without muscle fibres, muscle continuity under the prolabium is necessary for a functional lip. There is a need to release the abnormal attachment at the base of the ala from the vertical to horizontal and functional attachment.
7. The nasal deformity can be addressed either primarily or secondarily.

72.7.1 Techniques of Bilateral Cleft Lip Repair (Video 72.2)

72.7.1.1 Straight Line Repair

Bardach used a straight line repair. The prolabium was used for the entire central portion of the lip. This caused a problem in case of a short prolabium or a protruded premaxilla [71]. Salyer also used a straight line repair. In his repair, no tissue is discarded, the entire prolabium is lengthened and philtral and skin flaps are used for vestibular lining [72].

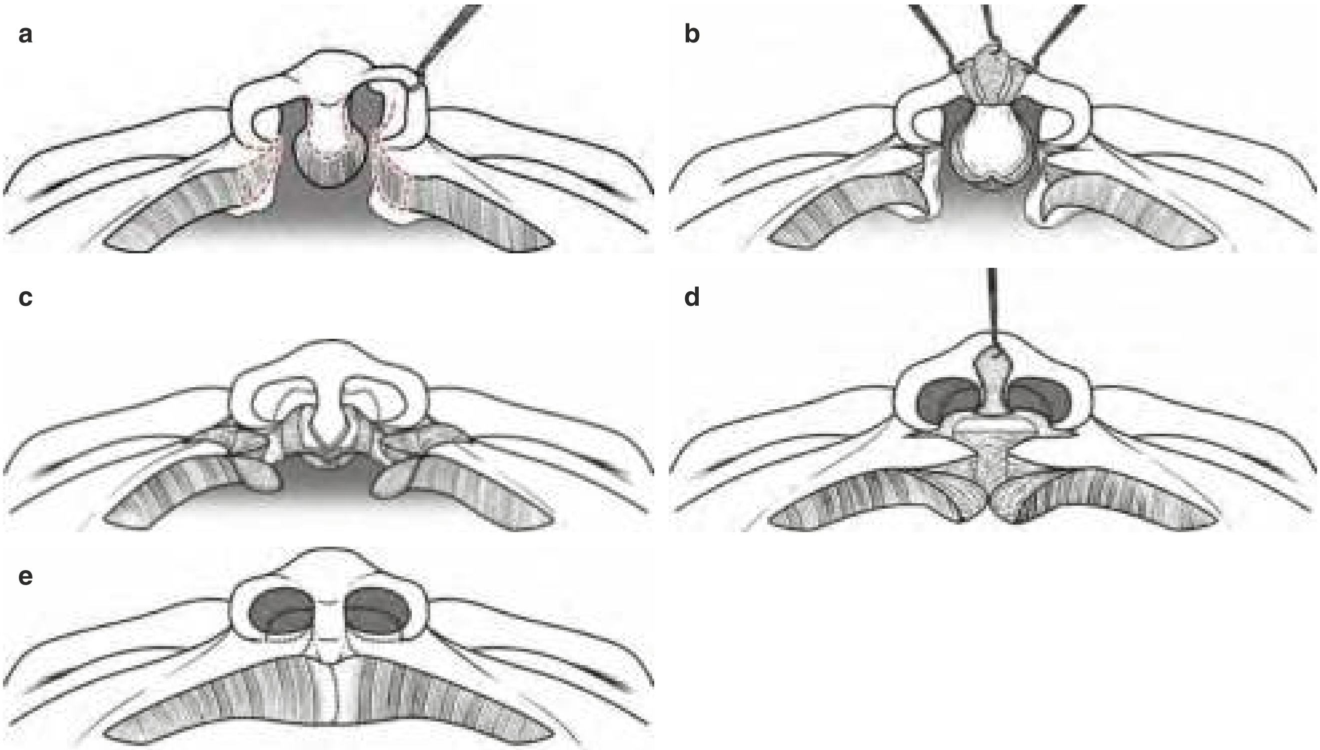

Fig. 72.35 (**a**–**e**) Millard's technique of bilateral lip repair

72.7.1.2 Millard's Repair

Millard's repair allowed rotation of the Cupid's bow with the gap filled from skin advanced from the lateral element [73]. It allowed complete elevation of the prolabium and suturing of the orbicularis across the premaxilla. In addition, Millard created lateral segments of the prolabium as "forked flaps". These flaps were banked to add columellar height at a later stage, thus addressing the vertical height deficiency, and it also corrected the wide alar bases (Fig. 72.35a–e). The key elements of bilateral lip repair are given in Box 72.6.

72.7.1.3 Mulliken's Repair

Mulliken designed a narrow prolabial flap with slightly concave sides; 2; 2.5 mm at base and 3.5–4 mm between Cupid s bow peak. The surgical stratagem is symmetrical labial repair and synchronous anatomic positioning of the alar cartilages with sculpturing/draping of the nasal soft tissues. It consists of following elements:

- Suture of the orbicularis oris in the midline.
- Fixation to anterior nasal spine.
- Positioning dislocated lower lateral cartilages: interdomal suture.
- Suspension over ipsilateral upper lateral cartilage with intercartilaginous suture.
- Suture of the orbicularis oris in the midline.
- Fixation to the anterior nasal spine.
- Positioning dislocated lower lateral cartilages: interdomal suture.
- Suspension over the ipsilateral upper lateral cartilage with intercartilaginous suture.

Box 72.6 Key Elements of Bilateral Lip Repair
- Bringing in a new white roll from the lateral lip elements.
- The prolabium parings are banked for future columella lengthening.
- Bringing lateral vermilion flaps beneath the prolabium.
- Reconstructing the orbicularis muscle beneath the elevated prolabium.

72.7.2 Bilateral Lip Repair: Author's Technique

Markings: Fig. 72.36 shows the marking of the prolabial flap and the lateral flaps.

- Once all incisions are designed, the lip is infiltrated with 1:100.000 epinephrine. We can start with either the prolabium or lateral flaps. Grab the lip between fingers for better control during incision and bloodless field.

- Incision starts on the prolabium following the previous markings, the medial flap is for philtral reconstruction, and two laterals segments of the skin are discarded (Fig. 72.37a).
- The philtral flap is dissected, leaving a generous amount of deeper soft tissues attached. The flap is raised in a pre-periosteal plane off the premaxilla and up to the base of the columella (Fig. 72.37b).
- Next step is creation of mucosal flap from the prolabium for sulcus reconstruction and exposure of anterior nasal spine.
- Incision in lateral lip following the marks in the skin and mucosa of the vermillion is made (Fig. 72.38).
- Incision is carried on the vermilion-cutaneous junction, dissecting the vermilion to the point where the peak of the Cupid's bow is marked.
- Full thickness cuts are made through the orbicularis oris and the oral mucosa of the upper lip.
- Incision in the sulcus to aid in the detachment of the abnormal lateral lip element, especially the muscle.
- Those incisions facilitate mobilization of the lateral lip elements so they can be brought up and over the premaxilla which aids in decreasing tension.

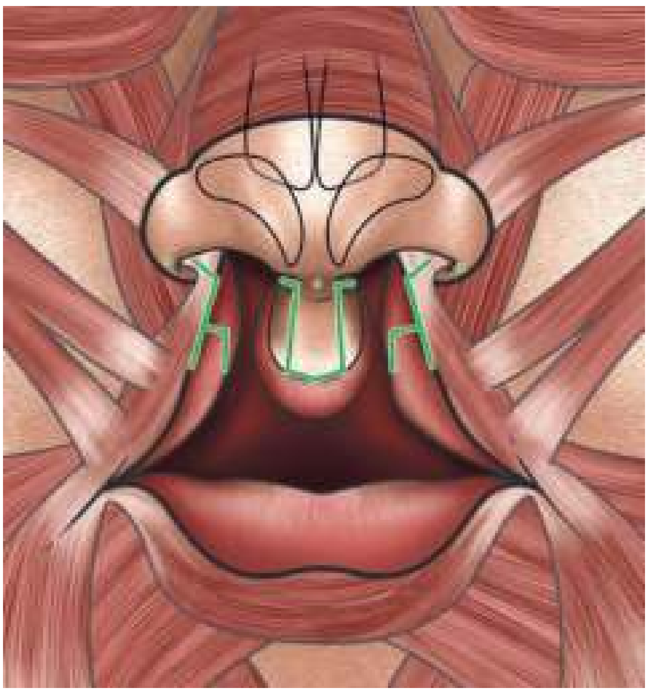

Fig. 72.36 Markings for bilateral lip repair

Fig. 72.38 Dissection of the lateral flaps

Fig. 72.37 (**a**) Marking of the prolabium flap and lateral flap. (**b**) The prolabium flap dissected

- The muscle is dissected as a separate layer from the mucosa not from the skin. Undermining of the soft tissue, dissection and release are carried up to the inferior orbital nerve.
- Subperiosteal dissection of the pyriform aperture towards the frontomaxillary pillar, to release the ala from its abnormal insertions.

Release and repositioning of the following structures from their abnormal attachment:

- Alar base.
- Muscular, ligamentous and lining attachments.
- Fibrous attachments with the accessory chain of the lateral crus.
- Full-thickness cut is made along the nasal lining at the pyriform aperture. This release creates a lining defect that will be filled with the septal flap.
- Dissection of mucoperiosteal flap from lateral nasal wall.
- Liberation of the orbicularis oris, freeing it from its abnormal attachment around the base of the nose.
- Reposition of the orbicularis from vertical to horizontal position with retrograde dissection without dissection of the muscle and the skin in the free border.

Suturing

(a) Nasal Floor

- Mucoperiosteal flap from lateral nasal wall and mucoperichondrial flap from the nasal septum are sutured to form the nasal floor. This helps to bring the base of the ala medially, thus narrowing the width of the nostril.

(b) Recreating the Sulcus

- Advance prolabial mucosal flap superiorly to establish the lining of the labial sulcus, trimmed as needed, and fixing it to the periosteum inferiorly to the nasal spine.
- Medial advancing of mucosal flaps and fixation to the mucosal flap of the prolabium, previously fixed. Then they are sutured together in the middle line from inferior to superior, starting in the red line (key stitch).

(c) Muscle Repair

- Medial advanced musculocutaneous flaps from the lateral lips.
- Muscle is brought across the midline below the prolabium.
- Apposition of the muscle is done from distal (key stitch) to proximal area (Fig. 72.39).
- Proximal segment fixed to the periosteum of the anterior nasal spine in the middle line.

(d) Vermillion Repair

- The midportion of the vermilion is reconstructed by bringing lateral vermilion flaps below the philtrum flap (Fig. 72.40).

Fig. 72.39 Lateral flaps sutured beneath the prolabium. Muscle sutured to create the continuity

Fig. 72.40 Position of the prolabium to create the future philtral column

(e) Skin

- Preventing or minimizing lip tension is the key to successful bilateral cleft repair (Fig. 72.41).
- Excessive tension: tethering of the columella, increased scarring and facial growth problems.
- Attention is given to construction of the Cupid's bow.

Fig. 72.41 Skin suturing done

72.8 Primary Chielorhinoplasty

A variety of options exists to address the nasal deformity with cleft lip. These include preoperative nasoalveolar moulding, overcorrection of the nostril width and alar cartilage at the time of lip repair and postoperative use of nasal conformers. Primary treatment of the nose at the time of lip repair has become popular, in order to gain early restoration of the symmetry by repositioning the alar cartilage and lengthening the columella. However, relapse is frequent due to the elastic deformed alar cartilage. Various theories and opinions have been popularized regarding correction of the septum, to either straighten the septum or leave for later correction. A study done by Mancini et al. involves three-dimensional analysis of unilateral cleft lip and palate patients treated with PNAM and primary rhinoplasty, which demonstrated significant improvements in nasal projection, columellar length, nasal symmetry and nasal width [74].

72.9 Postoperative Wound Care and Outcome Assessment

Postoperative wound care is extremely important in determining the results of lip repair and is often a factor resulting in the need of a lip revision.

1. Suture area should be cleaned daily with saline and baby soap twice; topical application of antibiotics is recommended for 10 days.
2. 3 weeks post-op, we recommend to massage the scar towards the mucosa to prevent scar contracture.
3. Massage can be done with vitamin E cream/silicone gel/oil. It is recommended to massage for at least 6 months.

72.9.1 Outcomes

Improper surgical technique and tissue dissection can lead to certain undesirable outcomes. Other factors such as wide deformities, severely displaced premaxilla, inadequate postoperative care, poor healing and infection can also lead to aesthetic results. Understanding the process and severity of the outcome helps in addressing the problem in secondary lip repair or lip scar revisions. The outcomes can be divided into the following types:

- Mucosal notching—As pointed above, the mucosal dissection should always be in the plane between the muscles and the mucosa plus minor salivary glands. Failure to maintain that results in a thin mucosa that inverts after suturing. This leads to mucosal notching. As a trainee, one can also give mattress sutures to achieve mucosal eversion. In case of very mild mucosal notching presenting at 3 weeks, it is advised to continue the massage. If notching persists after 6 months of lip repair, it can be treated by surgically improving placement of muscle; thus we recommend a lip revision.
- Scarring—A scar can present in various forms. A scar can be linear but hypertrophic in appearance. Such scars can be avoided if proper massaging is done in the postoperative phase. If the scar has keloid tendency, triamcinolone injections are to be given at an interval of 15 days followed by vigorous massage.
- Contracture—A scar can also present as a gross or mild vertical contracture. This usually results due to inadequate rotation, thus pulling the lip towards the nose resulting in vertical shortening of cleft side philtral column. Improper muscle closure or overzealous separation of the skin from the muscle can lead to scarring of the skin.
- Inadequate philtral column matching—This again results due to lack of a proper design and improper mobilization of the rotation flap.
- Complete breakdown of the surgical wound may be the most severe adverse outcome in the immediate post-operative phase.

72.10 Indications for Lip Revision

Scarred fibrous tissues with poor vascularity always make secondary surgery more challenging. Dissection and reapproximation of surgical landmarks are difficult in such cases. The basic surgical principles that should be followed are identification and preservation of all the vital anatomic structures.

The basic indications for a lip revision surgery are:

1. Unilateral.
   - The scar is not in line with the natural philtral column.
   - The lip length is short.
   - There is a mucosal notching.
   - There is a white roll to Cupid's bow mismatch.
   - There is a nasolabial fistula.
2. Bilateral.
   - There is a wide philtral column.
   - Mucosal notching.
   - Whistling defect.
   - No sulcus depth.

72.11 Conclusion

In our course of learning of cleft, we often understand embryology, anatomy and the surgical technique as separate concepts. In this chapter, we have tried to integrate them and tried to explain the rationale behind the surgical steps. Embryological basis of normal anatomy and then of cleft is pivotal to understand the arrangements of muscles, the vascular supply and thus the basis of incisions. We have described our surgical technique of cleft lip repair with long-term follow-ups. In the congenital deformity of cleft where there is paucity and deformation of tissues, preserving the tissues during surgery is one of the important principles of lip repair.

72.12 Case Scenarios

Figures 72.42, 72.43, 72.44, 72.45 and 72.46 represent cases of operated unilateral and bilateral cleft lip with long-term follow-ups.

Figures 72.47, 72.48, 72.49 and 72.50 represents cases of lip revisions with follow-ups.

73 Cleft Palate

P. V. Narayanan and H. S. Adenwalla

73.1 Introduction

It was Kilner who said, "Ask not for a spatula and torch to check your cleft palate repair, but listen to your patient speak." By this obvious but profound statement, he drew the cleft surgeons' attention to the fact that gone are the days of breakdowns and fistulae and that if your child does not speak well, your operation is a failure, for such a child would be out of the mainstream of life forever. In spite of the advances in technique and execution, experienced cleft surgeons all over the world still struggle to obtain perfect speech in a large percentage of cases.

In view of the obvious difficulties of intraoral surgery, it is not surprising that cleft lips were repaired way before anyone tried to repair a cleft palate. Credit for the first successful repair of a cleft palate goes to Le Monnier, a French dentist from Roven. Le Monnier in 1766 cauterized to freshen the cleft edges and sutured them successfully [1].

Cleft surgery then passed through a stormy period of uncertainty in the hands of giants like Ferdinand von Graefe [2], Roux, Dupuytren [3], Dieffenbach [4], and Warren [5]. Mucosal flaps were used, and even lateral osteotomies were tried to move the hard palate medially. In 1859, almost a hundred years after the first hard palate was repaired, von Langenbeck [6] emphasized the need to raise mucoperiosteal bipedicled flaps to repair a palate. Langenbeck procedure was a fundamental breakthrough, and with this major advance, breakdowns of the palate were reduced. In its wake refinements followed. In 1931, Victor Veau [7] parted from the bipedicled flap to single pedicled flaps based on the greater palatine vessels. Veau stressed the importance of repairing the nasal lining of the palate and the need to lengthen it.

In 1937, Kilner [8] working in Oxford and Wardill [9] working in Newcastle on Tyne independently used a four flap procedure for the complete cleft palate.

The weakness of this procedure was a high fistula rate at the junction of the four flaps. In the 1940s, Dorrance [10], Cronin [11], and others used various flaps to lengthen the palate. In 1966 Millard [12] introduced his island flaps based on the greater palatine arteries to lengthen the nasal lining. Ravin Thatte [13] went a step further and took two island flaps one for lining and one for cover and used a tongue flap on the denuded hard palate. All these procedures had their day but were short lived in popularity. However, special mention must be made of the buccal myomucosal flap originally called the cheek flap by Padgett [14]. This flap was revived 30 years later by Murari Mukherjee [15] of Calcutta. He changed the direction of the flap. Recently Ian Jackson has introduced muscle into this mucosal flap to make it more robust, and he calls it a myomucosal flap. He uses it in all his palates to lengthen the nasal lining by 1.5 cm and believes that as a result he achieves better speech. Robert Mann [16] does a Furlow's and coves the residual raw areas with two buccal flaps. His rationale is that there is deficiency of tissue in the palate and therefore, on first plastic surgical principles, bring in tissue from outside. This may become the philosophy of the future.

73.2 Embryology and Anatomy (Figs. 72.1 and 77.1)

73.2.1 Embryology

The primary palate is derived from the intermaxillary segment derived from the frontonasal and medial nasal

prominences. The main part of the definitive palate is formed by two shelf-like outgrowths from the maxillary prominences. These outgrowths, the *palatine shelves,* appear in the sixth week of development and are directed obliquely downward on each side of the tongue (Fig. 73.1a and b).

In the seventh week, however, the palatine shelves ascend to attain a horizontal position above the tongue and fuse, forming the *secondary palate* (Fig. 73.2a and b). Anteriorly, the shelves fuse with the triangular primary palate, and the *incisive foramen* is the midline landmark between the primary and secondary palates. At the same time as the palatine shelves fuse, the nasal septum grows down and joins with the cephalic aspect of the newly formed palate (Fig. 73.3a and b).

The secondary palate lies posterior to the incisive foramen and consists of the bony hard palate anteriorly and the soft palate posteriorly, terminating at the uvula. The hard palate consists of the palatine bony shelves on either side, attached to the vomer in the midline. The soft palate consists of a sandwich of muscles enveloped by oral and nasal mucosa.

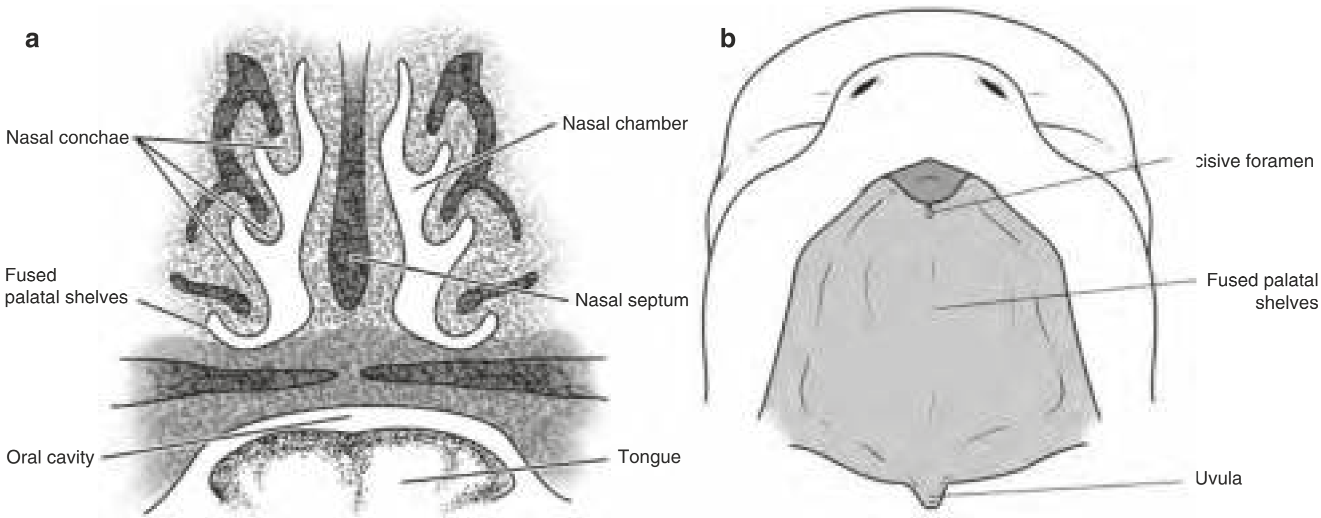

Fig. 73.3 (**a**, **b**) Embryology of palate—completion of palate

73.2.2 Muscles

The muscles of the soft palate include intrinsic muscle, i.e., musculus uvulae, and the insertions of several extrinsic muscles. Apart from this, large amount of.glandular material is present in the anterior inferior portion of the velum and an anterior aponeurosis. Extrinsic muscles of the velum include the tensor veli palatine, levator veli palatini, palatopharyngeus, palatoglossus, and fibers of the superior constrictor. Pharyngeal muscles usually described as having functional role in velopharyngeal movement include the superior constrictor and the salpingopharyngeus (Fig. 73.4).

Following is a tabular summary for the muscles of palate and their abnormal anatomy in a cleft palate (Table 73.1).

From functional standpoint, it is apparent that the levator veli palatini muscle is the principal and quite possibly the only muscle to function for elevation of the velum in speech. The differences between the normal and the cleft arrangement of the muscles of velopharyngeal closure occur because the muscles extending toward the central line of the soft palate cannot attach themselves in the midline of the velum so they insert at some substitute points. These points prevent the muscles from becoming fully functional, and therefore their development is retarded. With the preservation of normal origins, the atypical insertions and hypoplasia of the muscles are the main pathological features in the cleft palate. The abnormal insertions of levators in clefts illustrate that the function of these muscles in cleft palate is almost opposite to that in normal one. While the muscles of both sides normally join in the raphe to form a sling lifting the palate upward, in cleft palate each muscle pulls its own half of the soft palate in an entirely different direction, i.e., superolaterally, causing further widening of the cleft.

73.2.3 Vascular Supply (Fig. 73.5a and b)

The internal maxillary artery gives off the descending palatine artery, which in turn gives off several branches to the tonsils and soft palate. It then passes through the posterior palatine foramen, just above the periosteum, and proceeds forward close to the alveolar margin on each side as the greater major palatine artery to the incisive fossa. At that point it sends terminal branch through the incisive foramen to anastomose with the terminal branch of the sphenopalatine artery. The vascular supply of importance is discussed under two headings, anterior and posterior palate.

73.2.3.1 Vascular Supply of the Anterior Palate/Premaxilla

The blood supply to the anterior alveolar process of the maxilla comes from the arterial complex composed of the major palatine, anterior and superior alveolar, and branches of the sphenopalatine artery. The posterior septal artery arises from the sphenopalatine artery in the roof of the nasal cavity and courses down the groove of the vomer to the incisive foramen. In the complete bilateral cleft lip and palate, the union of the superior labial arteries is lacking; thus they do not contribute to the blood supply of the philtrum. Also the anastomosis of the posterior septal artery with the major palatine artery is absent. Therefore premaxilla and philtrum must derive their blood supply from the posterior septal artery and to some degree from the lateral and terminal branches of the anterior ethmoid vessels which pass through the columella. There is usually one well-developed vessel on either side of the premaxilla in the region where the incisive foramen should have been. Each of these vessels moves anteriorly and inferiorly into

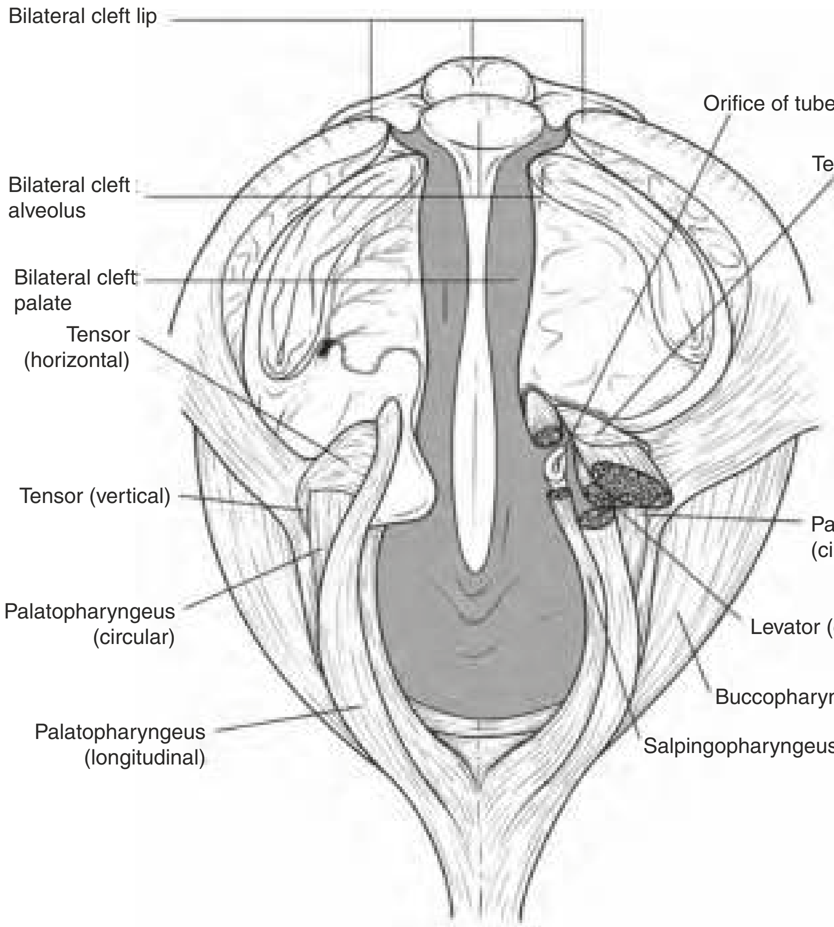

Fig. 73.4 Muscles of the palate demonstrated in a complete cleft of the lip, palate and alveolus (bilateral)

Table 73.1 Muscles of soft palate

Muscle	Origin	Insertion	Function	Pathological anatomy in cleft palate
Tensor veli palatini	Originates from the scaphoid fossa at the base of the medial pterygoid plate, spina angularis of the sphenoid and from the cartilaginous part of the auditory tube	The muscle descends anteroinferiorly and winds around the pterygoid hamulus, to which some fibers are attached, and passes into a tendon that fans out to form the palatine aponeurosis few fibers are attached to the maxillary tuberosity	The main role of the tensor is to dilate the Eustachian tube and its role in speech is insignificant	In a cleft palate child, the palatine aponeurosis is deficient, especially medially
Levator veli palatini	Arises from the petrous part of the temporal bone and from the cartilaginous part of the Eustachian tubes	The muscle descends on either side, enters the intermediate 40% of the soft palate, and forms a muscular sling with its counterpart on the other side	When the paired muscle contracts, it elevates the soft palate superiorly and posteriorly to enable closure of the velopharyngeal sphincter. The latter is formed by the soft palate anteriorly, the posterior pillars of the fauces on either side, and the posterior pharyngeal wall posteriorly	In a cleft child, as there is obviously no continuity across the midline due to the cleft, there are abnormal attachments of the levator muscle to the palatopharyngeus muscle posteriorly, to the edge of the cleft medially, to the tensor veli palatini, and to the posterior edge of the hard palate anteriorly

Table 73.1 (continued)

Muscle	Origin	Insertion	Function	Pathological anatomy in cleft palate
Palatopharyngeus	Has a palatine portion, a pterygopalatine portion and the salpingopharyngeal part. It arises from the lateral and posterior part of pharynx and attaches into the velum. Its superior fibers arise from complex intermingling with the superior constrictor muscle. Lower fibers of the palatopharyneus arise from the inferior part of the lateral wall of the pharynx, medial to the middle and inferior constrictor muscles. Some fibers may arise from the thyroid cartilage. These lower fibers pass through the palatopharyngeal arch to insert into the velum	It is found in the posterior pillar of the fauces. The fibers pass horizontally into the posterior three fourths of the soft palate inferior to the fibers of the levator palatini muscle	The muscle helps to narrow the velopharyngeal opening by bringing the palatopharyngeal arches together	The muscle is relatively well developed in the cleft palate child and ends partly along the cleft edge and partly along the posterior edge of the hard palate. Some fibers pass along the edge of the cleft along with the levator to form the muscle of veau
Palatoglossus	Arises from the tongue	Inserts into the soft palate	The paired muscle forms the anterior part of the sphincter and narrows the isthmus. It is antagonistic to the levator in its action, drawing the palate inferiorly	This muscle doesn't play a major role in cleft palate anatomy
Musculus uvulae	Arises from the posterior nasal spine and the palatine aponeurosis	Passes posteriorly along either side of the midline and inserts into the junction of the proximal and middle thirds of the uvula. The rest of the uvula contains only mucous glands	Contraction of the muscle aids the levator in forming the levator eminence, which is a hump like projection formed proximal to the uvula and aids in closure of the velopharynx during speech	The presence and extent of the muscle in a cleft palate child is disputed. It is also supposed to be absent in occult submucous cleft patients
Superior pharyngeal constrictor	Quadrangular muscle in the upper third of the posterior pharyngeal wall. Origin at the hamulus and the adjacent pterygomandibular raphe	Merges with the palatopharyngeus.. Fibers pass around and through the lateral pharyngeal wall, and merge with the corresponding fibers of the opposite side forming a tendinous strip- the pharyngeal raphe, which runs in the midline from the pharyngeal tubercle of the occipital bone through the entire length of the pharynx	The upper most fibers are responsible for the formation of the passavant's ridge, which is a projection on the posterior pharyngeal wall during speech. However, the edge is usually below the level of closure of the velopharyngeal sphincter, and in only about one third of the patients, it is believed to contribute to closure of the sphincter (the mistake of passavant)	

the philtrum and forms an arcuate anastomosis across the midline in the inferior part of the philtrum.

73.2.3.2 Vascular Supply of Posterior Palate

The greater palatine artery supplies the oral surface of the hard palate and gives off a few fine branches which perforate the horizontal plate of the maxilla to supply the nasal mucosa. It also sends twigs to the gingiva and the palatoglossal arch. The lesser palatine artery supplies the anterior half of the oral surface of the soft palate. A branch of the facial artery, the ascending palatine artery, is the largest vessel entering the soft palate. It ascends on the lateral side of the superior constrictor muscle to turn downward and forward into the soft palate, between the tensor and levator palati giving small branches to these muscles. Twigs from the tonsillar and ascending pharyngeal arteries also reach the soft palate. In the secondary palate, the existence or absence of cleft makes little difference to the vascular pattern. The palatal mucoperios-

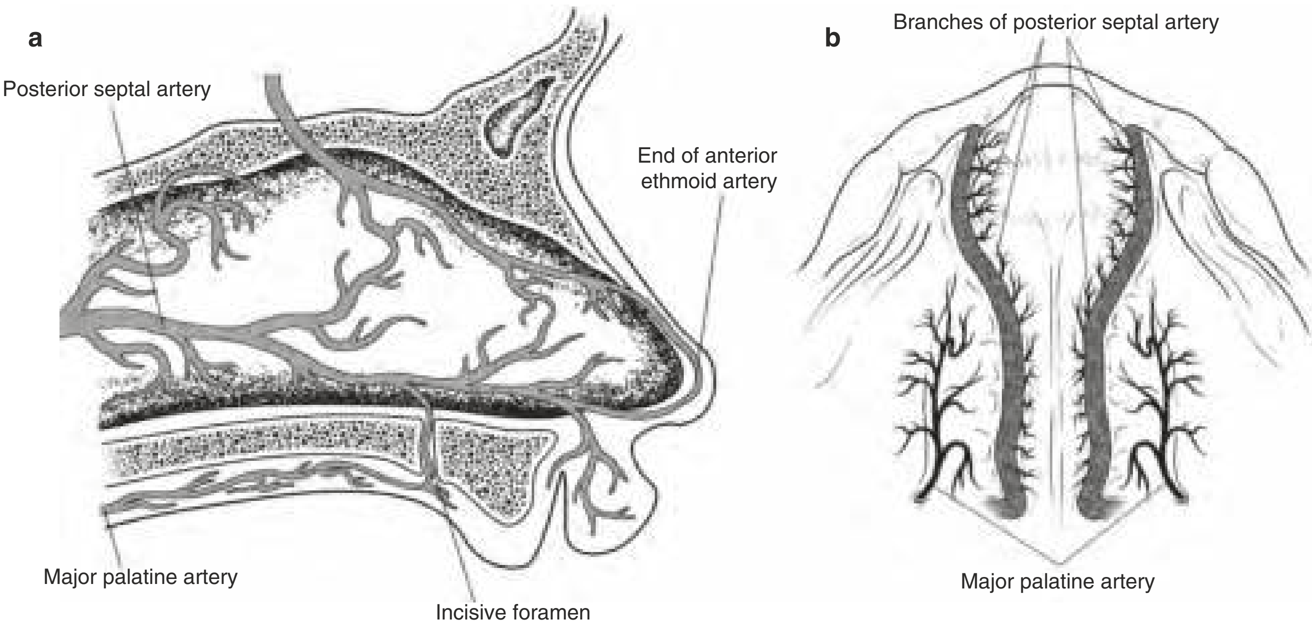

Fig. 73.5 (**a**, **b**) Vascular supply of the palate

teum is detached from its bony base in the palatal pedicle flap, and as a result the recurrent bony branches are severed. These branches result in bleeding from their cut stumps at the bony surface. This may be judged insignificant at the time of surgery; however, after the flap is repositioned, should bleeding continue, blood may pool beneath the repositioned flap [17].

73.3 Classification and Presentations of Cleft Palate

Many of the historical and contemporary classifications have been discussed in brief in the Chap. 72 on cleft lip. However, Veau's classification for palate is the most practical and therefore is mentioned again here.

Submucous cleft palate exhibits at least one of Calnan's three criteria [17]:

(a) A palpable notch on the posterior border of the hard palate.
(b) Zona pellucida or a bluish tinge in the midline of the soft palate due the paucity of muscle bulk at this level.
(c) Bifid uvula- this may extend from a mere groove on the uvula to complete bifidity.

Table 73.2 Veau's classification of cleft palate

I.	Cleft of the soft palate alone
II.	Complete cleft of the palate up to the incisive foramen
III.	Unilateral complete cleft of the palate and pre-palate. In these the vomer is attached to the maxilla on the non-cleft side
IV.	Complete bilateral cleft of the palate and pre-palate. These patients have a protruding premaxilla, and the vomer is in the midline

Victor Veau (1931) has classified cleft palates into four groups [7] (Table 73.2)

Clefts of the palate that are less extensive in magnitude include the submucous cleft palate and the occult submucous in cleft palate.

Sommerlad has devised a grading system for the submucous cleft palate with three points for each of the above criteria [18]. A lesser score in this system naturally denotes more trivial clefting. However, paradoxically a lower score reflects a poorer prognosis for speech according to this study. An occult submucous cleft does not exhibit any of Calnan's criteria but shows a trough-like depression on the superior surface of the soft palate as seen in nasoendoscopy. Croft believed that in these patients, the musculus uvulae is absent. It is suspected when a child with a normal palate speaks with nasal emission.

Fig. 73.6 (**a**, **b**) Picture of child with Pierre Robin Sequence

73.4 Clinical Evaluation of the Cleft Palate Patient

73.4.1 General Examination

A routine per-oral examination of the neonate reveals the cleft of the palate with or without cleft lip. The extent of clefting is noted. General examination is mandatory as it is important to identify syndromic patients. These are more common in isolated cleft palate patients [19]. Pierre Robin sequence is a fairly common presentation with micrognathia or retrognathia (Fig. 73.6 and b). As the bony abnormalities are believed to be the cause of the non-descent of the tongue in utero leading to the clefting of the palate, this is now believed to be a sequence and not a syndrome. Syndromic patients include Treacher Collins syndrome, Goldenhar syndrome, etc.

73.4.2 Clinical Assessment of the Cleft

The first clinical visit usually happens soon after birth. The extent cleft is assessed, i.e., the length of the palate and the width of the cleft. Randall has classified cleft palate on the basis of length into four types [20]. Clefts may be partial or complete. A partial cleft of the secondary palate is confined to the soft palate (Fig. 73.7).

A complete cleft includes both the soft and the hard palate up to the incisive foramen (Fig. 73.8). In patients with bilateral cleft lips, the associated cleft palate usually presents with a central vomer and clefting on either side of the vomer (Fig. 73.9).

A pediatric assessment is made for other anomalies, weight of the baby is noted, and feeding instructions are given during this visit. A squeezable feeding bottle is usually advisable to overcome child's difficulties in sucking. The child is fed with the head held slightly higher. Parents are counselled about the need for immunization. They are also explained about the need for surgery and are shown results of the procedure on similar patients. It is very important to allay their anxiety as they are very often crestfallen on seeing the deformity in their baby. Subsequent visits, possibly at monthly intervals, aim to assess the growth and development of the baby. Associated cardiac or other anomalies if present need investigation.

Fig. 73.7 A child with partial cleft palate

Fig. 73.8 A child with complete cleft palate

73.4.3 Imaging and Other Investigations

Routine imaging is not generally practiced in the evaluation of cleft palate patients. Syndromic patients require other investigations as part of the various manifestations of their syndromes. For instance, children with velocardiofacial syndrome may require echocardiogram in view of the associated cardiac anomalies. Children with delayed development, microcephaly, etc. will require neurological assessment and will usually need an MRI of the brain. Rarely a child may have a meningoencephalocele presenting behind the palate. MRI has been used to evaluate submucous clefts with a view to help in the planning of the management. If it can be shown that there is not adequate muscle continuity across the midline, an early decision can be taken to operate on the child at the usual time of cleft palate repair. On the other hand, if there is good muscle across the midline, these repairs can be justifiably delayed until the development of speech. MRI has also been used to assess the Eustachian tube function. Hearing assessment should be mandatory in all cleft palate patients.

Fig. 73.9 A child with bilateral cleft palate

73.5 Preoperative Factors (Box 73.1)

Box 73.1 Preoperative Considerations

- Timing of repair.
- One stage or two stage repair.
- Anatomy of the cleft.
- Airway.
- Feeding.
- Pediatric consultation.
- Cardiac consultation.
- Neuro consultation.
- Ent consultation.
- Anesthesia.

1. Timing and Age of the Patient.

   The dilemma regarding the timing of repair is between earlier repair with better prognosis for speech, but worse prognosis for maxillary growth, and late repair which is exactly the opposite. Most surgeons today agree that the cleft palate is to be operated close to 1 year. Some prefer 9 months, where others wait for up to a year and 4 months. At our center we have been operating on these children at about 11 months of age. The Oslo school of surgeons [21, 22] devised a protocol of operating on the lip with the soft palate in the first stage and operating on the hard palate much later. In some centers, the palate has been repaired first at initial presentation, and the cleft lip is repaired, subsequently, in view of the fact the children may not be brought back for treatment of the palate once the lip is repaired [23].

2. Airway.

   Airway management is important at the time of birth in cleft palate patients, as most of isolated cleft palates may be associated with a smaller airway at birth. This may be due to associated sequence or syndromes, such Pierre Robin sequence or Treacher Collins syndrome. Such patients might require emergency tracheostomy or tongue lip adhesion to secure airway. Definitive management for mandibular advancement and cleft palate repair can be undertaken at a later stage.

3. Feeding.

   As mentioned already, the parents are counselled about feeding practices during the first visit itself. Expressed breast milk is to be preferred. Special feeding bottles like the Haberman feeding bottle are used when the common methods like the use of simple squeezable bottles are not effective. As a cleft child swallows air along with the milk, frequent burping is essential to avoid regurgitation of feeds.

4. Anesthesia.

   The operation is performed under general anesthesia with an endotracheal tube. RAE tubes are preferred for cleft palate patients. Previously, Oxford red rubber tubes were used. These were well adapted to the needs of the cleft children but often caused laryngeal edema presumably due to the latex in the tubes. At our center we have given up the use of these otherwise very useful tubes.

   Preoperatively, the child must be assessed by a good pediatrician and also by a senior anesthetist. Respiratory infections are common in these children and must be treated if significant. X-ray of the chest is usually done to rule out heart or lung anomalies. Cardiology clearance is required when there are suspected cardiac anomalies. We have come across one case with a congenital absence of the lung.

   The anesthetist should be experienced in pediatric anesthesia. In patients with Pierre Robin sequence or other anomalies like shoulder or spinal anomalies, difficult intubation is to be anticipated, and appropriate equipment such as intubating endoscopes, etc. should be at hand, and the anesthetist must be familiar with its use.

73.6 Principles and Methods of Repair

There are various surgical techniques described in literature. The techniques have been mentioned (Box 73.2), with the author's surgical technique described in detail (Figs. 73.23, 73.24, 73.25, 73.26, 73.27, 73.28, 73.29, 73.30, and 73.31).

The major objectives of a cleft palate operation are:

- To produce anatomical closure of the defect.
- To create an apparatus for development and production of normal speech.
- To minimize the maxillary growth disturbances.

The basic principles of cleft palate repair are:

- Closure of the defect.
- Repositioning of the abnormal position of the muscles of the soft palate.
- Reconstruction of the muscle sling.
- Favorable retro positioning of the soft palate and uvula so as to achieve velopharyngeal closure during speech.
- Last and most important is tension-free suturing [24, 25].

Box 73.2 Methods of Cleft Palate Repair

Methods of repair

- *Von Langenbeck's bipedicle flap technique (*Fig. 73.10*).*
- *Veau-Wardill-Kilner Pushback technique (*Fig. 73.11*).*
- *Bardach's-Pinto-Wardill two-flap technique.*
- *Furlow double opposing Z-Plasty.*
- *Two-stage palatal repair.*
- *Whole in one repair.*
- *Palatoplasty.*
- *Alveolar extension palatoplasty (AEP).*
- *Primary pharyngeal flap.*
- *Intravelar veloplasty.*
- *Vomer flap.*
- *Buccal myomucosal flap.*

73.7 Surgical Technique (Figs. 73.12, 73.13, 73.14, 73.15, 73.16, 73.17, 73.18, 73.19, 73.20, 73.21, 73.22, 73.23, 73.24, 73.25, 73.26, 73.27, and 73.28)

Once intubated, the child is placed with the neck extended for adequate visualization of the palate. A pillow under the shoulder helps in this positioning. A suitable mouth gag is used. We use the Dott's gag (Fig. 73.12) with the Kilner suture carrier. A popular gag used widely is the Dingman's gag.

Infiltration: A solution of lignocaine with 1 in 200,000 adrenaline is infiltrated under the mucoperiostem of the hard

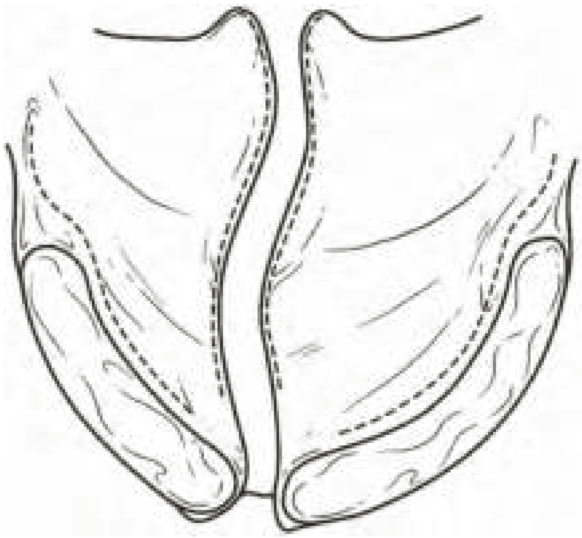

Fig. 73.10 Langenbeck procedure. Incisions are placed to raise flaps which remain attached in the anterior palatal region

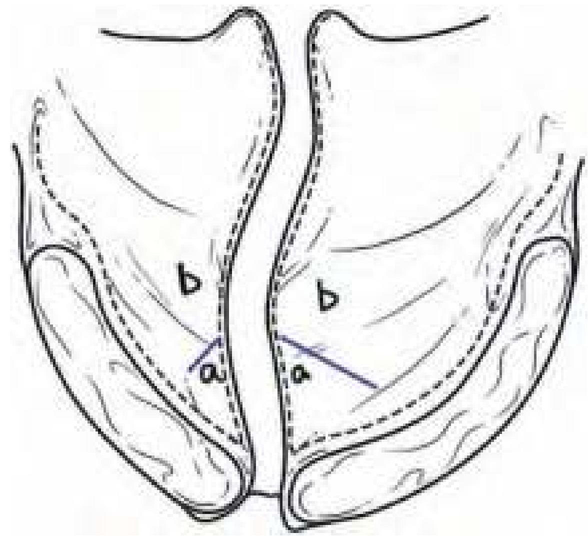

Fig. 73.11 Wardill's four flap palate repair. (**a**) are the anterior flaps while (**b**) form the posterior flaps that are closed in a "V to Y" fashion to gain length for the "push-back"

Fig. 73.12 Dott's gag

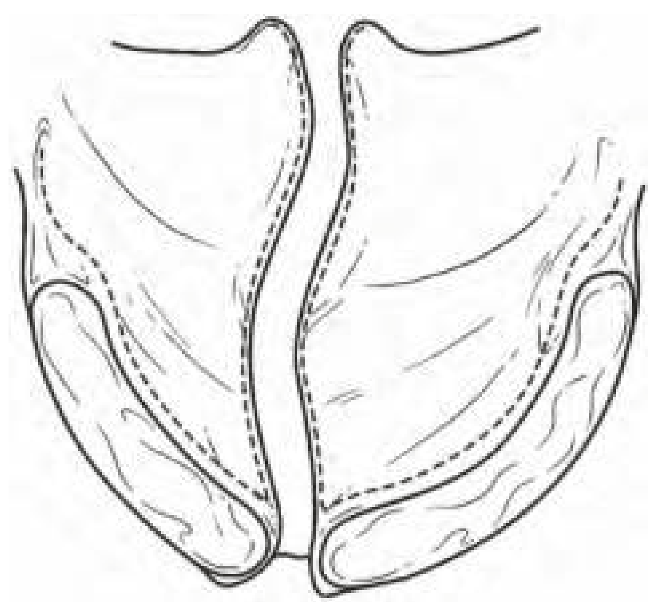

Fig. 73.13 Pinto Wardill (Bardach) two long-flap procedure. Classical method of raising two flaps detached at the anterior pedicled on the greater palatine artery

palate and above the nasal mucosa in the soft palate. A dental syringe with a short-beveled needle is very useful for this purpose.

Surgical procedure: At our center, we use the two long-flap technique popularized in India by Charles Pinto and the world over by Bardach (Fig. 73.13). The technique was originally used by Veau. The cleft edges are pared (Fig. 73.14).

The lateral incision is made from the maxillary tuberosity area toward the retromolar area posteriorly. The pterygoid hamulus is dissected, fractured, and detached (Fig. 73.15a and b).

This aids in mobilization of the nasal layer subsequently. However, there are many surgeons nowadays who do not believe in fracturing the hamulus. It has, however, been shown in different studies that fracture of the hamulus does not cause any deleterious effects on hearing [26].

The lateral incision is then carried anteriorly and the oral mucoperiosteal flap is lifted off till the medial edge of the hard palate using Kilner's palate elevators (Fig. 73.16a and b).

An incision is then made on the medial border of the hard palate, and the flap is also divided anteriorly taking care to secure the end of the greater palatine vessels. The oral flap is then raised till the posterior border of the hard palate. Laterally, the greater palatine vessel is identified and skeletonized, after incising the cone of periosteum which binds the vessel behind it (Fig. 73.17a, b, c and d).

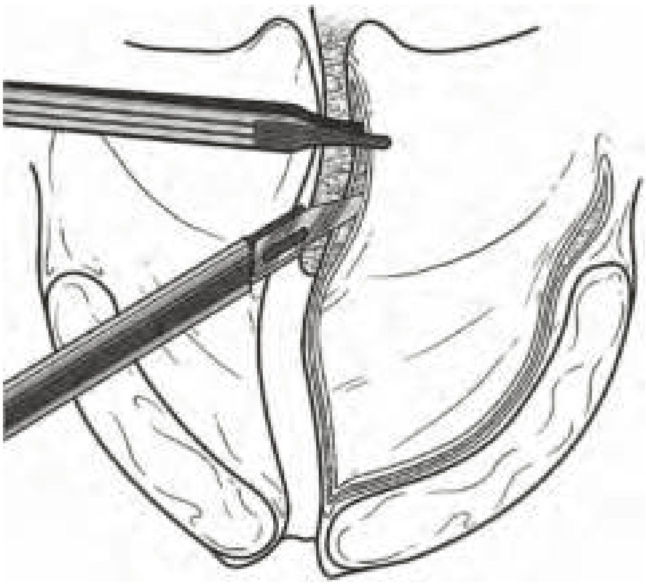

Fig. 73.14 Pared cleft edges

After the hamulus is fractured, the medial pterygoid plate is denuded of any soft tissue attachments (Fig. 73.18).

Similarly, the posterior border of the hard palate is also cleared of muscular attachments (Fig. 73.19a and b).

A Cumine Scaler is introduced over the bare medial pterygoid plate and then turned anteriorly to separate the nasal layer from the hard palate in one clean sweep. This dissection is then completed on a deeper plane with a Wallace's finisher (Fig. 73.20a and b).

This practice of separating the nasal layer from behind forward was originally introduced by Kilner [8] but has somehow not been followed widely. It is much easier than the alternative method of separating the nasal layer from the hard palate starting anteriorly. Very often this results in tearing of the nasal layer.

Similar dissection is performed on the other side also, raising a long oral mucoperiosteal flap. The vomer flap is raised (Fig. 73.21) and used when accessible and necessary.

Rarely, the vomer is receding and cannot be used. In a bilateral cleft lip patient, the vomer is in the midline, and a central incision on the vomer is made to raise two mucoperiosteal flaps, one on each side, to be sutured to the corresponding side in nasal layer of the hard palate.

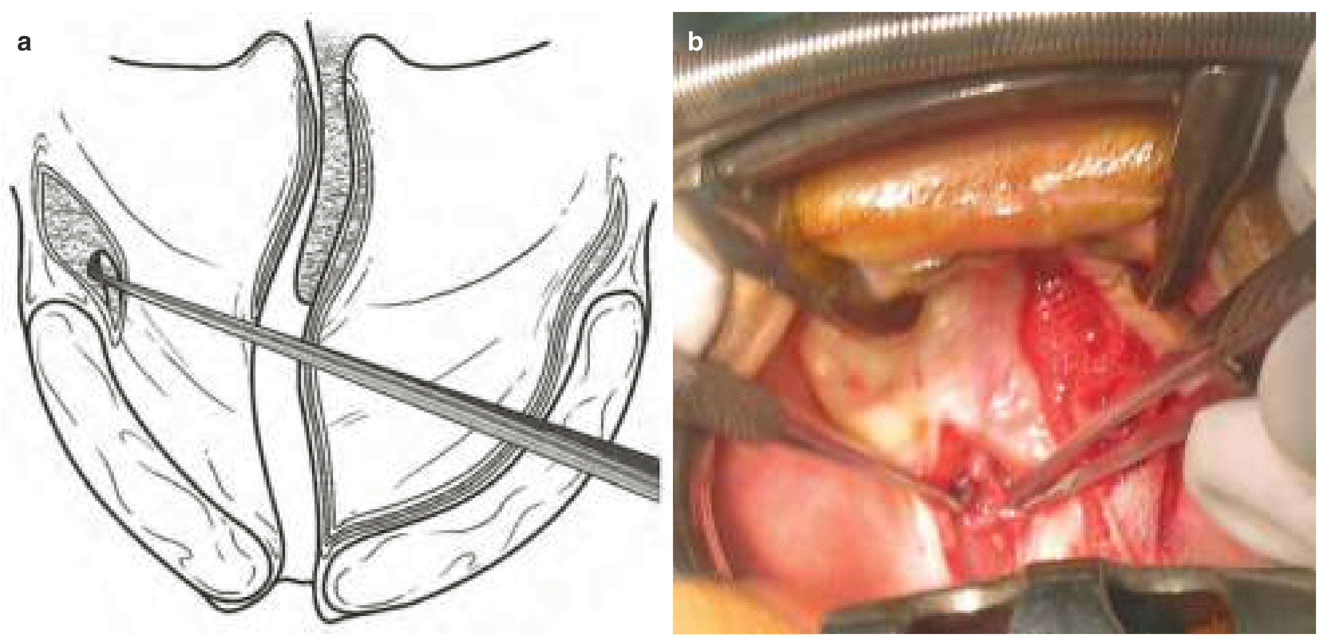

Fig.73.15 (**a**, **b**) Fracture of the pterygoid hamulus

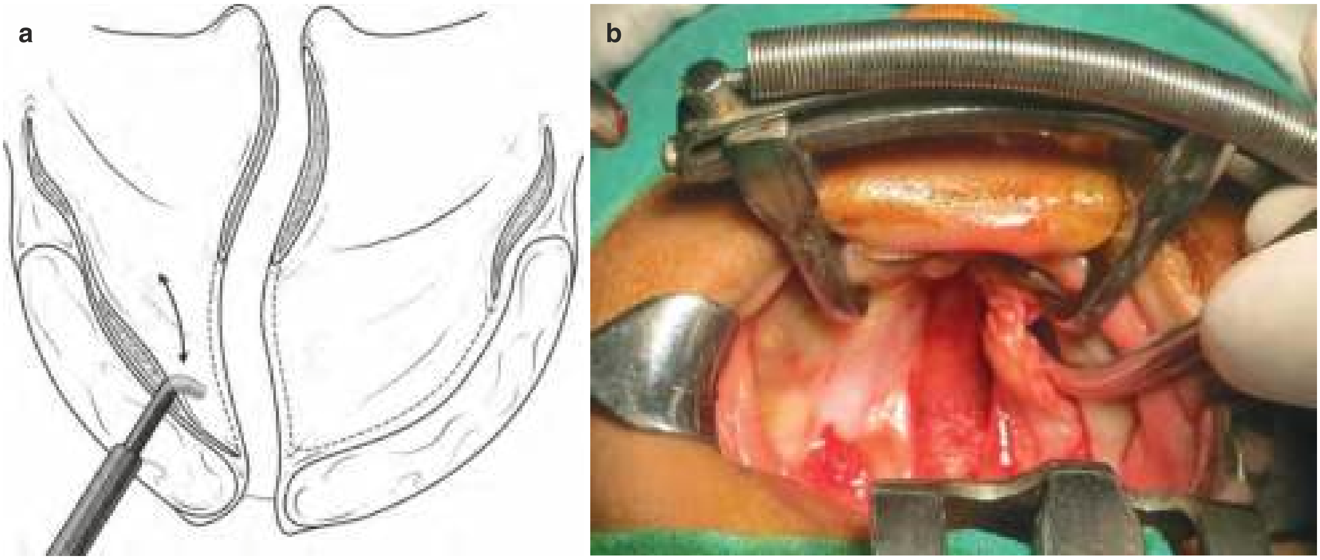

Fig. 73.16 (**a, b**) Elevation of the oral flap with Kilner's elevator

73.7.1 Dissection of the Soft Palate

The early techniques of cleft palate repair only detached all false attachments of muscles from the posterior border of the hard palate (Fig. 73.22).

Surgeons like Braithwaite [27] and Kriens [28] emphasized the importance of the dissection and retroposition of the levator veli palati muscle. This was popularized by Sommerlad [29] and Tambewekar in India.

Infiltration of lignocaine with 1:200,000 adrenaline is made between the nasal mucosa and the muscle (Fig. 73.23).

A transverse incision is made on the aponeurotic layer just beyond the hard palate (Fig. 73.24).

Then the muscle is dissected off the underlying mucosa leaving behind enough tissue on the nasal layer, to avoid its tearing during suturing. Also, a narrow layer of muscle is retained along the cleft edges to hold the sutures. The muscle is dissected till just short of the uvula. The muscle contains the levator veli palati mostly. However, it also contains other muscles like the palatopharyngeus ("muscle of Veau") (Fig. 73.25).

The extent of dissection of the muscle on the soft palate varies. The authors [30] only separate it from the nasal layer. Others like Sommerlad [29] also separate it off the oral layer. However, if there is any suspicion of injury to the greater palatine vessels during dissection, then the levator muscle should not be dissected free of the oral mucosa.

73.7.2 Suturing

Suturing commences on the nasal layer from anteriorly, proceeding backward. The sutures are not tied but held on the Kilner suture carrier.

73.7.2.1 Uvula

The last suture on the nasal layer is a mattress suture (Fig. 73.26) [30].

Next, an apical mattress suture is placed on the tip of the uvula, and this suture is left long and held on an artery forceps, thus turning the uvula over, providing access to the nasopharyngeal aspect of the uvula. Two or three simple sutures are placed between the mattress suture and the apical stitch (Fig. 73.27a).

Then two or three mattress sutures are placed on the oral aspect of the uvula (Fig. 73.27b).

The nasal layer sutures are then tied from behind forward.

"A" suture: this is the suture placed at the junction of the hard and soft palate. It goes through the nasal mucosa and later crisscrosses into the oral mucosa, resembling the letter A, but is like the figure of "8" when tied.

Anterior sutures are also tied but retained long.

Suturing of the oral layers then proceeds from behind forward, with every suture picking up a bite on the nasal layer to obliterate dead space. The dissected levator mus-

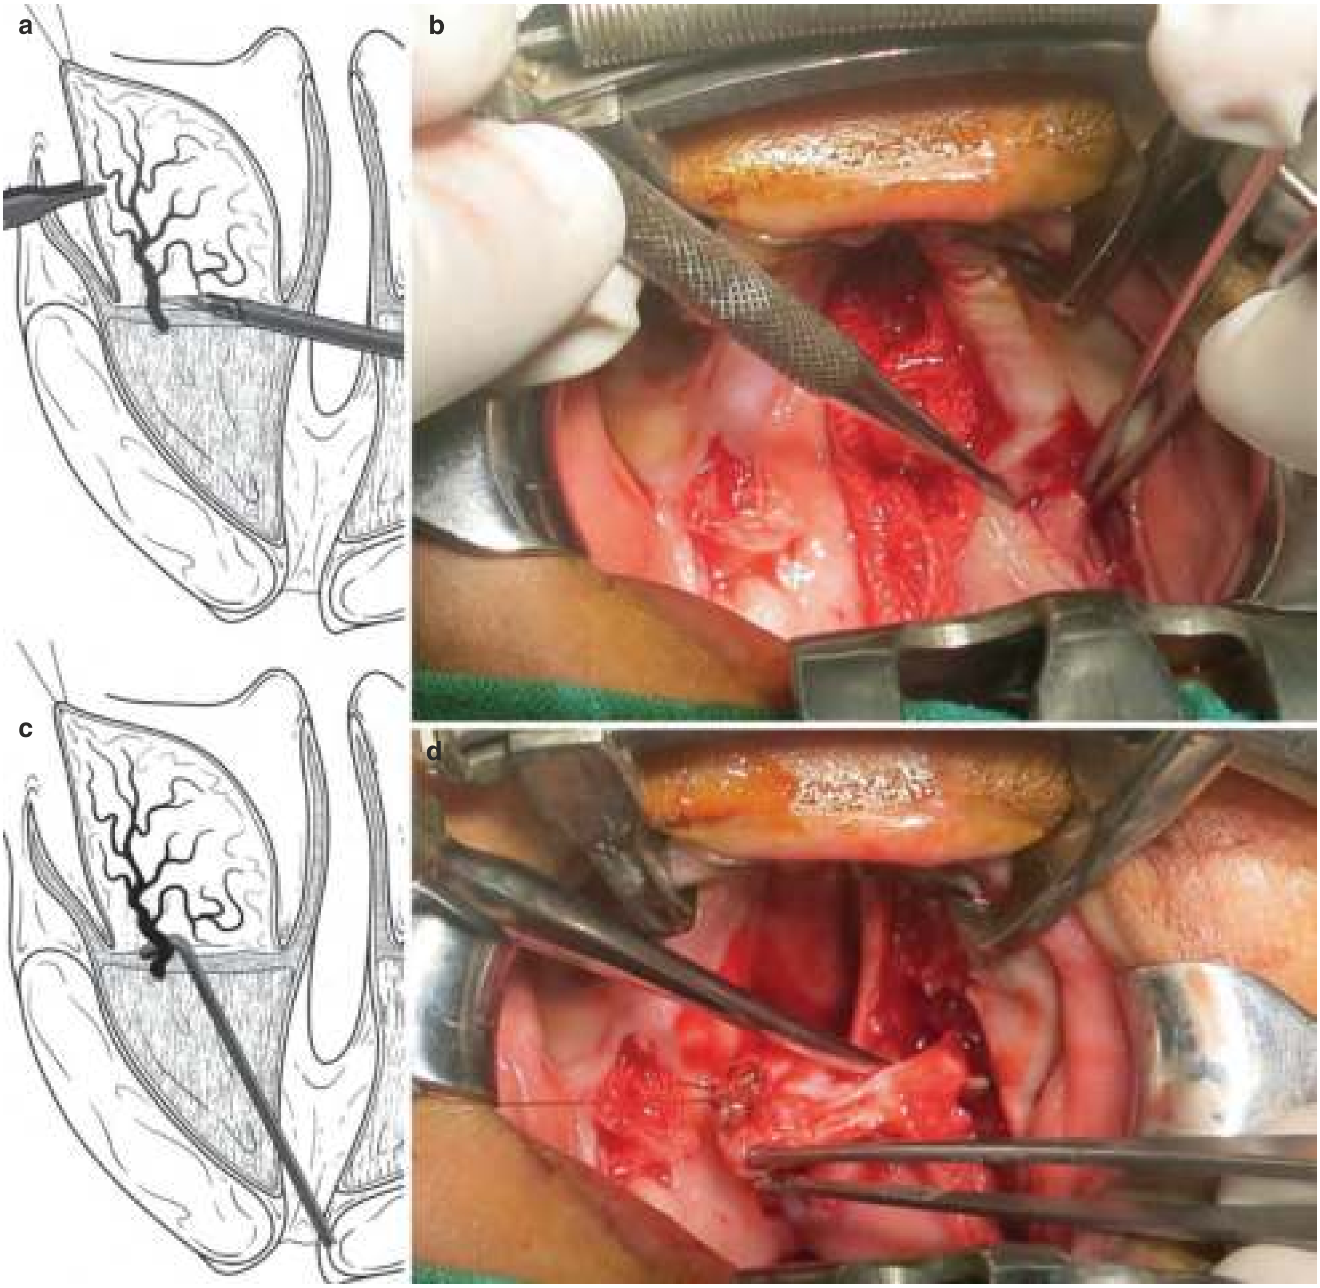

Fig. 73.17 (**a, b**) Incising the Periosteal cone to free the greater palatine artery. (**c**, **d**) Hooking out the greater palatine vessels (the vessel is pulled out like a bird pulls a worm out of the ground). This reduces the tension on the flaps on suturing

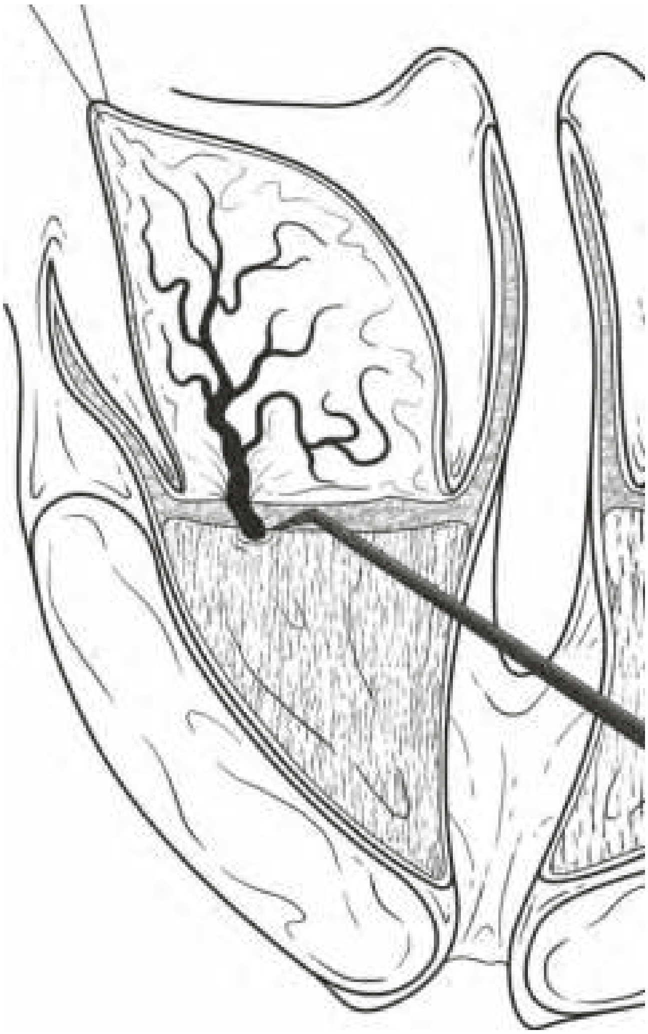

Fig. 73.18 Medial pterygoid plate dissection

cle is also included in these oral sutures. Some surgeons close the levator muscle as a separate layer. The anterior sutures are then brought through the oral layer also, helping in anchoring the oral layer. In the absence of the anchoring, the oral layer may sag postoperatively causing a "fallen palate."

Laterally the raw areas are sutured with interrupted sutures without tension. This helps in hemostasis (Fig. 73.28).

Previously, this area used to be packed with different materials, but there was often bleeding from the areas on removal of the pack postoperatively.

Buccal pad of fat harvested through a stab incision on the buccal aspect bilaterally has also been used to fill large lateral raw areas.

73.8 Complications: (Box 73.3)

Box 73.3 Complications
Immediate complications.

- Haemorrhage.
- Respiratory obstruction.
- Hanging palate.
- Dehiscence of the repair.
- Oronasal fistula formation.

Late complications.

- Bifid uvula.
- Velopharyngeal incompetence.
- Abnormal speech.
- Maxillary hypoplasia.
- Dental malpositioning and malalignment.
- Otitis media.

73.8.1 Early Complications

Hemorrhage
This is often from the apices of the long flaps, from the cut ends of the greater palatine vessels. Arterial bleeding points need to be ligated or cauterized using diathermy. Small venous bleeding areas can be controlled by the use of pressure with fingers or by the use of crushed ice or topical hemostatic agents like tranexamic acid.

Respiratory Obstruction
This may be from tongue fall and can be avoided by use of a tongue stitch at the time of palate repair. The tongue stitch has to be placed well posteriorly and must include a good bulk of the tongue tissue to avoid the sutures from tearing through.

When a wide cleft palate is closed, the child may have difficulty in learning to breathe adequately through the nose. Laryngeal edema due to endotracheal tube-related trauma may present with a hoarse cry and, in severe cases, chest retraction. Early detection is important, and this can be reversed by intravenous steroids and nebulization.

Breakdown of the Repair
It may result in fistulas or complete breakdown of the repair. The most common cause of these, especially at the junctional area, is suturing of the cleft edges under tension due to inadequate mobilization.

73.8.2 Long-Term Complications

Long-term complications include poor speech. Adequate muscle repair has helped in better speech results. Nonetheless, speech is an enigma that has not been adequately understood and mastered. The variables like width of the cleft, the gap between the uvula and the pharynx, and the adequacy of the muscle repair all have a bearing on the speech results. Despite all the advancements in the repair of the cleft palate, no surgeon can truly claim to achieve perfect speech results in all patients consistently.

73.9 Long-Term Results

The long-term evaluation of cleft palate patients should include the presence or absence of a fistula, the quality of speech, and the growth parameters of the maxilla, i.e., whether there is maxillary hypoplasia.

At present, many centers are able to produce fistula-free palates in a majority of patients. Tension-free closure of the palate and meticulous suturing are the key factors in the prevention of fistulas. A review of literature reveals a huge range in the incidence of fistula after cleft palate repair. The range is from 2.6 to 58%. In between these extremes, many have reported around 10%, some 15 and 23% [31, 32].

The emphasis on good levator veli palatini dissection and repair has led to improved speech results overall. However, one can never perfectly predict the speech outcome, as speech itself is an enigma. Probably as a result of the variation in the presentation, mode of repairs and age at the time of repair, etc., the published literature notes a VPI rate of 5.9–70% [32].

Maxillary growth continues to be a problem. Operations like these of Robert Mann show promise in this direction. Again, owing to variability involved in the type and extent of cleft, the time of repair and the nature of the surgery, the need for maxillary advancement may range from 10 to 40% in non-syndromic cleft patients [32].

73.9.1 Secondary Repair and Revision

The age old saying that primary surgery is the best chance for the surgeon to obtain optimal results is very apt in the repair of the cleft palate. A badly repaired cleft palate sometimes leaves behind a grossly scared palate with paucity of tissue. Small soft palate fistula can be repaired by freshening of the edge and two-layered closure. Small hard palate fistulas can be repaired by local turn over flaps for lining and oral mucoperiosteal flaps for the oral layer. Larger ones and those with poor speech will require revision palate repair. When there is gross deficiency of tissue, flaps like the tongue flaps, or temporalis musculocutaneous flap, facial artery muscle mucosal (Famm) flap may be necessary [33, 34].

Secondary palate repair is also required for velopharyngeal incompetence (VPI). A detailed discussion about the management of such incompetence is beyond the scope of this chapter. Diagnosis of VPI is by speech assessment, nasoendoscopy, or videofluoroscopy. Once a diagnosis is made, treatment modalities will include redo palate repair, sphincter pharyngoplasty, or flap pharyngoplasties, depending on whether it is the palate, lateral wall (palatopharyngeus) or the posterior wall, or a capacious pharynx as seen on investigations.

Subsequent interventions will be required for maxillary hypoplasia when significant. This is again out of the scope of this chapter. In brief, anterior maxillary distraction is done if the maxillary advancement required is significant and the facial bones are still growing. Some of these do require a LeFort 1 osteotomy later on if there is relapse. When the growth is completed, then a LeFort 1 osteotomy is required when there is significant maxillary hypoplasia. When the advancement required is more than in 1 cm, bi-jaw surgery is needed, with a LeFort 1 advancement in the maxilla and a bilateral sagittal split osteotomy of the mandible.

73.10 Recent Techniques

The use of the buccal mucosal flap in primary repair was pioneered by Padgett [14] and then used extensively by Murari Mukherjee [15]. Later Ian Jackson incorporated buccinator muscle into the flap and used it on the nasal layer transverse to provide for lengthening of the soft palate.

Furlow's Double Opposing Z plasty described by Furlow [35] is increasingly used both for primary and secondary repair of cleft palates. This illustrated in the figure (Fig. 73.29a, b, c and d). Robert Mann has described the extensive use of the double opposing "Z" plasty with the buccal flaps over the nasal and/or oral layers to avoid lateral incisions and to promote for better bony growth. This is probably the method of the future as it shows promise of good speech and good maxillary growth. However, extensive suturing of the buccal flaps is involved and this is not the optimal surgery for the novice to try. The Mann procedure is for the experienced cleft surgeons [36].

73.11 Case Scenario

Case 1

This is a patient with a partial cleft of the secondary palate (Fig. 73.30). The hard palate is intact. The cleft palate was repaired at the age of 11 months using the Veau-Wardill V-to-Y repair and radical muscle dissection in the soft palate. Subsequently the child is undergoing regular follow-up and speech assessment.

Case 2

This is a child with a complete cleft of the primary and secondary palate on the (Fig. 73.31). The cleft lip was repaired at 6 months of age using the Millard's rotation advancement technique. At 11 months, the cleft palate was repaired using the two long-flap procedure popularized in India by Charles Pinto, the mentor of the senior author, and, worldwide, by Bardach. The child is now being subjected to constant follow-up and speech therapy.

Alveolar Bone Grafting

74

Veerabahu Muthusubramanian
and Kalarikkal Mukundan Harish

74.1 Introduction

Attempts to graft the alveolus started in the early 1900. The rationale for the procedure however has changed over the period. From its use as a procedure for establishing continuity over a defect, it has evolved and made itself indispensable in both cleft-related orthodontics and orthognathic surgery. Over the years, the technique has evolved, and the materials used have also been constantly studied and improved upon. This chapter aims to elaborate on the morphology of the alveolar cleft, its implications on dentition as well as facial skeleton, and the various management strategies and evolving trends.

74.2 Normal Anatomy of Alveolus

The alveolar process is that part of the jaw that contains the tooth sockets and forms a bridge between the teeth and the basal bones. The alveolar process is present in both the maxilla and the mandible. The status of the alveolar process and its development depends on the status of the teeth; if the teeth are absent or lost in later life, it reduces in size, eventually disappearing completely.

74.2.1 Development of Alveolar Process (Figs. 72.1, 73.1, and 77.1)

The alveolar process begins to form in the end of the second month of fetal life. The maxilla and mandible develop a groove-like structure that opens toward the surface of the oral cavity. This groove contains the tooth germs, the dental nerves, and vessels. Gradually, bony septa begin to develop between adjacent tooth germs. Later the primitive mandibular canal is separated from the dental crypts through a horizontal plate of bone. The alveolar process remains fused to the body of the maxilla and mandible, and its formation is completed during tooth eruption.

74.2.2 Structure of Alveolar Process

There is no distinct boundary between the body of the maxilla or mandible and their corresponding alveolar processes. In conditions where the alveolus is not functionally related to teeth, it may be fused with and partly masked by bone.

Based on function, the alveolar process consists of two parts:

1. *Alveolar bone proper*: It consists of a thin lamella of bone which surrounds the root of the tooth and gives attachment to the periodontal membrane.
2. *Supporting bone*: It is the structure which surrounds the alveolar bone and gives support to the socket. The latter, in turn, consists of two parts.
   (i) The compact bone/cortical plate forming the vestibular and oral plates of the alveolar processes.
   (ii) The spongy bone between these plates and the alveolar bone proper.

The cortical plates are usually much thinner in the maxilla than in the mandible. They are thickest in the bicuspid and molar region of the mandible especially on the buccal side. In the maxilla, the outer cortical plate is perforated by many small openings through which blood and lymph vessels pass. In the mandible, the cortical bone of the alveolar process is dense and, occasionally, shows small foramina. In the region of the anterior teeth of both jaws, the supporting bone is, usually, very thin. No spongy bone is found here and the cortical plate is fused with the alveolar bone proper.

The interdental and interradicular septa contain the perforating canals of *Zuckerkandl and Hirschfeld*, which house

V. Muthusubramanian (✉) · K. M. Harish

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_74

the interdental and interradicular arteries, veins, lymph vessels, and nerves. The alveolar bone proper which forms the inner wall of the socket contains many openings which transmit branches of the interalveolar nerves and blood vessels into the periodontal membrane. It is named cribriform plate or lamina dura.

74.2.3 Functions of Alveolar Bone

The primary functions of the alveolar bone are highlighted in (Box 74.1).

74.3 Alveolar Anatomy in Cleft Patients

The alveolar cleft is usually represented either by a notch in the alveolus on the labial aspect or as a complete gap between the alveolar segments. In unilateral alveolar clefts, the cleft side of the maxilla (referred to as the lesser segment) is underdeveloped, causing abnormalities of the alveolus, as well as the lip, nose, and palate.

74.3.1 Abnormalities of the Alveolus and Dentition

The abnormalities of the alveolus and the dentition are projected in (Box 74.2).

74.3.2 Abnormalities of the Lip-nasal Complex

- The pyriform rim on the cleft side, when viewed sagittally, appears retrusive.
- The nasal floor is displaced inferiorly, and there is transverse constriction of the anterior bony nasal aperture.
- The nasal tip is asymmetrical.

Box 74.1 Primary Functions of the Alveolar Bone

1. Protection: Alveolar bone forms and protects the dental roots.
2. Attachment: It gives the attachment for periodontal ligament fibers, which are the principle fibers. These fibers which enter into the bone are called as Sharpey's fibers.
3. Support: It supports tooth roots on the facial and the palatal/lingual sides.
4. Shock absorber: It helps to absorb forces placed upon the tooth by disseminating the force to underlying basal bones.

Box 74.2 Abnormalities of the Alveolus and the Dentition

- There is medial collapse of the arch, producing dental crossbites (Fig. 74.1a).
- The position of the premaxilla may be altered with the arch being normal or rotated toward the non-cleft side. There is change in the position of the premaxilla.
- The central incisor is usually rotated toward the cleft side (Fig. 74.1b).
- The lateral incisor may be congenitally absent or hypoplastic or at times resemble a supernumerary tooth. It may also protrude through the nasal floor and lie within the cleft (Fig. 74.1c).
- The periodontal attachments of the central incisor and canine on the cleft side are poor and have high risk of future bone loss.

Fig. 74.1 Intraoral frontal picture demonstrating clinical features of cleft alveolus (left side). (Refer to Box 74.2 for description of a, b and c)

- The medial crus of the nasal cartilage is short, and the upper and lower lateral cartilages do not overlap. There is a mismatch in the level of lower lateral cartilages (Fig. 74.2a).
- The columella, caudal septum, and anterior nasal spine tend to deviate to the non-cleft side.
- The above factors result in lack of support for the external nose, especially around the alar base, which is displaced laterally, inferiorly, and posteriorly, widening the nasal aperture (Fig. 74.2b).
- The fibers of the orbicularis oris muscle do not run transversely and instead turn upward along the margins of the cleft, to terminate beneath the base of the columella medially and below the alar base and periosteum of the pyriform rim laterally. Due to the abnormal muscle attachment, there will be a bulge on the unrepaired cleft lip, distortion of the ala of the nose, and deflection of the nasal septum and anterior nasal spine.

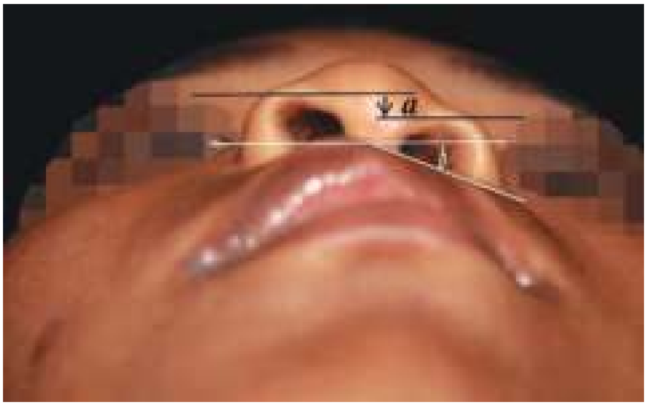

Fig. 74.2 Basal view picture demonstrating abnormalities of the lip-nasal complex (**a**) mismatch of the lower lateral cartilages and (**b**) widening of the nostril due to lack of support for the cleft side alar base

Box 74.3 Goals of Orthodontics in Alveolar Bone Grafting (ABG)

1. Alignment of arches in preparation for ABG.
2. Stabilize the arches.
3. Arch expansion to correct the transverse discrepancy.
4. Align the teeth.
5. Increase the cleft width in preparation to receive the graft.

74.4 Role of the Orthodontist in Patients with Alveolar Cleft (Box 74.3)

The objective of alveolar bone grafting (ABG) primarily involves restoring the structural and functional integrity of maxillary alveolar arch. This would further facilitate the eruption of the canine or lateral incisor into their respective position in the maxillary alveolar arch. The further employment of orthodontic treatment would help in stabilizing the arches and achieving proper alignment of misaligned teeth, The aim of orthodontics in ABG are highlighted in Box 74.3.

The orthodontist must be involved at all stages of dental development, namely, infancy, primary, mixed dentitions, and the permanent dentition stages.

74.4.1 Infancy

1. Pre-surgical orthopedics can be done with the use of appliances such as Latham's appliance, etc. It consists of a pin-retained device that is inserted into the palate with acrylic extensions onto the alveolar ridges. Further a screw mechanism is then used to manipulate the segments as desired.
2. Primary bone grafting is also an option, which is done in some cases, as it was believed that defect, which when corrected earlier, would allow normal development and function. However, it remains controversial, as there are no important benefits compared to secondary bone grafting done. In addition, scarring can cause deleterious effects and retard growth.
3. Gingivoperioplasty can also be done to improve the closure. It involves creation of a mucoperiosteal bridge across alveolar cleft region, thus creating a subperiosteal tunnel. This in turn facilitates bone generation.

   In case of untreated clefts, the maxillary development was found to be normal. Which indicates that early lip repair may affect maxillary growth.
4. In case of a bilateral cleft repair, posterior alveolar segments behind the premaxilla are collapsed leading to a protruded and superiorly positioned premaxilla.
5. Orthodontist's role would be to reposition the maxilla and expand the collapsed alveolar segments.

   Jackscrew and spring-loaded appliance are some of the orthopedic appliances used. However, the effect of these appliances are still controversial.

74.4.2 Primary Dentition

1. In a primary dentition, the orthodontist has no role to play unless the children have crossbites.
2. Routine dental screening is advised to detect any caries.

74.4.3 Mixed Dentition

1. Standard records for orthodontic diagnosis are procured for the patient. Some of them being OPG, IOPA, and occlusal radiographs.
2. Missing teeth, supernumerary teeth, and bone requirement are assessed with these radiographs.
3. Presence of posterior crossbite, malaligned upper incisors, and bone defects at the cleft area are documented.
4. Bone grafting should be done prior to any orthodontic treatment, which is to prevent root exposure or periodontal defects.
5. Arch expansion done should be limited if the patient is supposed to undergo orthognathic surgery later.
6. The expansion is usually limited by the zygomatic buttress and scar tissue present.
7. The direction of the expansion, its extent, the presence or absence of teeth, the resistance of tissue (which can

be high in scarring), surgical access to cleft area, and compliance of the patient are factors that determine the selection of appliance.

8. Spring appliances offer lighter forces with quad helix providing better control in the expansion.
9. Any fistulae that are present in the patient should be corrected during bone grafting.
10. In case of bilateral cleft, the mobile premaxilla is stabilized by grafting, and orthodontic treatment is started only after the bony union is complete, which may be a range between 2 and 6 months.
11. Orthopedic appliances like headgears can be given to patients with mild maxillary deficiencies.
12. Distraction osteogenesis or orthognathic surgery should be chosen depending on the patient's growth status (refer Chap. 69 on maxillary orthognathic surgeries, Chap. 75 on cleft maxillary hypoplasia and Chap. 87 on distraction osteogenesis).

74.4.4 Permanent Dentition

1. Fresh set of diagnostic records are obtained.
2. Most common problems which are seen are missing or malformed teeth.
3. Sometimes teeth may be present but compromised. Most often it is the lateral incisor. One must decide whether this has to be treated with canine substitution or prosthetic replacement.
4. In cases where there is (i) deviation of the dental midline toward the non-cleft side, with the canine erupted mesially with favorable root position, or (ii) the canine is small and wide with both premolars present on the cleft side, and the molar and canine relationships on same side are *class* II, the right choice of treatment would be canine substitution. It involves extraction of the malformed lateral incisor with poor periodontal support, followed by facilitating the eruption of canine in the place of lateral incisor.
5. In cases in which both the maxillary canine and the first molar have a class I relationship, or the canine is positioned with the crown mesially and root distally, with a shift of the maxillary midline to the cleft side, prosthetic replacement is ideal. Adequate space should be planned to accommodate the prosthesis.
6. Comprehensive orthodontic treatment starts almost a year or 2 prior to surgery.
7. Dental decompensation for cleft maxillary osteotomy surgery must be planned and executed. Surgical preparation should include wire placements, retentive hooks for IMF, and plans for post-surgical retention.
8. If relapse is noticed post-surgically, it is immediately addressed with class III elastics or a reverse pull headgear.

74.5 Alveolar Bone Grafting Procedure

74.5.1 History [1]

Attempts to graft the alveolus started in the early 1900s. In the beginning, the goal was to prevent collapse of the alveolar ridge. Therefore, it was done during infancy. In 1970, reconstructive surgeons like Boyne [2, 3] stated that the ideal age for grafting the cleft was between 9 and 11 years. This was done to allow eruption of the canine.

74.5.2 Classification

Alveolar bone grafting procedures are classified into four types based on the age and timing of the procedure:

- *Primary*—This is performed in infancy, with the patient being below 2 years of age. This is done following lip repair but before the palate is repaired.
- *Early secondary*—This is done between 2 and 5 years of age, prior to the eruption of incisors.
- *Secondary*—Performed between 8 and 11 years of age, prior to eruption of the maxillary permanent canine.
- *Late secondary*—Performed above 12 years of age, after the canine has erupted.

The advantages and disadvantages of the various methods are highlighted in Table 74.1.

74.5.3 Materials Used in Alveolar Bone Grafting

A variety of materials have been used in grafting in secondary cleft deformities.

These include autogenous, allogenic, or alloplastic materials.

The success rate differs for each type, but fresh autologous cancellous bone is considered to be superior because it allows cells that are immune-compatible and integrate fully into the maxilla and trigger osteogenesis. In addition, it is the only bone source which possesses all the properties that promote bone formation—osteogenesis, osteo-conduction, and osteo-induction.

74.5.3.1 Bone Grafts

- Cortical:
  Cortical bone refers to the compact outer part of the bone. This is generally less vascular, and so establishment of nutritional supply to cortical cells is a slow pro-

Table 74.1 Comparison of advantages and disadvantages of different ABG techniques

Procedure	Advantage	Disadvantage
Primary grafting	Limited dissection. Reduced maxillary growth discrepancy	Alveolar segments have to be aligned orthopedically. Requires additional surgeries. Reduced success rates [4]
Early secondary grafting	Possibly could facilitate eruption of lateral incisor as well	Not accepted widely in literature [4]
Secondary grafting	Minimal influence in maxillary growth as most of the maxillary growth is completed by 6–7 years [4]. Sufficient quantity of bone at donor site is available. Better patient cooperation. Orthodontic treatment acceptance is good. Allows eruption of permanent teeth through the graft, thus maintaining good periodontal health	Earlier intervention could result in eruption of lateral incisors as well
Late secondary grafting	No significant advantage. Mandibular symphysis could be considered as good donor site as the chances of damaging unerupted teeth are less	Less success rate. Loss of osseous support to teeth adjacent to cleft. Less chances of salvaging lateral incisor. Delay in orthodontic correction of underlying deformity

cess. Therefore, this graft generally resorbs and is replaced by invasion of bone cells originating from the recipient site. The rate of metabolic turnover and cortical bone remodeling is much slower than in cancellous bone. Therefore, keeping the tooth-bearing function in mind, cortical grafts may not be feasible for the alveolar process.

- Cancellous:
  Cancellous bone refers to the softer trabecular bone that is more vascular. This allows better ingrowth from the recipient site. The formation of new bone starts at the surface of the existing cancellous bone. Cancellous bone theoretically heals by osteogenesis, followed by bone resorption and deposition. This graft is harvested as a particulate form, so it may be difficult to stabilize it in the recipient site.
- Cortico-cancellous:
  A combination of the two produces good results and enables good vascularization to help incorporate bone with surrounding structures. It also adds good mechanical strength.

74.5.3.2 Autogenous Materials

The following sites are commonly used as sources for autogenous material used in alveolar bone grafting:

1. Cranium [5]
   - The cranium, or calvarial bone, is a source of both cortical and cancellous bone.
   - This site is associated with low morbidity and minimum postoperative pain.
   - Scar will be unseen within the hair with early discharge and good prognosis.
   - It has poor outcomes as compared to iliac crest bone.
2. Iliac Crest [6]
   - It has huge quantity of cancellous bone which aid osteogenesis. The process of condensing bone chips into the defect increases the reliability of this bone.
   - Bone from this region may be harvested using a trephine or through an open approach.
   - Approach needs to be planned well as it may leave an unacceptable scar.
   - The main disadvantage of using iliac crest is postoperative pain, which may require extended hospitalization, which can be surmounted by regional anesthetic techniques for post-surgical pain control.
   - This is the most preferred donor site and is used by 87% of European surgeons and 83% of North American surgeons performing ABGs [6].
3. Mandibular Symphysis [7]
   - Bone provided is more cortical and is limited compared to the ilium.
   - Damage to the adjacent teeth and mental nerve has been reported.
   - It is used by 4% of surgeons in Europe [7].
4. Tibia [8]
   - It has sufficient bone which is quick to harvest.
   - There is minimal scarring, and patient may be mobilized early but is restricted from sports for 3 weeks.
   - In children where the tibia is usually small, there is a possibility of damage to the epiphyseal cartilage.
   - Used by 3% of European and 2% of North American surgeons [8].
5. Rib [9]
   - This is rarely used, as it provides limited amount of bone.
   - Postoperative risk of chest infections and prolonged discomfort may be present.
   - Esthetically identical scar to other sources.
   - 0.5% of European and 3% of North American surgeons use this method [9].
6. Femur
   - Bone may also be harvested from the intermedullary canal of the femur, but it carries the risk of high morbidity.

74.5.3.3 Alloplastic Materials

Alloplastic materials that have been used for ABG include rhBMP-2 (recombinant human bone morphogenetic protein), undecalicified freeze-dried bone, TEOM (tissue-engineered osteogenic material), and bioglass.

1. rhBMP-2
   - This is recombinant bone morphogenic protein, with superior bone quality reported in BMP-2 group [10].
   - Studies have shown that this material, when used for ABG, had high chances of successful grafting as is considered very effective in situations involving a larger bony defect, and does not demonstrate any detrimental effect on neighboring anatomical structures and no evidences of ectopic bone formation [11].
2. TEOM
   - This material contains MSC (mesenchymal stem cells), PRP (platelet-rich plasma), human thrombin, and mixed air.
   - Available in a gel form.
   - Claimed rate of success is about 70%.
3. Bioactive Glasses
   - This commercially available material is made up of silicone dioxide, sodium dioxide, calcium oxide, and phosphorus pentoxide.
   - It binds both to the soft tissue and bone.
   - Designed to engender surface reaction, which leads to osseointegration.

74.5.3.4 Allogenic Materials

These materials are comparable to autogenous materials and allow for eruption of teeth while avoiding donor site morbidity. However, they do not have osteogenic potential, which causes delayed graft incorporation.

These materials include:

- Undecalcified freeze-dried bone.
- Allograft CTBA [Cells and Tissuebank Austria].
- Osteograft.
- Maxgraft.

Most of the abovementioned products involve bone obtained from genetically dissimilar individuals. These allogenic bone particles are subjected to various processes to ensure the allogenic graft material is devoid of any microbial contamination however retaining the organic matrix and the inorganic components. They are available in various particle sizes or as block grafts or can even be milled for specific patients using CAD CAM technology.

Box 74.4 Goals of ABG

- To allow closure of the oronasal fistula.
- To provide tension-free, watertight closure to retain the graft and establish soft tissue continuity.
- To pack adequate volume of graft in the defect and restore bony continuity.
- Aid in the eruption and alignment of teeth.
- Add stability to the maxilla as a single unit while planning for orthognathic surgery.

74.5.4 Technique for Alveolar Bone Grafting

The technique of alveolar bone grafting must be performed with the following goals in mind (Box 74.4).

Alveolar bone grafting procedure is performed under general anesthesia. It can be performed comfortably using both naso-tracheal and oro-tracheal intubation. When iliac crest is the chosen donor site, a two-team approach can be followed simultaneously. The surgical sequence for unilateral ABG (Figs. 74.3a–f and 74.4a–f) and bilateral ABG (Fig. 74.5) are detailed below.

Surgery in the oral cavity is begun with infiltration of local anesthesia containing adrenaline to assist hemostasis. It has to be borne in mind that the reconstruction of cleft alveolus involves neat and precise development of labial/palatal/nasal layers and creating of a pocket for placement of graft, as this will ensure creation of structural and functional integrity of the alveolar arch. A fine needle gauge is used to probe the bony edges of the cleft in order to identify the site of the first incisions (Fig. 74.5b). The initial incision must be made through the mucosa lying over the cleft and must pass down to the bony margins (Fig. 74.3a, b). Try to preserve the soft tissue on the labial and palatal sides. Adequate (and sometimes excess) tissue is usually present within the oronasal fistula, which may be sacrificed after planning for the oral layer closure. In the region of the pyriform aperture, there is no bony margin. Hence, at this site the soft tissue is divided to provide a layer for the superior most extent of the nasal closure. A similar kind of division of the mucosa is necessary on the palatal side too (Fig. 74.3c).

Next, incisions are made around the cervical region of the teeth on the labial aspect of the alveolus. The incisions should extend several teeth posteriorly from the cleft with the exact distance determined by the width of the cleft. A full-thickness mucoperiosteal dissection should be begun to raise a large advancement flap. A similar procedure is carried out on the palate, where incisions are made around the neck of the teeth followed by full-thickness mucoperiosteal dissection. As an alternative oblique sliding flaps can also be raised (Fig. 74.3a, b). As these dissections are proceeding,

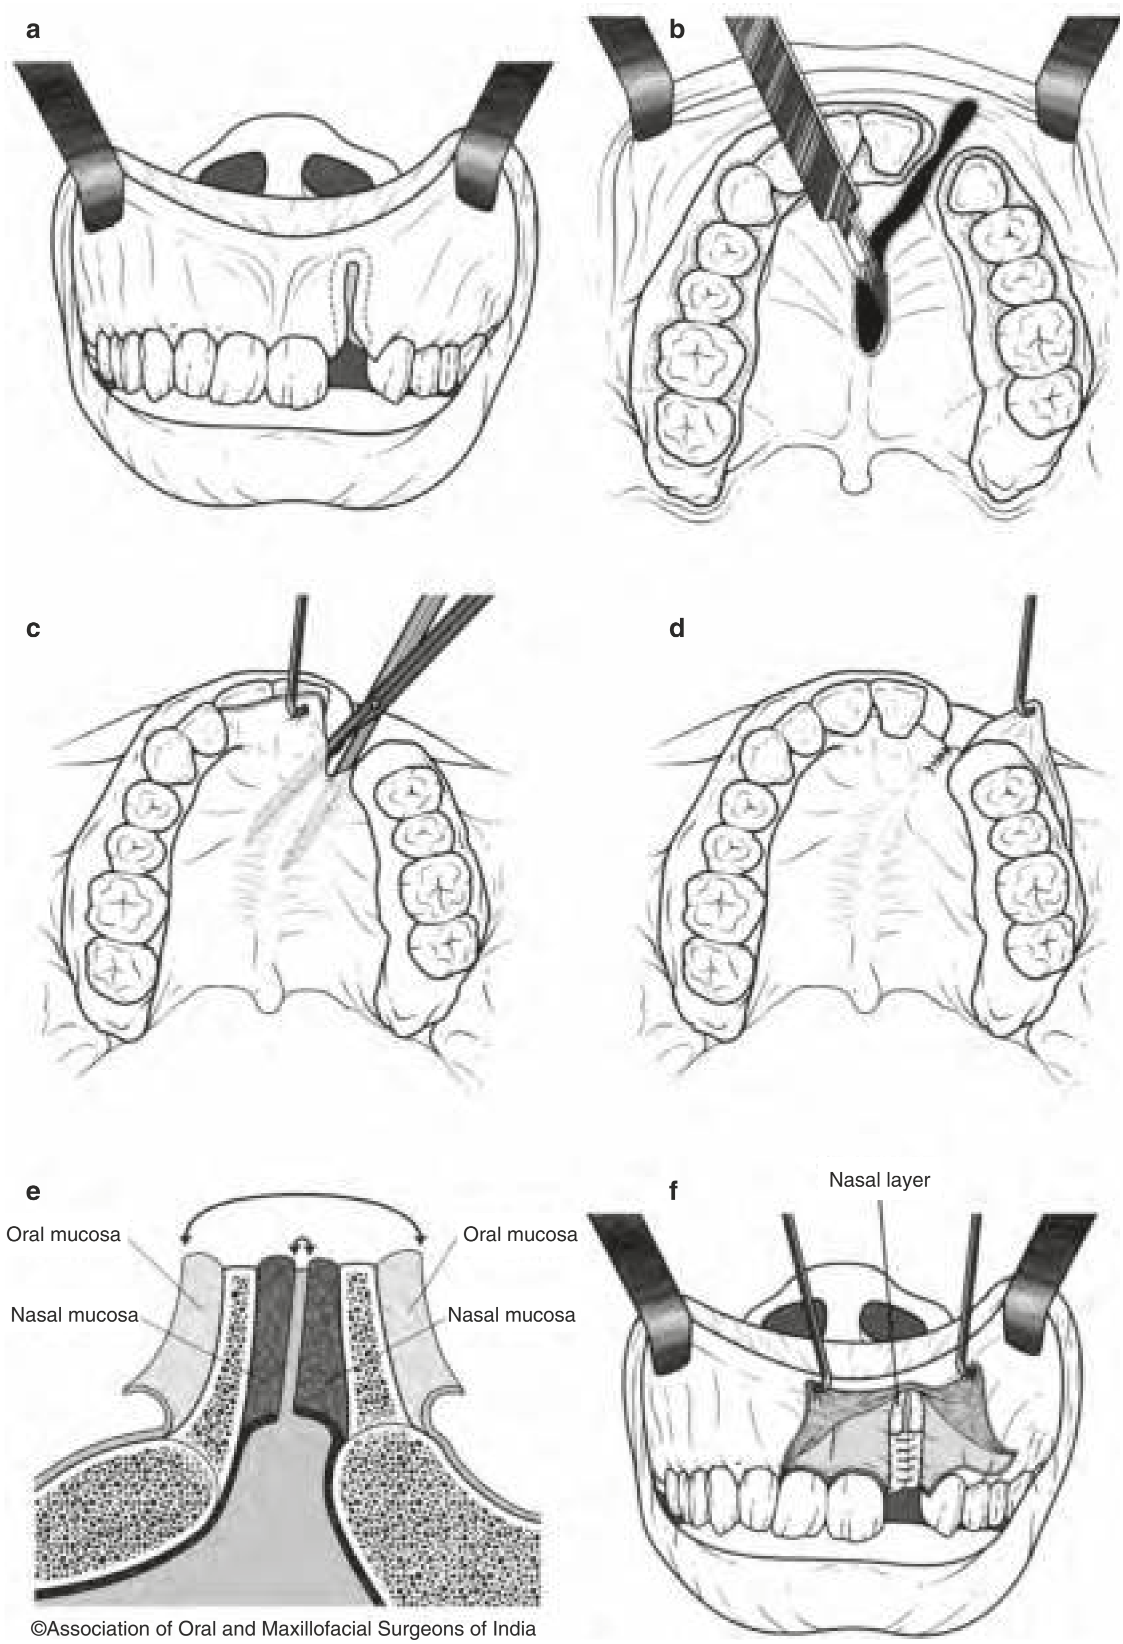

Fig. 74.3 (**a**–**f**) (**a** and **b**) Incisions around the cleft margin and for developing oblique sliding flaps (dashed lines), (**c**) Palatal flaps are developed sharply with scissors. This also separates the nasal mucosa from the palatal tissue. (**d**) Palatal closure. This can be done before or after the nasal mucosa is closed. (**e**) Depiction of the nasal mucosal flap along with the closure of the oral mucosa. (**f**) Nasal mucosal flaps are reflected from the bony walls of the cleft. The palatal flap facilitates packing and protects the palatal closure [4]

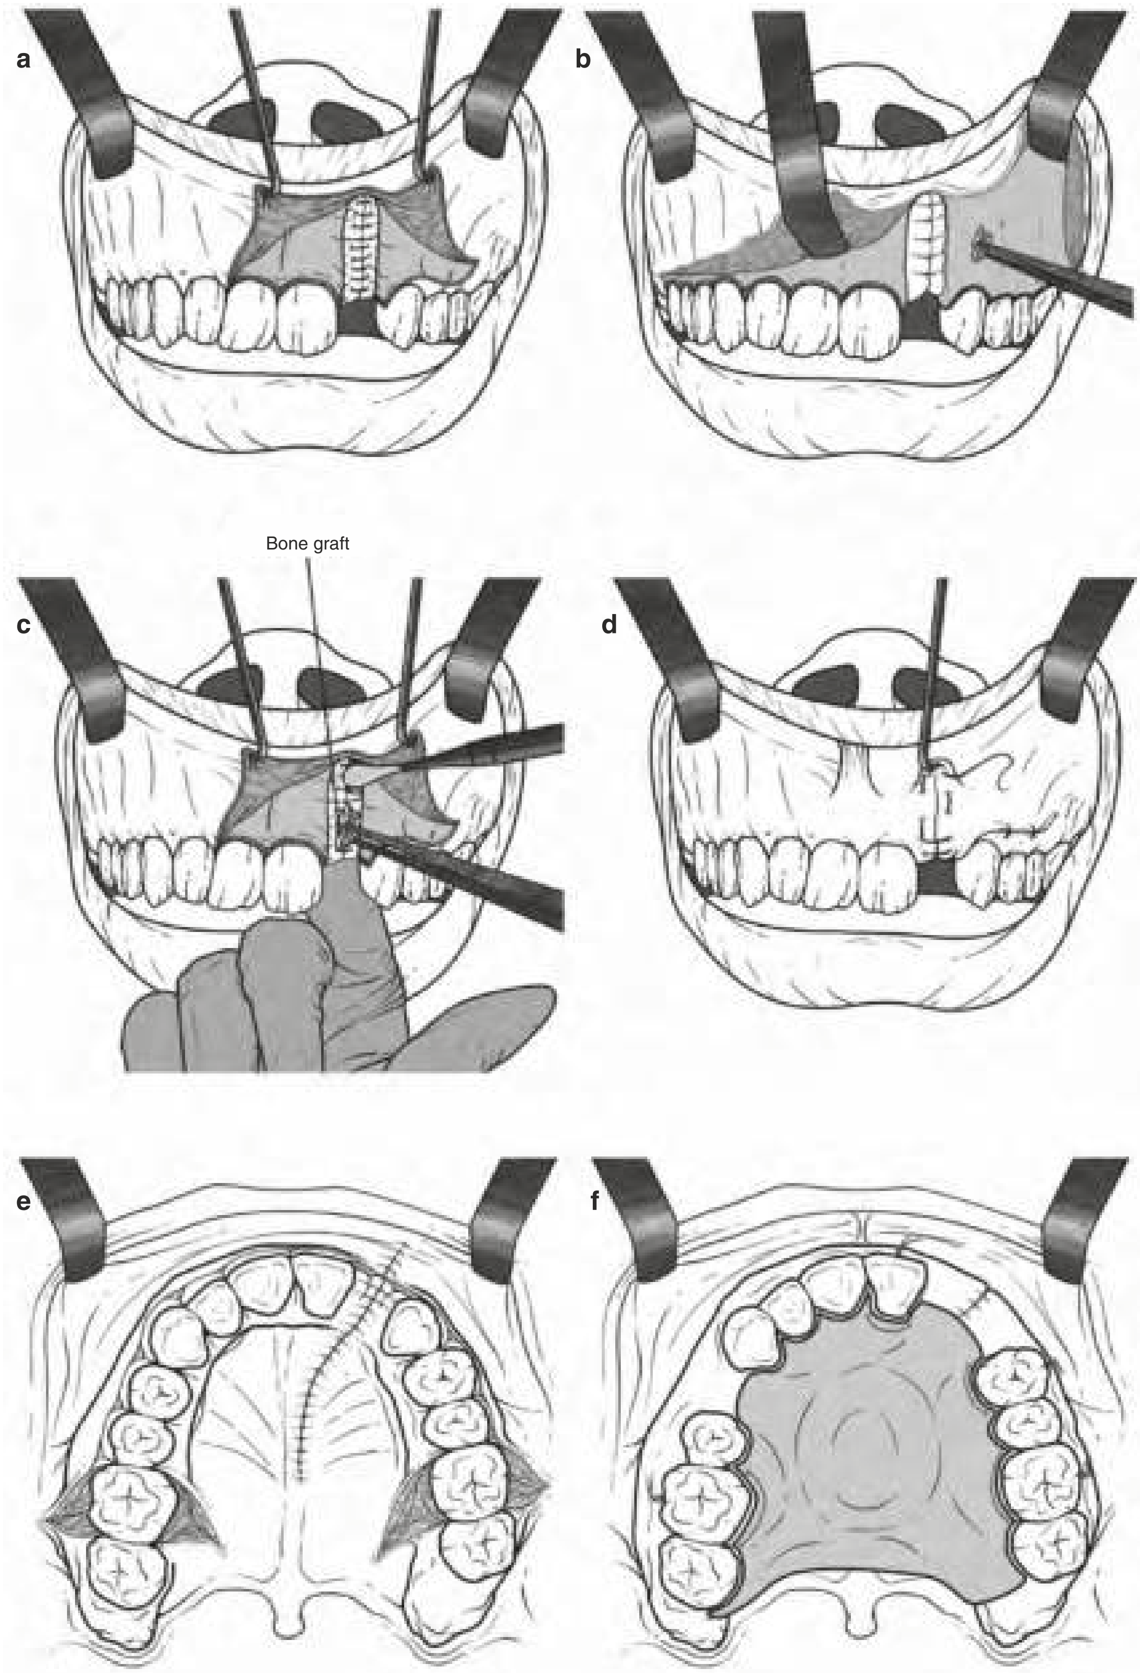

Fig. 74.4 (**a**–**f**). (**a**) Nasal flaps are approximated with sutures burying the knots when possible. (**b**) The closure of the nasal mucosa and the introduction of the bone graft to the alveolar defect. (**c**) Bone is packed into the defect with a periosteal elevator or orthodontic band pusher. Digital pressure against the palatal flap facilitates packing and protects the palatal closure [4]. (**d**) Closure of the labial oblique sliding flap. (**e**) Final mucosal closure of the labial and palatal oblique sliding flaps. (**f**) A palatal splint placed over the closure area to prevent formation of a hematoma and stabilize the bone graft

the periosteal elevator may be carried around the cleft to allow the mucoperiosteum within the fistula to be rotated superiorly. This allows the full extent of the bony cleft to be visualized. Excess tissue within the nasal portion of the cleft can be trimmed, and then the nasal flaps are sutured to provide closure of the nasal floor. This helps in the closure of a persistent oro-nasal fistula (Figs. 74.6, 74.7, and 74.8). It is ideal to evert these flaps into the nose and to use inverted

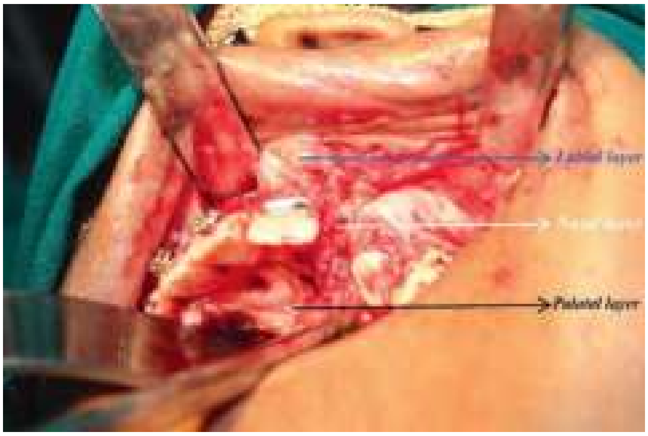

Fig. 74.8 Clinical picture demonstrating labial and palatal flap reflection and closure of nasal layer

Fig. 74.9 Clinical step in which a periosteal elevator is used to define the alveolar cleft after closure of the nasal layer

Fig. 74.10 Creation of a pouch with closure of the labial flaps in the alveolar cleft region to facilitate bone grafting

Fig. 74.12 Cancellous bone graft harvested from iliac crest

sutures so that the knots are on the nasal side. One should mobilize the palatal flaps toward the cleft (Fig. 74.8), utilizing releasing incisions if necessary. The palatal flaps may be sutured using interrupted sutures (Figs. 74.9 and 74.10).

The harvested bone is then (Figs. 74.11 and 74.12) condensed into a syringe prior to placement and packed tightly into the exposed bony cleft. While placing the bone graft, it is important to establish a normal contour to the pyriform aperture region. The labial flaps can be then advanced over the graft. This usually requires the utilization of the periosteal-releasing incisions made perpendicular to the direction of the advancement. A tension-free closure is mandatory for this technique (Fig. 74.13).

The two palatal and two labial flaps are then closed, utilizing a suture that simultaneously approximates all four corners. The final closure is completed with interrupted sutures closing the labial flaps and the interdental releases (Fig. 74.14). Closure is performed in a way that retains the attached gingiva overlying the reconstructed alveolus. Rarely, it may not be possible to obtain adequate advancement of flaps which necessitate the use of a cheek flap or a free gingival graft.

74.5.5 Postoperative Assessment of Alveolar Bone Grafting

The success of alveolar bone grafting depends on certain outcomes, which include Box 74.5.

Box 74.5 Factors Determining Success of ABG
1. Closure of the oronasal fistula.
2. Adequate bone support that allows eruption of the canine and support for adjacent teeth.
3. Architecture of the grafted bone.

Several scales are used to assess the success based on the above criteria. These scales use periapical, panoramic, or occlusal radiographs. A few of these scales are given below:

- *Bergland scale* [12] (Fig 74.15a–d).
  This scale is the gold standard of assessment, and success is judged based on the height of the post-graft interdental bone septum. It is assessed after the eruption of permanent canine. Four categories of success are defined, with

Types I and II being satisfactory outcomes and Types III and IV being unsatisfactory:
Type I: Interdental septum height is almost normal (<25% of bone resorption).
Type II: Interdental septum height is equal to or greater than ¾ of the normal height (bone resorption 25%–50%).
Type III: Interdental septum height is less than ¾ of the normal height (bone resorption 50%–75%).
Type IV: Bone graft failure; no continuous bony bridge is visible across the cleft (bone resorption ≥75%) (Fig. 74.15).

- *Chelsea scale* [14] (Fig 74.16a–f).
  This scale evaluates the presence of bone in relation to the teeth adjacent to the cleft. Based on this, six categories have been identified. Only Types A and C represent satisfactory outcomes.

Type A: Bone tissue is present at the cementoenamel junction of the teeth adjacent to the cleft. At least 75% of roots on either side are covered by bone.
Type B: Bone tissue is present at the cementoenamel junction of the teeth adjacent to the cleft. At least 25% of roots on either side are covered by bone.
Type C: Bone tissue is present and surrounds at least 75% of the roots on either side of the cleft, in an apical direction.
Type D: Bone tissue surrounds at least 50% of roots on either side of the cleft, with an apical to coronal direction.
Type E: Bone tissue bridge is present in the cleft, except in the apical and coronal directions.
Type F: Less than 25% of bone tissue is present around both roots in the apical direction (Fig. 74.16).

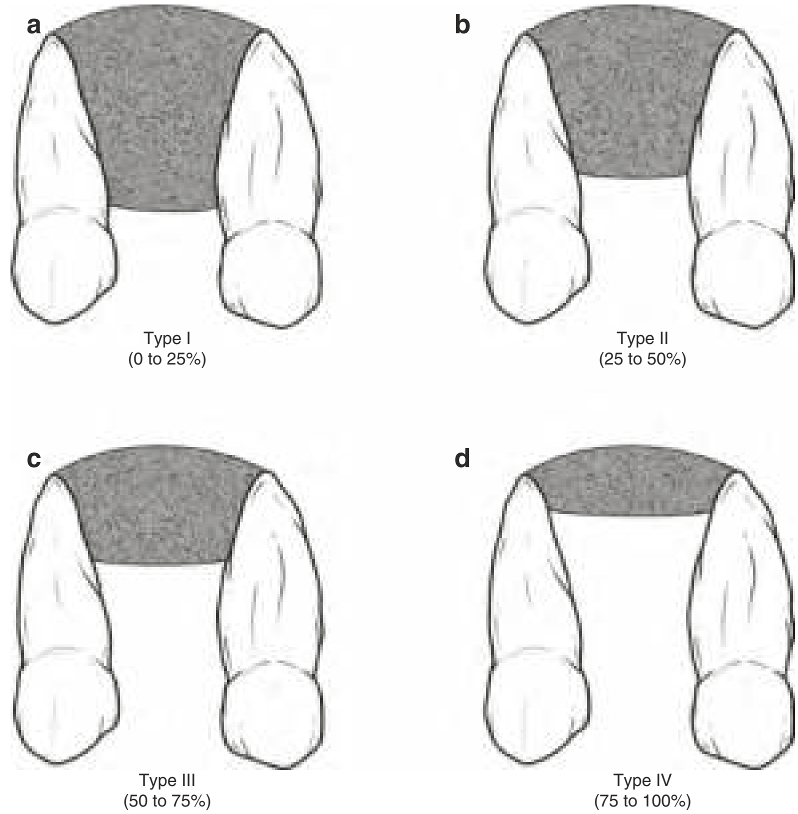

Fig. 74.15 (**a**–**d**) Bergland scale [13]

- *Trindade-Suedam scale* [15].
  These authors modified the Bergland scale described above and used alphabets to describe success or failure:

> *E* (*Excellent*): Interdental septum height is normal.
> *G* (*Good*): The bony septum is visible, with minimal disability.
> *R* (*Regular*): Bone graft is enough to allow for canine eruption. However, tooth movement is deficient, or a defect that is more than 25% of root length is seen.
> *B* (*Bad*): Deficient bone in the nasal region, which does not permit tooth movement.
> *F (Failure):* Bone graft is completely resorbed.

- *Kindelan scale* [16].
  This scale compares pre-operative and postoperative occlusal radiographs, to assess the percentage of bone fill. This also considers the eruption of the canine.

> Grade 1—Bone fill >75% (Fig. 74.17).
> Grade 2—Bone Fill 50–75%.
> Grade 3—Bone fill <50%.
> Grade 4—Complete absence of bone.

74.6 Complications of Alveolar Bone Grafting

The complications of alveolar bone grafting may be witnessed at the donor as well as the recipient site.

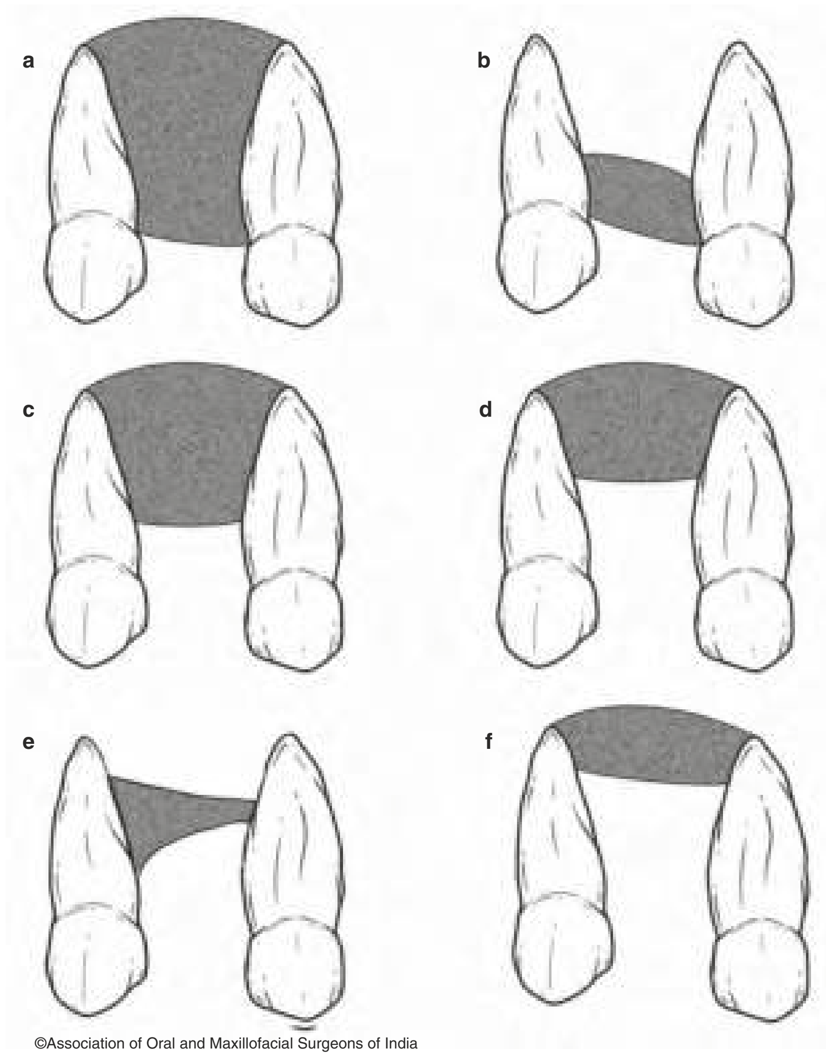

Fig. 74.16 (**a**–**f**) Chelsea scale [13]. (**a**) bone present at the Amelo-cemental Junction (ACJ) and covering 75% of both the roots, (**b**) bone present at the ACJ covering atleast 25% of both the roots, (**c**) bone covering atleast 75% of both the roots from the apical direction, (**d**) bone covering atleast 50% of the roots from the apical direction, (**e**) bony bridge present across cleft but no bone apically or coronally and (**f**) less than 25% bone cover from the apical direction

Fig. 74.17 Occlusal radiograph after bone graft with a Kindlean score of 1

74.6.1 Donor Site Complications

The site-specific donor site complications are highlighted in Box 74.6.

74.6.2 Recipient Site Complications

1. Damage to canine or central incisor roots.
2. Graft resorption: Graft resorption signifies complete failure of ABG, which can occur due to the following reasons:
   (a) Osteoresorptive cells and an environment suitable for bone resorption—this occurs with deciduous tooth extraction.
   (b) Excessive tension or trauma after surgery, resulting in exposure and loss of the graft.
   (c) Overpacking of the graft, causing alveolar notching and graft resorption. (d) Poor oral hygiene.

74.7 Conclusion

Alveolar bone grafting aims at restoring the functional integrity of the alveolar arch. In addition, they facilitate the eruption of teeth through the grafted bone into their respective positions. The timing of alveolar bone grafting is very crucial and can be effectively assessed by evaluating the thickness of bone covering the crown (of the lateral incisor or of the canine), rather than the degree of root formation of these teeth. The usage of autologous cancellous bone from the iliac crest is the most widely accepted graft in the mixed dentition period. In recent years, bone substitutes have also been used because of a tendency toward limited bone harvesting. These allograft or alloplastic sources of bone graft are especially useful in case of deficient donor autogenous bone material or to minimize donor site morbidity or in complicated cases. However, autologous bone is still the ideal choice for alveolar bone grafting, and none of the currently available methods can replace autologous bone completely. The future trend in alveolar bone grafting could be related to the usage of stem cells for bone regeneration; however many long-term clinical trials have to be conducted using stem cells to ensure its wide usage and cost-effectiveness.

Box 74.6 Donor Site Complications

(a) Iliac crest:
- Excessive blood loss.
- Hematoma.
- Delayed wound healing.
- Long and adherent and scars under belts or clothing which may be painful.
- Hypoesthesia or anesthesia over the lateral femoral cutaneous nerve and in its distribution areas.

(b) Cranium:
- Risk of inner table penetration.

(c) Rib grafts:
- Postoperative chest infection.
- Pneumothorax.

(d) Mandible grafts:
- Injury to mental nerve.

Disclosure Authors have no financial conflicts to disclose.

74.8 Case Scenarios

Case 1 (Fig. 74.18a–f)

An 11-year-old female patient who was treated for unilateral cleft lip and palate on the left side presented with the complaint of leakage of fluid from the nose and escape of air from the oral cavity. She had undergone primary unilateral lip repair when she was 6 months old, and a palatal repair was done when she was 2 years old.

Procedures, which were performed at this stage—fistula closure and alveolar bone grafting.

A sulcular incision along with incision around the fistula was performed both on the labial and palatal side so to enable direct access to the fistula and bony defect. Oral and nasal layers were separated. The nasal layer was initially closed in a watertight manner. Cancellous bone graft was obtained from the iliac crest, and the bone graft was placed into the defect, and watertight closure was obtained.

Future treatment required—pre-surgical orthodontics, orthognathic surgery, post-surgical orthodontics, and rhinoplasty (if required).

Case 2 (Fig. 74.19a–j)

Case Presentation

A 10-year-old female patient who was diagnosed with unilateral cleft lip and alveolus on the left side (Fig. 74.19a, b) reported to us with a chief complaint of leakage of fluid from the nose. She had previously undergone primary lip repair at 8 months of age. An OPG and IOPA revealed the extent of alveolar cleft (Fig. 74.19c, d). Pre-surgical orthodontic treatment was started to align the teeth and facilitate the eruption of 23 (Fig. 74.19e).

Procedures, which were performed at this stage—fistula closure and alveolar bone grafting.

A sulcular incision was placed around the involved teeth both on labial and palatal sides which exposed the fistula and the alveolar defect. A careful dissection was performed so as to separate the nasal layer and oral layer. The nasal layer was initially closed in a watertight manner. An adequate quantity of cancellous bone graft was harvested from the iliac crest. Thus obtained bone graft was placed into the alveolar defect, and a watertight closure was performed (Fig. 74.19f). The alveolar bone graft was assessed 6 months post-surgery using IOPA (Fig. 74.19g). The orthodontic treatment was completed after facilitating the eruption of canine and achieving leveling and alignment of teeth (Fig. 74.19h, i, j).

Future treatment required—Patient has to be assessed after growth completion, and if required the following treatment will have to be carried out:

- Pre-surgical orthodontics.
- Orthognathic surgery.
- Post-surgical orthodontics.
- Rhinoplasty.

75 Cleft Maxillary Hypoplasia

Philip Mathew, Mustafa. K, and Paul Mathai

75.1 Introduction

Studies of adult patients with unoperated cleft lip and palate (CLP) indicate that the maxilla in the unoperated patient is normally positioned or protruded. There are two major factors contributing to the protruded maxilla. The first is the absence of normal functional forces that are provided by the perioral muscle and tissue continuity. The tongue pressure pushes the teeth and the alveolus forward while the pressure from the cleft lip and affected perioral tissues is insufficient to balance this force out. The second factor contributing to the prognathic maxilla is the missing surgical scar [1–3].

Studies comparing unoperated cleft lip cases versus those with cleft lip repair show minimal difference in the growth of the maxilla. Thus, it has been proven that cheiloplasty has little effect on the growth of the maxilla and its dentition. On the other hand, palatal surgery has been identified as the main cause of inhibition of midface growth. Scar tissue forms across sutural areas as a result of palatoplasty surgery. This scar tissue interferes in the downward and forward translation of the maxilla that plays a major role in normal development. Furthermore, the scar tissue across the palate causes the constriction of the maxilla leading to a collapsed bite or crossbite [1–3].

Maxillary hypoplasia is a secondary deformity that occurs as a result of cleft lip and palate surgery with a reported incidence of about 9–45% with isolated cleft lip cases having the lowest incidence. The need for surgical correction of the same can be identified as early as age 10. Factors frequently associated with maxillary hypoplasia are congenitally missing maxillary teeth, revision palatoplasty procedures, pharyngeal flaps, and delayed orthodontic care [4–7]. However, recent evidence has suggested that presence of a pharyngeal flap does not affect maxillary growth [8].

75.2 Features of Cleft Maxillary Hypoplasia

Cleft maxillary hypoplasia presents as a three-dimensional deficiency. The degree of deficiency increases with the severity of orofacial clefting and affects different anatomical subunits, e.g., dentoalveolar, para-nasal, infra-orbital, and zygomatic regions. The clinical features associated with cleft maxillary hypoplasia are described in Boxes 75.1–75.3 [1–3, 7].

The presence of the cleft alveolus causes the dentoalveolar segment to collapse palatally on the affected side(s) leading to the creation of anterior and posterior crossbites. The failure to perform an alveolar bone grafting and orthodontics during the growing phase increases the severity of the malocclusion [9, 10]. The extent of this abnormal growth of the midface varies from mild to severe and is also affected by genetic endowment, the severity of clefting (extent of orofacial and labio-palatal involvement), timing of surgery, surgeon skills, and the number of primary and revision surgeries performed in the process of re-habilitating the patient. It has not been conclusively proven if any particular palate closure technique or if a staged technique has reduced effects on maxillary growth. It is the author's opinion that techniques that leave a raw area on the palate like push-back palatoplasty are generally associated with greater maxillary regression [1–3, 11–15].

Disclosures: The authors have no financial conflicts to disclose

Box 75.1: Primary Features of Cleft Maxillary Hypoplasia

- Concave facial profile
- Class 3 skeletal relationship,
- Increased scleral show,
- Lack of normal cheek contour,
- Inadequate support of nasal tip and upper lip,
- Short upper lip and Acute nasolabial angle [subject to variability],
- Steep mandibular plane angle,
- Retruded chin,
- Decreased posterior facial height,
- Increased anterior facial height,
- Anterior and posterior cross bites,
- Increased mandibular plane – cranial base angle,
- Anterior open bite [less common],
- Chin and mandibular skeletal asymmetry [less common].

Box 75.2: Secondary Residual Deformities in Cleft Lip and Palate Patients

– Speech and hearing impairments (chronic otitis and velopharyngeal insufficiency)
– Residual oronasal fistula
– Residual bony defects
– Obstructive nasal breathing (septum deformity/ enlarged inferior turbinates/intranasal strictures/ enlarged tonsils and adenoids/pharyngeal flaps)

Box 75.3: Dental Anomalies in Cleft Lip and Palate Patients

– Delayed eruption of teeth, severe crowding of arches (with impacted, malformed and supernumerary teeth)
– Palatally collapsed dentoalveolar segments (cleft side)
– Anterior and posterior crossbites
– Anomalous or missing lateral incisor, infra-erupted, rotated, and tipped cleft-adjacent teeth

In most cases, photographic and cephalometric analysis reveals that the mandibular plane-cranial base angle is increased leading to a more backwardly placed mandible. Thus, the mandible tends to have a mild retrognathic appearance in spite of having normal dimensions. An anterior open bite is observed if the patient has an underlying tongue thrust habit as well. In certain rare cases, the chin and mandible may also exhibit a degree of skeletal asymmetry [1–3] (Box 75.2).

The need for orthognathic surgery should be based not only on occlusion and jaw relationship but also on facial proportions, midface projection, and complaints of the patient [1–3].

75.3 Objectives of Treatment (Box 75.4)

Box 75.4: Objectives of Treatment in Cleft Maxillary Hypoplasia

1. To improve facial aesthetics
2. To improve psychological health
3. Achieve adequate occlusion for efficient mastication
4. Improve phonation and airway dimensions
5. Avoid deterioration of velopharyngeal insufficiency

75.4 Sequencing Treatment in CMH (Box 75.5)

Box 75.5: Sequencing Treatment in CMH

1. Growth modulation—7–16 years.
2. Phase 1 orthodontics—7–11 years
3. Alveolar bone grafting—8–11 years
4. Phase 2 orthodontics—12–17 years
5. Anterior maxillary distraction—after 12 years
6. Orthognathic surgery at 17 years and up
7. Phase 3 orthodontics after orthognathic surgery

75.5 Orthodontics in Cleft Lip and Palate Patients

Owing to the severity of the condition, period of orthodontics can be prolonged and is carried out in three phases. Sometimes patients with CLP have a limited ability to open their mouth further increasing the difficulty of orthodontic treatment.

Phase 1 Treatment It is carried out between 7 and 12 years of age. Maxillary transverse expansion is carried out in cases that present with maxillary constriction. Maxillary protraction may be carried out in cases with significant midface regression. This phase also involves monitoring facial growth, space management, monitoring eruption of permanent teeth, and preventing ectopic eruption of permanent teeth [1–3].

In preparation for secondary alveolar bone grafting, extractions of supernumerary teeth and deciduous teeth on either side of the cleft and closure of oronasal fistulae are performed [16]. Box 75.6 outlines the controversy regarding whether maxillary expansion should be performed before or after alveolar bone grafting [17–19].

Box 75.6: Arch expansion, before or after Alveolar Bone Grafting (ABG)

Expansion before ABG	Expansion after ABG
Greater expansion can be achieved with the lower bony resistance between the maxillary segments	Though expansion is possible, the degree of expansion obtained is less predictable
Nasal floor mucosa layer can be easily visualized and reconstructed as the cleft has been widened	Difficult to visualize and reconstruct the nasal floor mucosa layer as the cleft is narrow
Widening of the cleft alveolus leads to increased tension on the overlying suture site after grafting, which increases the risk of wound dehiscence and graft failure	As the cleft is narrow at the time of grafting, there is lesser tension on the overlying suture site after grafting, which reduces the risk of wound dehiscence and graft failure
Increased risk for cleft-adjacent teeth moving into the cleft alveolus while widening, thus compromising their periodontal support	Decreased risk of loss of periodontal support as the teeth will move into an already grafted cleft alveolus
Clinical studies have shown that there is minimal risk for graft loss when expansion was performed before grafting	Clinical studies have shown that bone graft was not lost when expansion was performed after grafting; instead, some degree of stimulation of graft took place

Phase 2 (Presurgical phase) Treatment It is carried out between 12 and 17 years of age. It involves maintaining the previously attained expansion and further expanding the arch in cases of relapse or if no prior expansion was done. In case the skeletal discrepancy is minimal, we can also consider camouflage orthodontics to correct the occlusal discrepancy. Camouflage orthodontics involves correction of crowding and rotations, extraction of teeth that have erupted ectopically and cannot be accommodated, proclination of maxillary incisors, and retraction of mandibular incisors.

In case the skeletal discrepancy is moderate to severe, then we will have to consider surgical correction (distraction osteogenesis or orthognathic surgery) of the deformity. Presurgical fixed orthodontics is started to facilitate the planned skeletal movements and is described in Box 75.7.

Box 75.7: Objectives of Pre-surgical Orthodontics

- Removal of dental compensations
- Alignment of teeth, de-crowding and de-rotation of teeth
- Flattening of the curve of Spee
- Incorporating divergence in roots for segmental osteotomies
- Co-ordination of dental arches

In case the lateral incisor is missing, the decision to maintain space for prosthetic rehabilitation or substitute it with the adjacent canine needs to be made during this phase [1–3]. There is also a need to extract the mandibular third molars in case a bilateral sagittal split osteotomy is planned. There is an increased risk for bad splits associated with un-erupted and impacted mandibular third molars in the age group of less than 20 years on account of thinner and immature cortical bone [20].

Phase 3 (Postsurgical Phase) Treatment It is performed after surgical correction of the facial deformity (orthognathic surgery or distraction osteogenesis). It involves fine-tuning of the occlusion and maintaining achieved results in the long term through retentive appliances. One may have to consider re-creating dental compensations to accommodate for increased rates of relapse after cleft-orthognathic surgery.

75.6 Considerations Before Surgery

75.6.1 Timing of Surgery

Facial growth is normally completed by 16 years of age in females and by 17 years of age in males. It is advisable to perform orthognathic surgery only after skeletal maturity is achieved, in order to increase stability of the surgical results in the long term. In selective cases, orthognathic surgery is performed during growth for psychosocial or functional reasons. However, this has shown unpredictable results because of continued growth of the mandible with relapse rates in the range of 50–70% when operated before 18 years of age [2, 21, 22].

As an alternative, one may consider distraction osteogenesis prior to 17 years of age. A study by Meazzini et al. [23] reported a relapse rate of 26% in the long term when distraction osteogenesis of the maxilla was carried out during the growing phase. A systematic review by Liu et al. [24] reported a relapse rate 12–46% at "point A" and 26–77% for the SNA angle in the long term. Thus, the patient will require additional surgery after skeletal maturity for correction of the residual facial deformity, irrespective of whether distraction osteogenesis or orthognathic surgery was performed.

75.6.2 Status of Alveolar Bone Grafting and Oronasal Fistulae

Patients with cleft lip and palate usually present with a cleft alveolus. This cleft communicates with the nasal cavity, thus, creating an oronasal fistula. The cleft is also a source of weakness in the maxillary arch and increases the risk of arch collapse, thus, creating dentoalveolar deformities (e.g., crossbites) which make later surgical procedures like orthognathic surgery unstable. Lastly, the permanent teeth that erupt into the cleft will have a poor prognosis due to lack of bony support and inadequate periodontium. Thus, it is of utmost importance to graft the cleft alveolar region, and the benefits associated with it are described in Box 75.8 [9, 25].

Box 75.8: Benefits of Alveolar Bone Grafting

Reduction of oronasal fistula, creation of continuity of the maxillary alveolar arch, eruption of permanent teeth into the cleft site, elevation of the alar nasal base, and stability for future surgical procedures like orthognathic surgery and rhinoplasty

A prerequisite to a successful alveolar bone grafting is the closure of oronasal fistulae. Small fistulae can be closed at the time of grafting. However, the presence of a large fistula requires a staged reconstruction with the fistula closure initially and alveolar bone grafting later.

It is not rare to see a patient with a complaint of maxillary regression who presents at a later age (17 years and above) with a history of no alveolar bone grafting or failed alveolar bone grafting. If we proceed with a LeFort I osteotomy in this clinical scenario, the difficulty of the surgical procedure increases significantly as the maxilla is not a single unit. There are three possible treatment protocols that we can follow:

1. The patient is willing to undergo a staged approach with alveolar bone grafting followed by orthognathic surgery at later stage. Though this is the ideal approach, it adds to the cost and time of overall treatment. It is important to note that tertiary alveolar bone grafting has an overall lower success rate [26, 27].
2. The patient is willing to undergo alveolar bone grafting as long as it is done simultaneously with orthognathic surgery. This approach saves time and cost of overall treatment. Keeping in mind that tertiary alveolar bone grafting already has a lower success rate; it is the author's opinion that risk for graft failure might increase when this step is combined with orthognathic surgery. This is on account of the compromise in vascularity that occurs as extensive mucoperisoteal flap refelction is performed to accomodate orthognathic surgery.
3. In case the patient wants to avoid bone grafting, one can use the modified LeFort I osteotomy approach by Posnick et al. [3, 28, 29]. It allows for simultaneous correction of maxillary hypoplasia, cleft dental gaps, alveolar defects, and small residual oronasal fistulas through the use of modified skeletal osteotomies. The cleft alveolar defect is closed by differential repositioning of the cleft maxilla segments. This technique requires a transverse plate to be placed across the cleft site just below the pyriform aperture so as to convert the cleft-maxilla into a single unit. In a study by Posnick et al. [30], the modified LeFort I osteotomy technique had stable results in more than 90% of the subjects at 1 year with a low complication rate. It is the author's opinion that along with the midline transverse plate, one can also use a dental prosthesis (fixed partial denture) spanning the cleft alveolus site to add stability to the cleft maxilla. However, there is a risk for failure of the prosthesis and loss of abutment teeth in the long term due to increased movement across the cleft alveolus site.

75.6.3 Velopharyngeal Insufficiency (VPI)

If air or sound is allowed to leak through or resonate in the nasal cavity during the production of the non-nasal sounds (all phonemes except /m/, /n/, and /ng/), speech will be marked by hyper-nasality (nasal twang) and nasal air emission. VPI describes a structural or anatomic defect that prevents closure of the velopharyngeal mechanism during function. It is most commonly observed in patients with an overt cleft palate (unoperated > operated cases) and submucous cleft palate. In operated cleft palate patients, the incidence of VPI can range between 20 and 50% [31]. Chua et al. [32] and Pereira et al. [33] proposed the usage of perceptual speech assessment, acoustic measurement with nasometer, video nasoendoscopy (or video fluoroscopy), and cephalometric analysis for the assessment of preoperative speech and VPI.

When the maxilla is advanced in operated cases of the cleft palate, speech articulation is improved on account of improved lip competency and correction of previous dental malocclusion [34, 35]. There is also an associated increase in the velopharyngeal cavity depth [36]. As compared to the normal palate, the scarred cleft palate has decreased ability to adapt to such changes as it is unable to stretch adequately [37] This leads to an increase in the risk for worsening of preoperative VPI. The effect of maxillary advancement on VPI, especially in cleft palate patients, is still a controversial topic [34, 38].

There are two methods that are commonly used to advance the maxilla as given in Box 75.9.

Box 75.9: Methods Used for Maxillary Advancement

1. Distraction osteogenesis: total maxillary distraction and anterior maxillary distraction
   (a) Total maxillary distraction: internal maxillary distraction and rigid external distraction
2. Conventional orthognathic surgery

The theoretical advantage of distraction is that the maxilla is advanced slowly which allows the patient to adapt to the changes in the velopharyngeal dimensions through increased velar muscle activity. Furthermore, distraction can be halted at any point of time that speech begins to deteriorate. Orthognathic surgery, unlike distraction, creates an immediate surgical advancement of the maxilla and does not allow speech to be assessed incrementally or allow for gradual adaption of the palate to the increase in the velopharyngeal cavity depth.

A randomized controlled trial by Chua et al. [32] for moderate maxillary advancement (4–10 mm) in cleft patients demonstrated that distraction osteogenesis had no advantage over orthognathic surgery for the purpose of preventing velopharyngeal incompetence and speech disturbance. Furthermore, no correlation was found between the amount of advancement and speech parameters. However, it should be noted that extreme advancements of the maxilla (greater than 10 mm) were excluded from the study.

A study by McComb et al. [37] helped identify predictors for worsening of VPI in cases of cleft maxillary advancement using conventional orthognathic surgery. Short preoperative soft palate, large postoperative velopharyngeal cavity depth, preoperative perceptual speech assessment, nasometry, and video nasoendoscopy were identified as clinically significant predictors. Preoperative velopharyngeal cavity depth was not considered a satisfactory predictor as changes in the velopharyngeal space did not correspond proportionally to maxillary advancement [39]. Lastly, the span of maxillary advancement (2–16 mm) did not show a significant association with the worsening of VPI [37].

Janulewicz et al. [35], Philips et al. [40], Alaluusua [41], Smedberg [42], Seok-Kwun Kim et al. [43], Kelly Schultz et al. [44], and Pereira et al. [33] studied the relation between postoperative worsening of VPI and maxillary advancement using conventional LeFort I osteotomy in cleft patients. They established that preoperative borderline and higher grades of VPI were highly prone to worsening in the postoperative phase. Absent to negligible VPI pre-operatively, carries minimal risk of worsening during the post-operative period. Furthermore, the amount of maxillary advancement and the cleft type did not influence the degree of worsening of VPI. In the author's opinion, the only confounding factor in the above studies was that some of the patients already had a preoperative pharyngeal flap.

A study by Trindade et al. [45] suggested that deterioration in the VPI after orthognathic surgery was transient and improved over time. Compensatory changes are known to occur in the velopharyngeal region during that time as documented by the study of Yu Wu et al. [36]. The velar length and angle and the velopharyngeal depth all increased. However, velar thickness, posterior pharyngeal wall thickness, and velar motility remained unchanged. During certain phonations, the motion of the posterior pharyngeal wall and the thickness of the Passavant's ridge increased significantly. Thus, it is advisable to wait for at least 1 year prior to considering surgical correction for VPI [35].

Poole et al. [46] and James et al. [47] suggested alternative surgical approaches to the routine LeFort I maxillary advancement which involved transecting the palatal mucosa followed by mobilizing the soft palate lying distal to the incision. This was combined with strategically placed vertical incisions in the maxillary buccal mucosa to avoid circulation injury. The advantage of the procedure was that the maxilla could be advanced by large amounts without worsening of speech and VPI as the soft palate did not move anteriorly with the maxilla. The disadvantage of the procedure was that a significant portion of the palate was left denuded and was expected to heal secondarily. Though the results were promising, the techniques did not become mainstream.

Anterior maxillary distraction (AMD) is a versatile, stable, and simple technique that can be used to correct the maxillary dentoalveolar regression in the cleft maxilla after the mixed dentition phase (Video 75.1). As the osteotomy is anterior to the junction of the hard and soft palate, the velopharyngeal dimensions and soft palate activity are not affected. Thus, it is considered optimal for the correction of cleft maxillary regression in cases with preoperative moderate to severe VPI. When used in the age group of 10–16 years, there is also an associated posterior movement of the distal maxilla owing to the elasticity of the bone which may also reduce preoperative VPI to a certain extent. An added advantage is that the increased arch length can be used to accommodate un-erupted teeth and correct crowding [48–53].

In case postoperative VPI develops, it is advisable to wait and watch for at least 1 year prior to resorting to surgical correction. During this period, one can try conservative methods like speech therapy and bulb palatal lift prosthesis and minimally invasive methods like autologous fat injections into the soft palate and the posterior pharyngeal wall [31, 54, 55]. If the VPI does not improve to a clinically acceptable level even after a year, then surgical options need to be considered.

In terms of risk of development of postoperative obstructive sleep apnea, Furlow palatoplasty and buccal myomucosal flaps have the least adverse effect followed by sphincter pharyngoplasty and finally pharyngeal flap which has the most adverse effect [56, 57]. Nonetheless, the pharyngeal flap is the most commonly used method, and a recent paper by Dentino et al. [58] demonstrated that the superiorly based pharyngeal flap was highly successful in correcting VPI after cleft maxillary advancement.

75.6.4 Degree of Maxillary Hypoplasia

The classification of cleft maxillary hypoplasia is given in Box 75.10.

Box 75.10: Classification of Maxillary Hypoplasia

- Mild cases—reverse overjet below 6 mm
- Moderate cases—reverse overjet between 6 and 10 mm
- Severe cases—reverse jet between 11 and 16 mm
- Extreme cases—reverse overjet equal to or greater than 17 mm

The above classification of maxillary hypoplasia needs to be combined with the age at which the patient presents for optimal treatment planning. It should be noted that the regression is calculated only on the basis of reverse dental overjet. The presence or severity of para-nasal hollowing is not accounted for in the above classification.

75.7 Treatment Plans

75.7.1 Pearls for Treatment Planning

- If surgical treatment (distraction osteogenesis or orthognathic surgery) is performed prior to the skeletal maturity, there is a high chance of relapse due to continued skeletal growth. Thus, additional surgery will be required to correct the residual skeletal deformity. Nonetheless, distraction osteogenesis is preferred over orthognathic surgery in the growing patient.
- Time constraints and patient's needs might require you to modify the ideal treatment plan. Though the overall facial profile is important, it is equally essential to establish a functional occlusion with positive overjet and good intercuspation as they go a long way in preventing relapse.
- Procedures like camouflage orthodontics, face mask protraction, and anterior maxillary distraction produce a greater change at the dentoalveolar level and fail to significantly improve para-nasal hollowing. In case of AMD, the anterior maxillary osteotomy does not extend sufficiently enough in to the posterior and superior aspect of the zygomaticomaxillary buttress region.
- Orthognathic surgery and total maxillary distraction (TMD; subtypes, internal maxillary distraction and rigid external distraction) can both correct para-nasal hollowing when combined with a modified high-level LeFort I osteotomy.
- While operating, the facial profile and occlusion can be immediately appreciated during orthognathic surgery. Results can similarly be approximated in total maxillary distraction (TMD) by activating the distractor to the desired extent on the operating table. This is possible as the posterior extent of a conventional LeFort I osteotomy lies in the region of the more mobile soft palate.
- While performing anterior maxillary distraction, the final facial profile and occlusion cannot be immediately appreciated on the OT table as the posterior extent of the maxillary osteotomy lies anterior to the permanent first molar. The palatal mucosa in this region is firmly attached to the underlying bone, and excessive activation of the distractor can lead to stripping of the mucosa from the underlying bone.
- Masticatory efficiency is not significantly compromised during AMD, as the device is fairly rigid and the posterior limit of the osteotomy is anterior to the permanent first molars. A complete LeFort I osteotomy, like that used in total maxillary distraction (TMD), reduces masticatory efficiency on account of increased mobility of the whole maxilla on the application of masticatory loads.
- One needs to take into account that a reverse overjet of "x mm" requires a net advancement of "$x + 2$ mm" to obtain adequate overjet and overbite. Hence, a reverse overjet of 8 mm requires a net advancement of 10 mm for adequate correction. If one wants to accommodate for expected relapse, then one needs to overcorrect by at least 20%. Hence, the actual amount of advancement required would be 10 + 2, i.e., 12 mm.
- Limits of movements with orthognathic surgery: Conventional orthognathic surgical advancement of the maxilla beyond 10 mm increases the risk of relapse on account of the scar tissue in the soft palate and upper lip

regions. As the mandible is usually unaffected in cleft maxillary hypoplasia, a setback beyond 8 mm leads to a poor aesthetic result and is also associated with higher relapse rates.

- A reverse overjet of 16 mm in cleft maxillary hypoplasia requires a net advancement of 18 mm. The maxilla can be advanced by 10 mm, and the mandible can be setback by 8 mm to achieve the desired correction. Thus, a reverse overjet of 16 mm can be treated by orthognathic surgery with acceptable stability in the long term. Although it is possible to treat a reverse overjet greater than 16 mm with orthognathic surgery, it is associated with a higher relapse rate.
- When the cleft maxilla is advanced > 10 mm, there is an increased risk of damage to the palatal vascular pedicle on account of the inability of the scarred soft palate to stretch and accommodate the change [59]. Furthermore, there is also risk of suture site dehiscence in the maxillary labial vestibule as this region would be closed under tension on account of the presence of scarred tissue with minimal elasticity [37, 60].
- Distraction osteogenesis (AMD/TMD) can be used for all spans of maxillary advancement and is preferred for advancements > 10 mm on account of the stability of results in the long term [61, 62]. There is also minimal risk of damage to the palatal vascular pedicle as the advancement is gradual and a certain degree of histogenesis accompanies the distraction osteogenesis.
- The span of movement (small or large) or mode of advancement (total maxillary distraction or orthognathic surgery) is not to be associated with an increased risk for deterioration of preoperative VPI.
  – Determining preoperative speech and VPI status is a must: perceptual speech assessment, acoustic measurement with nasometer, video nasoendoscopy (or video fluoroscopy), and lateral cephalometric analysis.
  – If there is no preoperative VPI, then there is minimal risk for worsening of speech and occurrence of VPI postoperatively.
  – If there is borderline (or greater) VPI preoperatively, then there is a high risk for worsening of VPI postoperatively.
  – Wait for at least 1 year before considering surgical correction of postoperative VPI.

75.7.2 Age Group of 6–11 Years (Fig. 75.1)

The patient has a mixed dentition during this phase. There are multiple un-erupted dental follicles present that can pose a problem to certain surgical procedures. Alveolar bone grafting is preferably performed during this phase as it is associated with higher success rates [26]. Large oronasal fistulae, if present, need to be closed prior to secondary alveolar bone grafting.

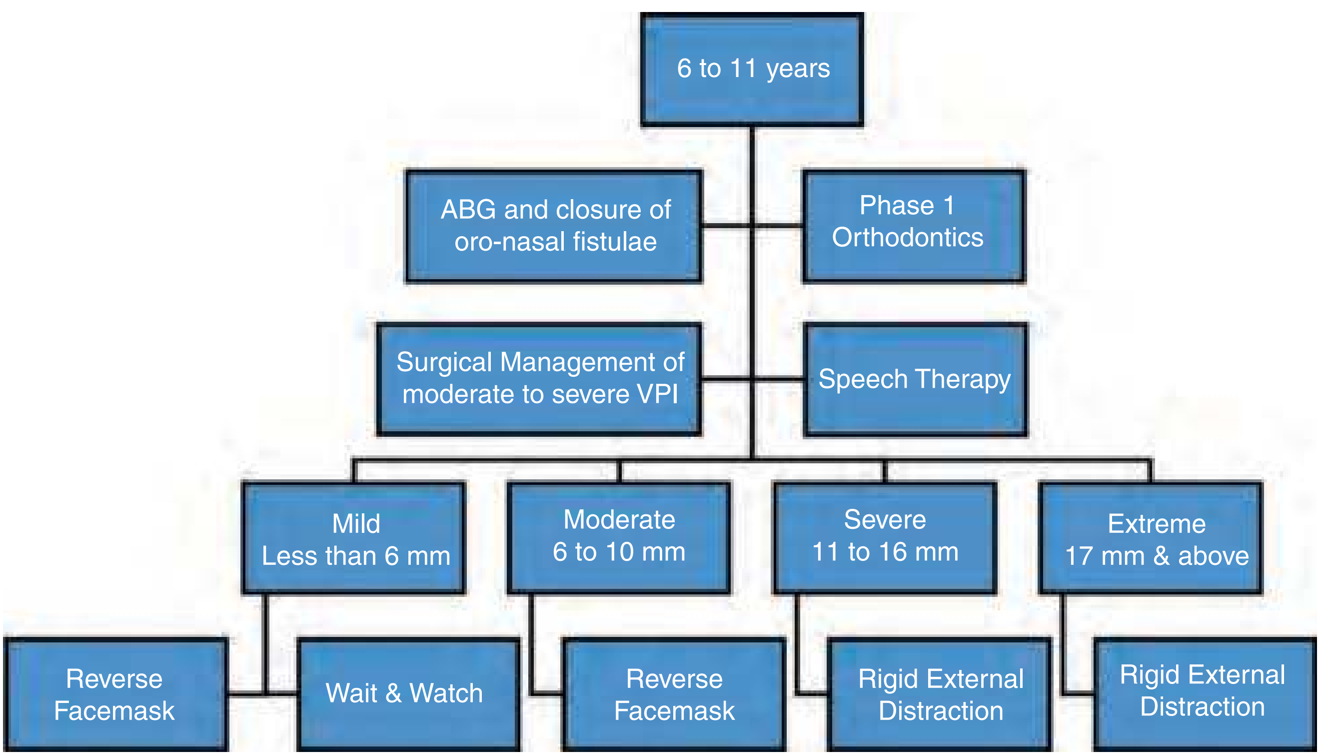

Fig. 75.1 Treatment plan for age group 6–11 years

If the child presents with a mild regression, one can choose to wait and watch or proceed with dentofacial orthopedics using a reverse pull headgear to achieve protraction of the maxilla. If the child presents with moderate regression, then one must proceed with reverse pull headgear therapy to achieve some degree of correction.

The usage of reverse facemask therapy requires considerable patient co-operation and works by stimulating growth at the various maxillary suture sites (Fig. 75.2a–c). It is usually combined with a maxillary expansion appliance that helps disrupt the circum-maxillary sutural system and increase the effects of the orthopedic face mask. The general effect produced is that of a downward and forward movement of the maxilla, backward rotation of the mandible, and a net increase in the lower facial height. However, the response varies widely from individual to individual, and long-term stability is also questionable [7, 63–66].

The stability and extent of correction with reverse facemask therapy reduces with increasing severity of labio-palatal clefting and absence (or failure) of prior alveolar bone grafting [63–66]. The degree of ossification of the zygomaticomaxillary buttress also plays an important role in the results of facial protraction therapy. Earlier stages (younger age group) of ossification are associated with a greater span of movement and skeletal and dental changes. Later stages of ossification (older age group) are associated with a smaller span of movement and mainly dento-alveolar changes [67, 68]. Today, skeletal anchorage is slowly replacing traditional tooth borne anchorage on account of better control of degree of rotation of the mandible and greater potential for skeletal movements [69, 70]. In patients who are less co-operative, one can consider using a modified technique with inter-maxillary elastics between a miniplate secured to the zygomaticomaxillary buttress region posteriorly and another miniplate secured to the mandible anteriorly (Bone-anchored maxillary protraction - BAMP). This technique has provided promising results which are comparable to traditional reverse facemask therapy. However, this modification can be performed only after the eruption of the mandibular canine to allow for plating in the anterior mandible [69, 71, 72].

Very rarely will a child present with severe or extreme regression in this age group. Rigid external distraction (RED) is the only option available for the correction of such a severe discrepancy and is mainly used in syndromic patients presenting with moderate to severe obstructive sleep apnea and in patients with a poor psychological status. RED allows for high osteotomies as it does not rely on rigid fixation techniques to secure the distractor. This helps avoid injury to tooth follicles in the growing patient while simultaneously correcting para-nasal hollowing. On the contrary, internal total maxillary distraction (ITMD) and anterior maxillary distraction (AMD) cannot be used as the lower-level osteotomies used in these procedures will damage the un-erupted dental follicles. The plates of the internal distractor also need to be secured to the bone with screws, which will also cause damage to the tooth follicles.

In spite of the above treatments, it is difficult to maintain results in the long term on account of continued mandibular growth. Thus, surgery will mostly be required once the patient reaches skeletal maturity to correct any residual skeletal deformity. However, the final amount of maxillary advancement will be much lesser resulting in increased post-operative stability of the cleft maxilla.

75.7.3 Age 12–16 Years (Fig. 75.3)

All permanent teeth (except the third molars) have erupted. The absence of un-erupted dental follicles makes procedures like AMD and ITMD (internal total maxillary distraction) feasible in this age group. Due to deficient arch length, there may be moderate to severe crowding. Some permanent teeth may have remained un-erupted, impacted, or erupted ectopically adding to the complexity of the treatment. If alveolar bone grafting has not been done prior or has failed, it needs to be performed during this phase. Large oronasal fistulae, if present, also need to be closed in preparation for orthognathic surgery.

If the regression is mild to moderate, one can consider camouflage orthodontics, maxillary protraction therapy, or AMD in order to create an acceptable occlusion. Alternatively, we can choose to wait and watch and directly correct the maxillary hypoplasia once growth is complete (Fig. 75.4a, b).

Severe to extreme maxillary regression is preferably treated with AMD. The available span of most commercially available hyrax screws does not exceed 13 mm. Thus, there are two options available to the clinician: repeat the AMD twice in a single stage or in a two-staged manner (at least 1 year apart) [50]. The author prefers to repeat the AMD activation twice, in a single stage. This requires the fabrication and immediate application of a fresh appliance, once the first appliance has attained complete activation of the incorporated Hyrax screw. Great care should be taken to avoid excessive pressure on the anterior maxilla while fitting the new appliance as the callus is not fully mature and large forces may easily destroy it. Alternatively, we can consider total maxillary distraction (ITMD or RED) (Figs. 75.5a–d and 75.6a–f) as long as the patient does not have moderate to severe preoperative VPI (Also see Fig. 70.17).

In spite of the above treatments, it is difficult to maintain results in the long term on account of continued mandibular growth. Thus, surgery will mostly be required once the patient reaches skeletal maturity to correct any residual skel-

etal deformity. However, the final amount of maxillary advancement will be much lesser resulting in increased postoperative stability of the cleft maxilla.

75.7.4 Age 17 Years and Above (Fig. 75.7)

If prior alveolar bone grafting has failed or has not been performed, a decision should be made as to whether it needs to be performed or not. Large oronasal fistulae, if present, need to be closed in preparation for orthognathic surgery.

If the regression is mild to moderate and VPI is absent or negligible, then either total maxillary distraction, AMD, or orthognathic surgery can be performed. Orthognathic surgery is preferred in this scenario as we can achieve immediate improvement in facial profile and occlusion (Figs. 75.8a–h, 75.9a–h). If there is moderate to severe VPI preoperatively, then it is advisable to perform AMD to avoid further deterioration of the same.

If the regression is severe to extreme and the VPI is absent or negligible, then either orthognathic surgery (Fig. 75.10a–f), AMD, or TMD can be performed. AMD may have to be repeated twice in the same sitting or in a stage manner as described previously. If optimal esthetics is the goal, then AMD followed by conventional LeFort I maxillary advancement is the ideal treatment plan (Fig. 75.11a–g). The only drawback of this procedure is the prolonged treatment duration as a minimum waiting period

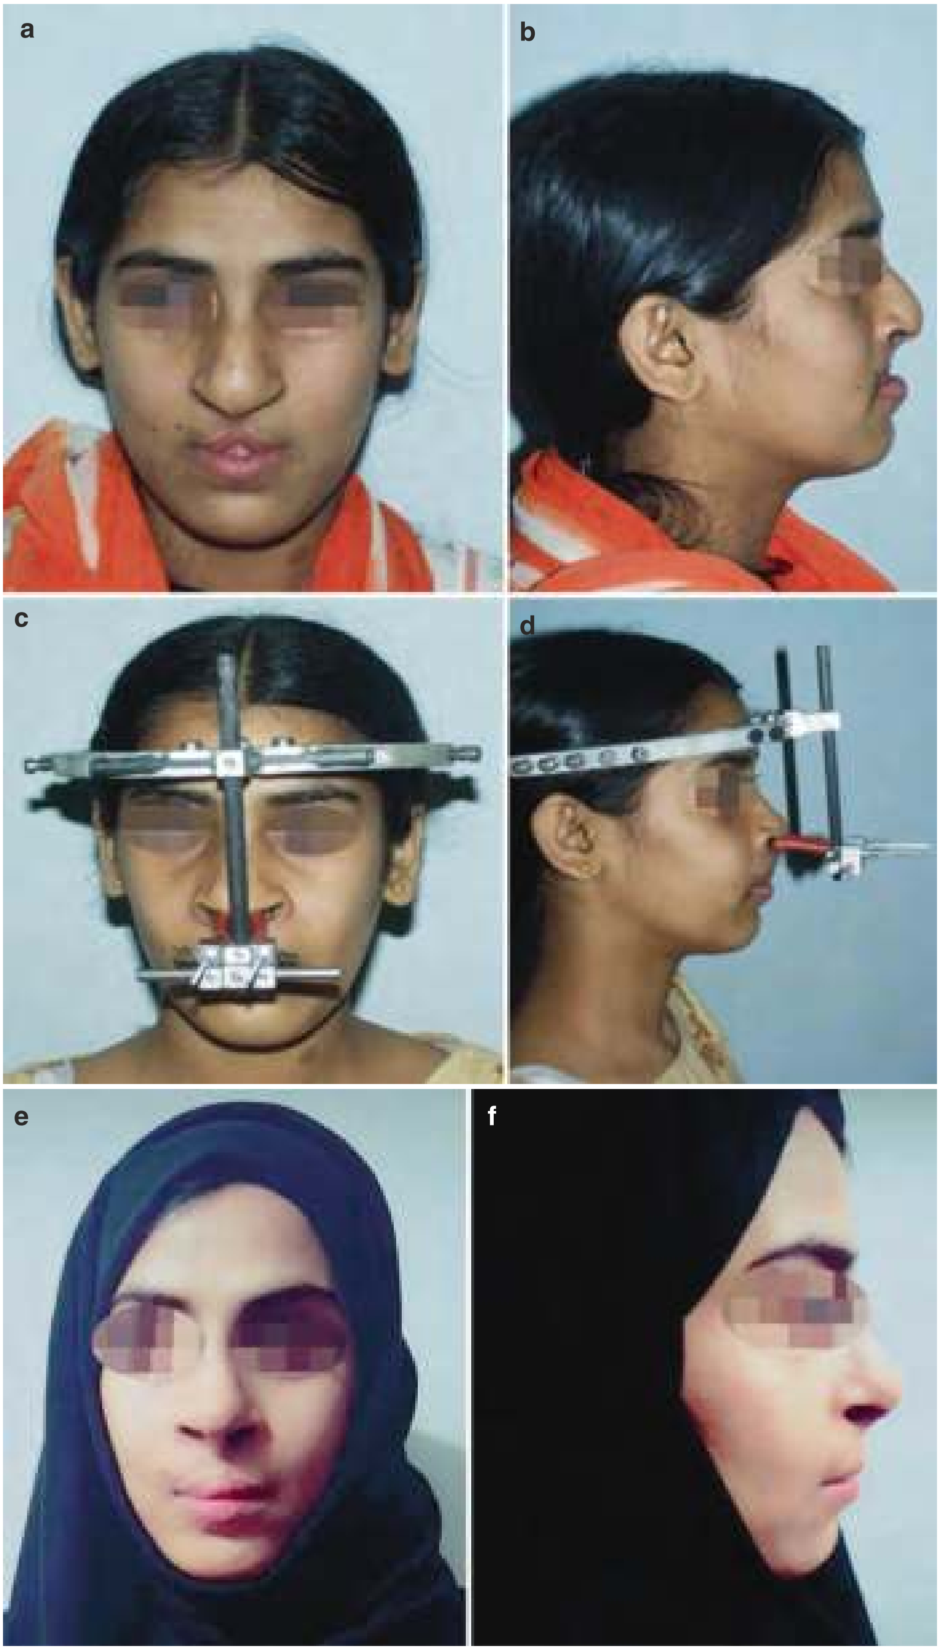

Fig. 75.6 (**a**–**f**) Patient treated with rigid external distractor (RED). (**a**, **b**) Pre-operative frontal and profile photographs, demonstating hypoplastic midface and concave profile. Fig. 75.7 Treatment plan for age group 17 years and above

of 1 year is needed between both surgeries. If there is moderate to severe VPI preoperatively, then it is advisable to perform AMD to avoid further deterioration of the same. As a means of saving time or if the mandible is truly prognathic, AMD and TMD can be combined with a mandibular setback (using bilateral sagittal split osteotomy) in a simultaneous or staged manner to reduce the span needed to be distracted [73].

75.8 LeFort I Procedure for Cleft Maxillary Hypoplasia

The protocol preferred by the authors is described below.

75.8.1 Preoperative Investigations

The preoperative investigations are described in Box 75.11.

Chronic Maxillary Sinusitis Most CLP patients suffer from chronic maxillary sinusitis on account of the presence of nasal obstructions and residual oronasal fistulae. It is the author's opinion that such patients need to be referred to an ENT specialist at least 3 months prior as active sinusitis affects the quality of the bone in the maxilla.

Box 75.11: Preoperative Investigations

Primary Investigations

Clinical diagnosis, pre-anesthetic assessment (blood investigations, chest x-ray, ECG, additional investigations for any significant medical history), facial photographs, cephalometric analysis (lateral cephalogram and postero-anterior cephalogram), articulated study models with bite registration and facebow transfer, dental model analysis, orthopantomogram, perceptual speech assessment, video nasoendoscopy (or video fluoroscopy) for velopharyngeal insufficiency, psychological screening, and patient education regarding realistic expectations

Adjunctive Investigations

3D computed tomography scans, stereolithographic model, sleep studies, and 3D virtual surgical planning

Fig. 75.8 (**a**–**h**) Mild reverse overjet and no preoperative VPI. The patient was treated with single jaw orthognathic surgery (maxillary advancement). (**a**, **b**) Pre and post-operative frontal photographs. (**c**, **d**) Pre and post operative profile photographs (left side). (**e**, **f**) Pre and post-operative profile photographs (right side). (**g**, **h**) Pre and post-operative lateral cephalograms

75.8.2 Preoperative Preparation

A single dose of 8 mg dexamethasone (half-life of 36–54 h) is given preoperatively to help reduce postsurgical airway and maxillofacial edema. It also has a synergistic analgesic effect when combined with postoperative analgesics. As a only a single dose is given, it is associated with minimum side effects [74, 75]. A single dose of 1 gm tranexamic acid is given 1 h preoperatively as it helps reduce intraoperative blood loss [76].

75.8.3 Intubation

Nasal intubation is preferred followed by submental intubation. In case a pharyngeal flap or nasal obstruction (enlarged inferior turbinates or deviated nasal septum) is present, it is advisable to perform fiber-optic assisted awake intubation. Alternatively, it may be necessary to pass a more rigid tube or catheter initially after which the endotracheal tube is passed over it.

The author always prefers to use a flexometallic nasoendotracheal tube as the tube is able to maintain its integrity even if damaged during the LeFort I osteotomy on account of the additional strength imparted by the metal coils.

75.8.4 General Anesthesia

The author commonly uses hypotensive anesthesia during orthognathic surgery as it provides a clean hemostatic field, reduces blood loss, and shortens hospital stay. There is an association between hypotensive anesthesia, forces generated during pterygomaxillary dysjunction, and optic nerve damage. Risk for optic nerve damage increases when hypotensive anesthesia is used in head and neck surgery which is

Fig. 75.9 (**a**–**h**) - Moderate reverse overjet and mild preoperative VPI. The patient was treated with orthognathic surgery alone (maxillary advancement and advancement genioplasty). (**a**, **b**) Pre and post-operative frontal photographs. (**c**, **d**) Pre and post operative profile photographs (left side) (**e**, **f**) Pre and post-operative profile photographs (right side). (**g**, **h**) Pre and post-operative lateral cephalograms

prolonged (>6 h) and large amount of blood loss (> 1 l) has taken place [77–82].

A larger amount of force is needed for pterygomaxillary dysjunction in CLP patients on account of the thicker pterygomaxillary junction. The stray forces, generated as a result of the dysjunction, can dissipate toward the orbital cavity and optic foramen with a magnitude potent enough to cause damage to the optic nerve. This is possible due to the orbital extensions of the palatine and sphenoid bones [7, 83, 84]. Thus, the author prefers to maintain hypotensive anesthesia during the entire orthognathic surgery except during pterygomaxillary dysjunction.

75.8.5 Cleft LeFort I Osteotomy (Video 75.2)

In cases of unilateral CLP, a routine incision in the height of the maxillary vestibule is used, and care should be taken that it extends only to the mesial surface of the first maxillary molars on both sides [7, 30, 85] (Refer Chap. 69 on Maxillary orthognathic procedures).

In cases of bilateral CLP, the incision is modified such that it extends from the lateral incisor to mesial surface of the first molar on both sides. A vertical stab incision is made in the midline to allow for placement of the nasal septal osteotome. This is to preserve blood supply to the pre-maxillary segment as most of its blood supply comes from the upper lip [2, 7, 28, 30].

Frequent surgery in the cleft maxilla leads to creation of scar tissue in the buccal, palatal, and upper lip regions. This scar tissue has compromised vascularity and healing ability. Therefore, it is essential to maintain an adequate soft tissue pedicle. There have also been suggestions to use modified vertical incisions instead of circumvestibular incisions, but it increases the difficulty of the procedure manyfold due to poor access and visualization [2, 3, 86]. Careful and gentle retraction of tissues (especially the pedicles) is essential throughout the procedure and especially during the down-fracture process.

Fig. 75.10 (**a**–**f**) Severe reverse overjet and mild preoperative VPI. The patient was treated with bi-jaw orthognathic surgery. (**a**, **b**) Pre and post operative frontal photographs. (**c**, **d**) Pre and post operative profile photographs. (**e**, **f**) Pre and post operative lateral cephalograms

The nasal mucosa is routinely elevated from the walls and floor of the nasal cavity prior to starting the LeFort I osteotomy. In the cleft maxilla, there is no intervening bone between the oral and nasal cavity in the region of the cleft; instead, the nasal mucosa is fused to the palatal mucosa due to the previously performed palatoplasty. This tissue should be sharply dissected close to the nasal floor, and care should be taken to avoid perforating the palatal mucosa. This step also aids in the down-fracture and mobilization of the maxilla.

The cleft maxilla usually exhibits para-nasal hollowing. Hence, the routine LeFort I osteotomy may not suffice for complete correction of cleft maxillary hypoplasia. Instead a high LeFort I osteotomy is used which has the added advantage of correcting the para-nasal hollowing as well [7, 30, 86]. Care should be taken to avoid damage to the tooth roots and the infra-orbital nerve as it exits from the infra-orbital foramen (Fig. 75.12). One should keep in mind that the descending palatine artery is closer to the lateral pyriform rim while performing the lateral nasal wall osteotomy.

To completely mobilize the maxilla during a LeFort I osteotomy, it is necessary to perform a pterygomaxillary dysjunction which separates the maxilla from the pterygoid plates. The maneuver is essentially blind and involves orienting a pterygoid chisel (curved osteotome) in a downward, medial, and anterior direction such that it engages the lower part of the pterygomaxillary fissure while maintaining a safe distance from the internal maxillary artery [87–89].

Studies have revealed that the medial pterygoid plate is shorter and the pterygomaxillary junction is thicker in cleft patients as the region around the hamular notch is fre-

(**g**) Lateral cephalogram after stage 2 -orthognathic surgery

quently manipulated during palatoplasty. The shorter medial pterygoid plate, by virtue of its smaller dimensions, may be more prone to fracture which increases the risk for vascular complications [87, 88]. Furthermore, the thicker pterygomaxillary junction requires a larger magnitude of force to achieve adequate separation. The usage of greater force leads to less control over this blind manoeuvre, thus increasing the risk for vascular complications (internal maxillary artery damage, carotid cavernous sinus) and neurologic (optic nerve damage) and skull base fractures (sphenoid fractures) [84].

There have been many modifications suggested to the original technique with an intention to reduce complications [87, 88, 90–95]. However, their use has never been documented widely in CLP cases. One may also attempt to use a piezo-surgical instrument or sequentially increase the size of the osteotomes to help reduce the force required for final pterygomaxillary separation [96, 97]. Another important consideration would be the preference of a third molar vertical osteotomy cut instead of a pterygomaxillary disjunction. This manoeuvre is anatomically less hazardous, allows greater mobility of the segments, allows a larger vascular pedicle to be maintained and permits the use of interpositional bone graft in the osteotomised area, after the advancement in order to prevent relapse.

Once pterygomaxillary dysjunction has been performed, the maxilla is down-fractured using leverage or specialized instruments like the Smith's spreader. If the nasal mucosa has not been dissected from the palatal mucosa previously, then it has to be done at this point [2, 7, 30]. After the down-fracture, it is important to suture the divided edges of the nasal mucosa to regain continuity of nasal lining. In the author's opinion, the edges of the divided nasal mucosa are a common source of bleeding postoperatively if left un-sutured (Fig. 75.13a, b). The presence of nasal obstructions like enlarged inferior turbinates can be corrected at this time.

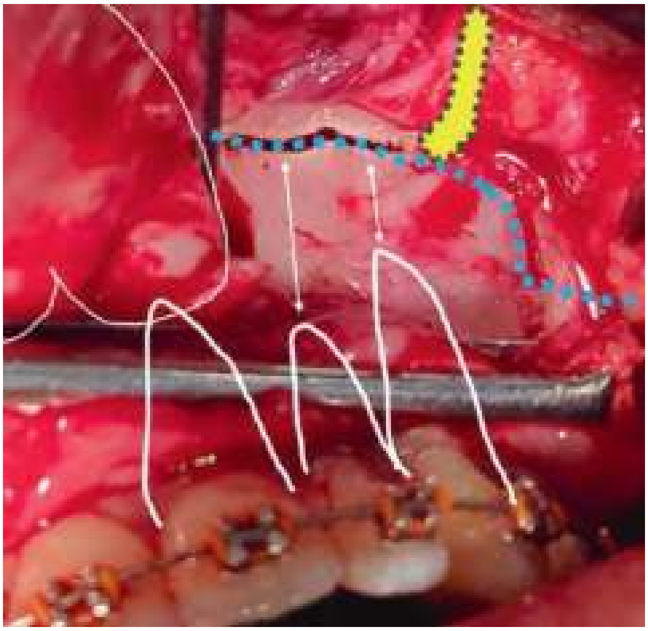

Fig. 75.12 Modified high LeFort I osteotomy (blue) cut to help correct para-nasal hollowing. Avoid damage to the infra-orbital nerve (yellow) and roots of teeth (white) while making the osteotomy. The pyrifiorm rim is marked in orange

After the down-fracture, the process of mobilizing the maxilla is done in a gradual progressive manner as the scarred tissues are less compliant. Specialized instruments like the Tessier's mobilizer can be used. If a pharyngeal flap is present and is impeding maxillary advancement, it may need to be incised. The maxilla is finally advanced to its desired position and should be seated in a passive manner. Signs of resistance at this point may indicate that the maxilla has not been adequately mobilized, and the previous steps need to be revisited. If resistance to the desired maxillary position persists, then one must consider to switch to maxillary distraction or set-back the mandible to avoid postoperative relapse. In situations where an alveolar bone grafting procedure has not been performed, or where the take of the grafting is sub-optimal, the cleft maxilla may present as a two-piece (unilateral cleft) or a three-piece (bilateral) maxilla. This may necessitate the use of transverse maxillary plating (Fig. 75.14a, b), for stabilization of the segmented bone.

There may also be need for segmental osteotomies as it is difficult to completely co-ordinate both arches with presurgical orthodontics on account of the variable anatomy of the cleft maxilla. The cleft alveolar gap can be opened or closed

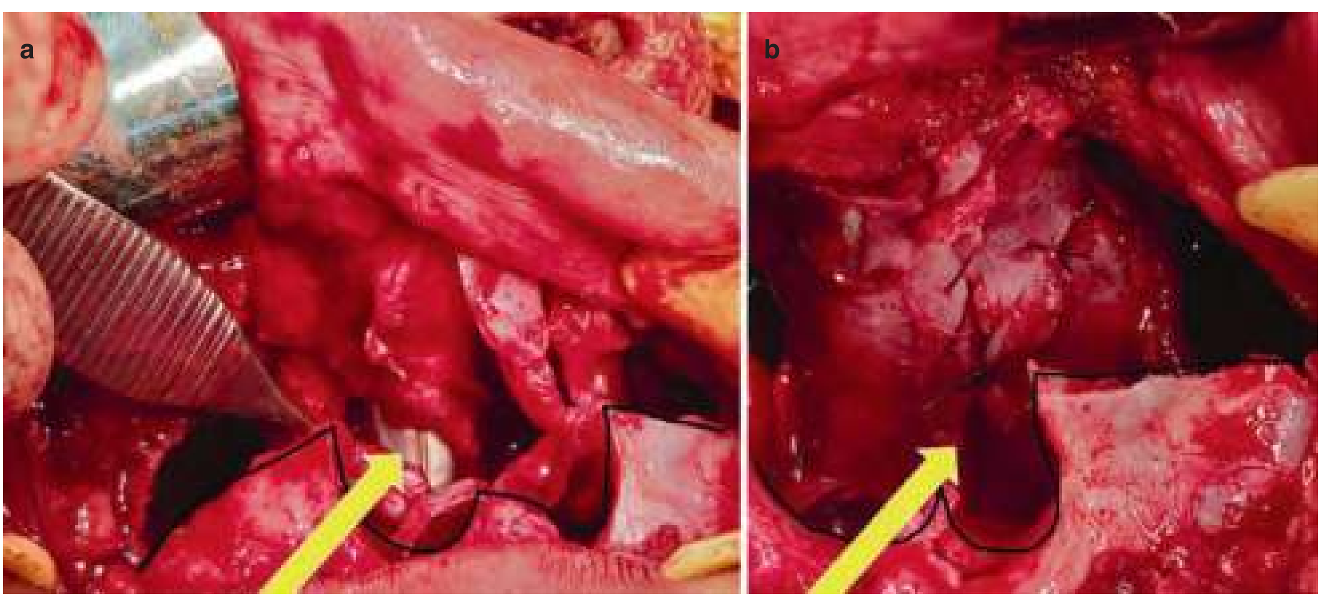

Fig. 75.13 (**a**) Torn nasal floor mucosa after down-fracture of maxilla. The endotracheal tube is visible. (**b**) The torn edges should be sutured back to prevent postoperative bleeding

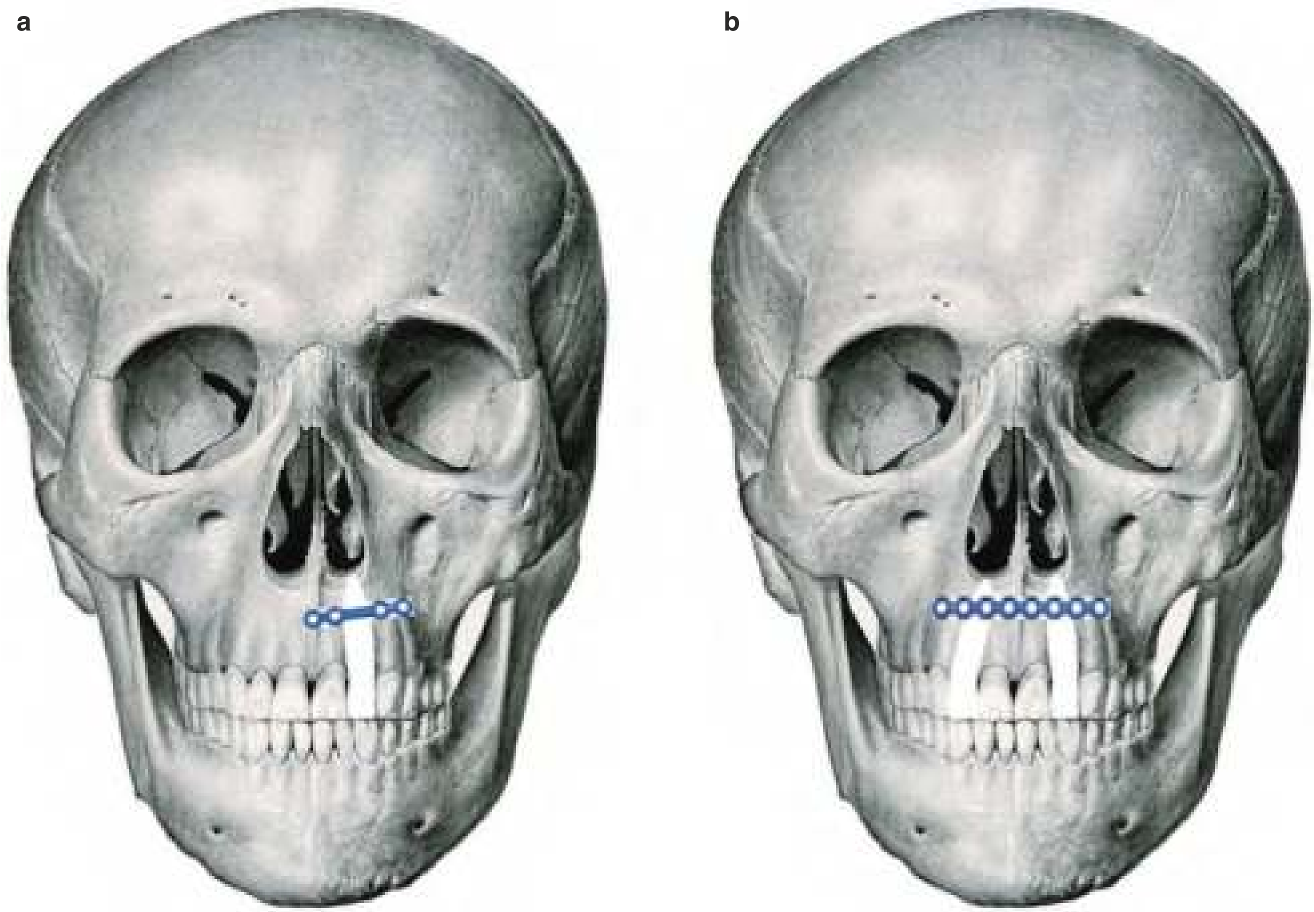

Fig. 75.14 Transverse plate across maxilla for stability during LeFort I osteotomy in a cleft. (**a**) Unilateral cleft of maxilla (**b**) Bilateral cleft of maxilla

to facilitate alveolar bone grafting or close alveolar fistulas. It can widen the maxillary arch within acceptable limits, allow differential movement of greater and lesser segments, align the occlusal plane, and maximize intercuspation to improve postoperative stability [98].

The presence of a persistent oronasal fistula and alveolar cleft defect requires careful soft tissue closure and bone grafting. One can also augment the deficient area along the lateral piriform rim on the cleft side to improve the contour of the alar base. The maxilla can fracture at the cleft alveolus site into two segments during the down-fracture and mobilization, even when the alveolar cleft site has been previously grafted. A preoperatively fabricated surgical palatal stent helps stabilize the maxilla in this situation.

Rigid fixation with mini plates and screws is preferred to stabilize the maxilla in its final position with a preference for the lateral pyriform rim and zygomaticomaxillary buttress regions as the bone here is thicker [83, 99]. One should pay attention while suturing and prevent entrapment of soft tissues into the osteotomy sites. The soft tissue of the upper lip may be tight with a shallow vestibular depth and deficient vermilion show that may become worse following maxillary advancement. "V-Y" closure can be used to reduce lip shortening.

75.8.6 Additional Steps Performed on a Case-to-Case Basis

75.8.6.1 Deciding the Level of Midface Advancement (Fig. 75.15a–f)

In most of the cases, a traditional LeFort I (Fig. 75.15a) osteotomy is advocated. However, in some rare instances, it may need a LeFort II (Fig. 75.15b) or LeFort III (Fig. 75.15c) osteotomy depending on the severity and the extent of the involvement. As the CMH involves the pyriform, the para-nasal, and the zygomatic areas, though not symmetrical, the LeFort I osteotomy design in such situations may need modification to involve the para-nasal (Fig. 75.15d) and/or zygomatic (Fig. 75.15e) areas unilaterally (Fig. 75.15f) or bilaterally as the case may be.

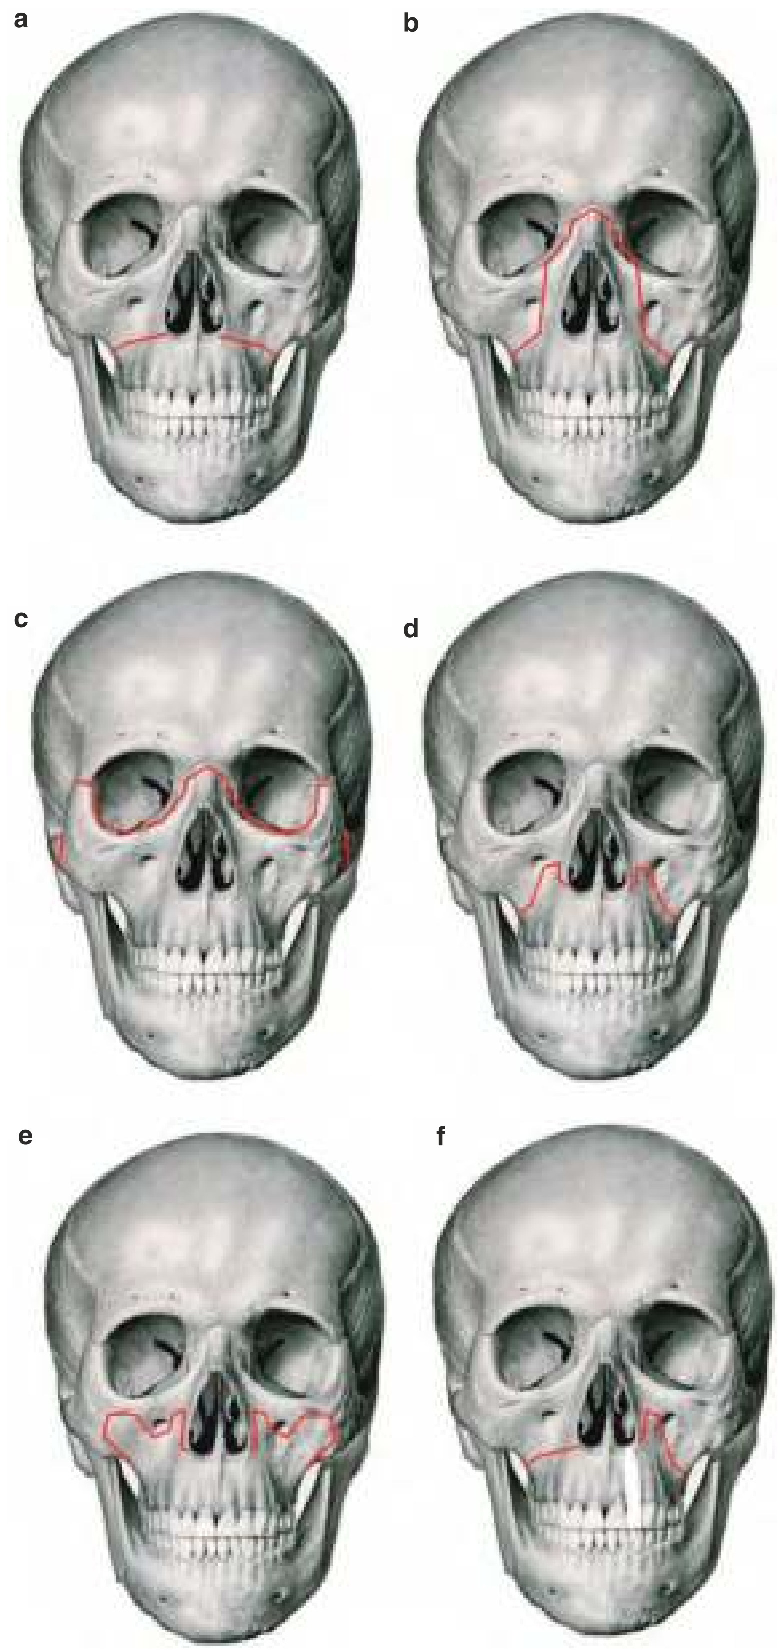

Fig. 75.15 Levels of midface advancement (**a**) LeFort I, (**b**) LeFort II, (**c**) LeFort III osteotomies. Modifications of LeFort I osteotomy (**d**), para-nasal extension, (**e**) para-nasal and zygomatic extensions, and (**f**) conventional LeFort I on the unaffected side and para-nasal extension on the affected side

75.8.6.2 Preserving the Descending Palatine Artery

Studies by Bell et al. established that the descending palatine artery did not contribute significantly to the re-vascularization of the maxilla after a total maxillary osteotomy in routine cases [100, 101]. However, the greater palatine arterial network in CLP patients may become narrow and develop vascular anomalies because of the presence of scar tissue created by the palatoplasty procedure [7, 60, 83]. Considering the unique scenario of the cleft maxilla, it is advisable that efforts should be made to preserve the descending palatine artery and secure it as an additional source blood supply for the osteotomized maxilla [7, 102]. Techniques to identify and preserve the descending palatine artery have been documented in the literature [103–108]. However, the above technique needs to be tailored to the cleft maxillary anatomy as it is highly variable. Studies have established that the distance between the lateral pyriform aperture and the descending palatine artery is on an average 3–4 mm lesser in CLP patients. Similarly, the posterior and lateral distances to the descending palatine artery were greater on in CLP patients on account of the thickened pterygomaxillary junction [7, 83, 84]. The perpendicular process of the palatine bone surrounding the descending palatine artery is also of the dense cortical type adding to the difficulty of isolating the vessel [99]. The author reserves this step only when the patient has undergone a large number of revision surgeries in the palate.

75.8.6.3 Grafting of the Osteotomy Site

The cleft maxilla is deficient in all three dimensions, and hence its correction requires complex large movements. Cortico-cancellous bone grafts can be placed across the gap created in the region of the lateral osteotomy [2, 3, 7, 86, 109]. The ideal source of autogenous bone grafting is the anterior iliac crest [110]. As an alternative, one can also use autogenous genial grafts, allogenic grafts, or synthetic hydroxyapatite bone blocks [111–114]. The author prefers to graft the osteotomy site only when down-grafting the maxilla or advancing the maxilla more than 10 mm.

75.9 Clinical Morbidity and Psychological Response

According to Stork et al. and Chua et al., there was no major difference between clinical morbidity between distraction osteogenesis and orthognathic surgery and between grafted and non-grafted patients, the source of graft being the anterior iliac crest [115–117].

Patients undergoing distraction osteogenesis experienced greater levels of stress in the short term. Over time, the distraction group had a higher satisfaction with life [118–120]. This may be because of the better stability of the distraction osteogenesis in the long term as well as the self-perceived contribution of the patients to the success of their treatment. There is also an aspect of superior soft tissue response to distraction as compared to orthognathic surgery which may improve the final aesthetic result (refer Chap. 87 to read more about Distraction Osteogenesis) [121].

Nonetheless, psychological support from family and friends is recommended for patients undergoing either distraction or orthognathic surgery so as to achieve a better life satisfaction in the long term.

75.10 Stability of Results

The postoperative stability after orthognathic surgery in cleft patients is lower than non-cleft patients [2, 3, 7, 86]. Maximum relapse in cleft orthognathic surgery occurs in the first 6 months, and the situation stabilizes 2 years postoperatively [122].

75.10.1 Soft Tissue Envelope

The presence of scarred tissue in the palate and the lip prevents the maxilla from being adequately mobilized. Though the maxilla might be secured into its desired position with the help of rigid fixation and bone grafting, the excess stress placed on the maxilla due to the scarred soft tissue envelope leads to relapse in both the sagittal and vertical dimensions [2, 3, 7, 86, 123]. The severity of labio-palatal clefting and history of multiple revision surgeries increase the risk for relapse.

75.10.2 Magnitude of Planned Surgical Movement

The amount of surgical movement is the most important factor that determines the degree of relapse in cleft and non-cleft cases. Thus, most surgeons tend to overcorrect by an additional 20% to account for the possible relapse [2, 3, 7, 86, 124].

However, a recent study by Watts et al. [125] suggested that amount of linear advancement was not a major cause for skeletal and dental relapse rate in cleft orthognathic. Studies by Bhatia et al. [59] and Hoffman et al. [126] suggested the same. Nonetheless, the general trend is to perform bi-jaw orthognathic surgery or distract the maxilla if more than 10 mm advancement is needed.

75.10.3 Status of Alveolar Bone Grafting

Lack of alveolar bone grafting increases the difficulty of performing cleft orthognathic surgery. However, though alveolar bone grafting contributes to transverse stability of the maxillary arch and improve outcomes in orthodontia, it does not improve stability of sagittal, vertical, or rotational movements [122, 124].

75.10.4 Intraoperative Factors

Inadequate separation at the pterygomaxillary junction due to its thicker form in CLP patients, the presence of a pharyngeal flap, a shallow overbite, and the absence of multiple teeth leading to poor intercuspation may contribute to relapse as well [2, 3, 7, 86, 124]. Segmentation of the maxilla as compared to one-piece maxilla was not associated with greater relapse rates in CLP patients and instead could correct orthodontic and occlusal problems that were distinctive to the cleft maxilla. Nonetheless, no attempt should be made to significantly widen the cleft maxilla as using a segmental osteotomy is a highly unstable procedure [98, 127, 128].

In the author's opinion, poor-quality bone in the cleft maxilla makes rigid fixation difficult and increases the risk for relapse [2, 3, 7]. Thus, it is advisable to always secure plates in the region of thick cortical bone, i.e., the zygomaticomaxillary buttress region posteriorly and the lateral pyriform aperture anteriorly (Fig. 75.16a–c). Bony fenestrations can be encountered in cases with prior AMD during maxillary orthognathic surgery; extra care must be taken during plating the same (Fig. 75.17).

Owing to the large advancements commonly performed in cleft orthognathic surgery, the gap between the osteotomized segments is large. When the contact area between the bony shelves is small, there may be instability or fibrous union between segments which increases the risk for relapse. By grating these gaps, there is increased bony contact which helps in optimal healing. Rarely, the space posterior to the maxillary tuberosity after advancement of the maxilla is also grafted to help prevent relapse [46]. Owing to the hostile environment of the cleft maxilla, it is general consensus that autogenous bone grafts provide the best results in terms of take up of the graft and significantly lower complication rates. It is interesting to note that a recent study by Stork et al. [115] suggested that grafting was not a major factor in preventing postoperative skeletal relapse in cleft and non-cleft patients contrary to the currently accepted methodology. A study by Hoffman et al. [129] in non-cleft patients suggested the same. The author's opinion is in line with both the above authors and grafts the osteotomy site only when advancing the maxilla more than 10 mm or down-grafting the maxilla.

75.10.5 Timing of Surgery

As previously mentioned, surgery performed before skeletal maturity is associated with a higher relapse rate in both horizontal and vertical dimensions due to continued growth. This is applicable irrespective of the type of surgery being performed: orthognathic surgery or distraction osteogenesis [21, 23, 24]. Secondary surgery for the correction of residual growth deformities is required after growth is complete. It is

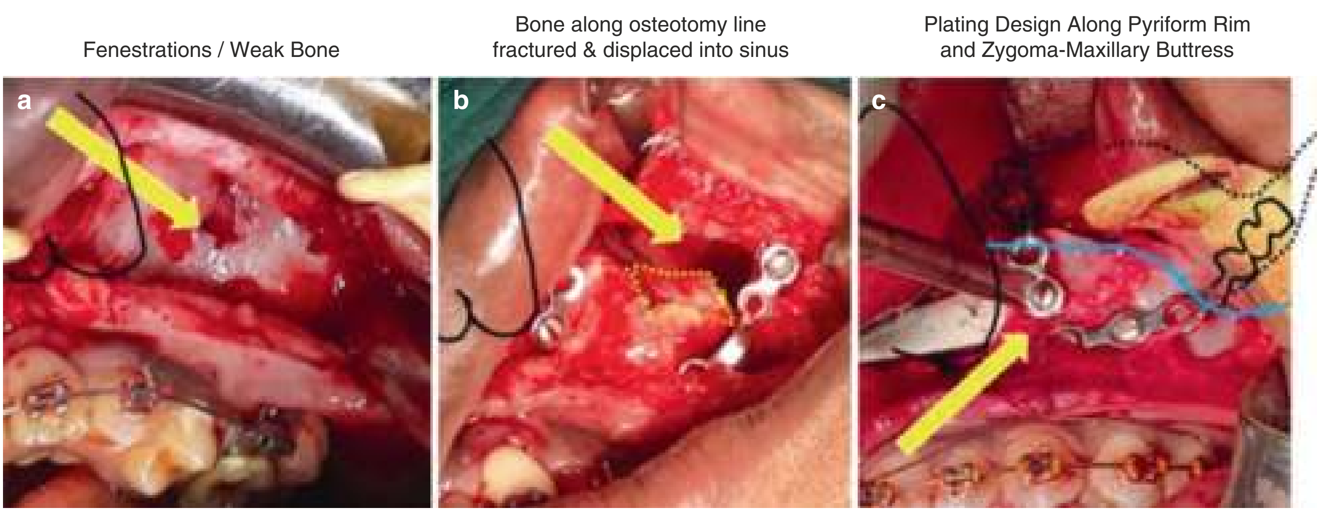

Fig. 75.16 (**a**–**c**) Poor-quality bone seen in the anterolateral and posterolateral walls of the maxilla. Always plate along the lateral pyriform rim and zygomamaxillary buttress (dotted) region which are known to have good-quality bone. Part of the miniplate obscured by the retractor and tissues has been traced for better understanding of the plate position. Blue line denotes line of osteotomy on the dental side

Fig. 75.17 Large bony fenestration in anterolateral wall of the maxilla at the time of orthognathic surgery. It is commonly found where prior anterior maxillary distraction was done. The presence of such a large fenestration can make plating difficult

important to note that distraction osteogenesis was more commonly preferred in the growing patient [2, 3, 7, 22, 130, 131].

75.10.6 Degree of Relapse

A review by Kloukos et al. [120] established that results obtained with distraction osteogenesis were more stable as compared to conventional orthognathic surgery 5 years postoperatively. A review by Saltaji et al. [132, 133] reported average horizontal relapse rates of 10 % in distraction cases and 25–30 % in orthognathic cases for cleft patients. Vertical relapse rates in cleft orthognathic patients were high with an average rate of 40–50 %. Similar results have been documented in other studies and reviews with up to 5-year follow-ups [134–140]. The rate for re-operation in cleft orthognathic surgery was approximately 12.2% [140]. Internal distractors were also found to be more stable than external distractors. This can be attributed to the rigidity provided by the internal distractor during the consolidation phase. The use of rigid fixation with miniplates was attributed with the least amount of relapse in cleft orthognathic surgery [2, 3, 7, 132].

Based on the above evidence, distraction osteogenesis has become the mainstay for the management of severe to extreme cleft maxillary hypoplasia (reverse overjet greater than 11 mm) as the slow distraction of bone and the accompanying histogenic abilities help reduce skeletal relapse. Orthognathic surgery is preferred for mild to moderate cleft maxillary hypoplasia (reverse overjet lesser than 11 mm).

75.10.7 Clinical Suggestions to Avoid Relapse

Commonly used methods to prevent or control relapse are as follows: overcorrection of the final surgical result by 20%, prolonged intermaxillary fixation during the postoperative phase, using face masks with reverse traction of the maxilla, interpositioning bone grafts between the gaps created by maxillary advancement, and performing bi-jaw surgery or distraction when advancements greater than 10 mm are required [114]. A study by Tabrizi et al. [141] established that the use of rigid fixation after the consolidation phase of cleft maxillary distraction did not increase stability of results. In anterior maxillary distraction, it is essential to lock the appliance with wire or acrylic plug during the consolidation phase to prevent backward rotation of the hyrax screw.

75.11 Complications

A study by Metalwala et al. [142] established that there is increased risk for infection and prolonged hospital stay in patients with craniofacial anomalies undergoing orthognathic surgery. The incidence of complications in non-cleft patients has been reported at 6.4% as compared to 25.2% in cleft patients [83].

Studies by Yamaguchi et al. [140] and Moran et al. [143] revealed that an average of 15–30 % of patients present with perioperative complications. The most common complications were closure failure of pre-existing palatal fistula, velopharyngeal impairment, temporary paresthesia of the infra-orbital nerve, and surgical site infection. A review by Santos et al. [144] established that cleft maxilla patients present with the highest incidence of cranial nerve damage on account of the anatomically higher modified LeFort I osteotomy cut and excessive forces needed at the time of pterygomaxillary dysjunction. Rare and severe complications like arteriovenous fistula, maxillary aneurysm, cavernous sinus thrombosis, skull base fractures, and maxillary necrosis blindness are more common among patients with craniofacial anomalies but have an incidence of lesser than 0.5% [140, 143, 145]. It has been suggested by Eduardo et al. [146] that the use of piezo-electric surgical instruments in orthognathic surgery is associated with a lower complication rate.

With the author's experience (PM) of approximately 900 cleft orthognathic cases while using the traditional dysjunction technique, there has been no major vascular complication or skull base fractures. However, two patients experienced transient blindness with partial recovery of vision in the long term [79].

75.12 Conclusion

Skeletal surgery is a critical component of surgical management of CLP. On account of the unique anatomy of the cleft maxilla that has been subjected to previous lip & palate interventions, the conventional LeFort I osteotomy technique and orthognathic surgical principles need to be adapted accordingly. The ultimate goal of treatment should be to achieve intelligible speech and an acceptable appearance with good balance of facial skeleton, soft tissues, and occlusion. Distraction osteogenesis is a useful technique in the management of severe maxillary deficiency, but does not replace conventional orthognathic surgery. Maxillofacial surgeons who treat these deformities should be part of a craniofacial team to provide interdisciplinary care for the patient. The aim of the team should be to help the child to develop into a confident young adult.

76 Cleft Rhinoplasty

Sunil Richardson and Rakshit Vijay Sinai Khandeparker

76.1 Introduction

Rhinoplasties in cleft lip and palate (CLP) patients are considered one of the most difficult and challenging surgeries to carry out. The reasons understood for this are twofold: the principal reason being the simultaneous involvement of all the layers of the nose, including the skin, cartilage, skeleton and vestibular lining, and the other the significant scarring that accompanies multiple previous surgical interventions. The deformity has a major impact on nasal aesthetics as well as function and can range from being absolutely inconspicuous to catastrophic.

The literature is flooded with numerous techniques for ultimate correction of unilateral and bilateral cleft lip-nasal deformities. More recently, most cleft surgeons have started opting for primary rhinoplasties at the time of lip repair with or without presurgical orthopaedics. These early interventions have definitely improved the nasal deformity and the overall nasal symmetry; however, definitive rhinoplasty may still be required at a later date as the child grows. Despite all the recent developments in cleft surgery, an optimal surgical modality that addresses the issues of desired nasal form coupled with long-term stability for correction of cleft lip-nasal deformity still fails to exist.

76.2 Pathologic Anatomy

A clear understanding of the associated complex anatomical and pathological abnormalities is paramount to obtaining desired nasal form and function [1].

76.2.1 Unilateral Cleft Nasal Deformity

The hallmark of unilateral cleft nasal deformity is a three-dimensional asymmetry of the nasal tip and the alar base (Fig. 76.1a–c). The characteristic features include:

1. **Asymmetric nasal tip**: This is principally due to a shorter medial crus and longer lateral crus of the lower lateral cartilage (LLC) on the cleft side as compared to the non-cleft side. This contributes to a poorly defined nasal tip with less projection [2]. Furthermore, the angle between the medial and lateral crura on the cleft side is increased.
2. **Alar dome is flat and wider on the cleft side** due to posterolateral displacement of the alar dome [2].
3. **Deviation of the columellar base to the non-cleft side**: The unilateral cleft results in a discontinuous insertion of the orbicularis oris muscle into the columellar base on the non-cleft side rather than a horizontal insertion and continuous decussation as seen in the normal lip. The contraction of the orbicularis oris muscle results in an unopposed pull of the columella, caudal septum and premaxilla to the non-cleft side [3].
4. **Alar base on the cleft side is directed laterally, posteriorly and inferiorly**: Two factors contribute to this: one being the insertion of the orbicularis oris into the alar base and the other the deficient maxillary skeletal framework at the alar base [3].
5. **Hypoplastic maxilla on the cleft side**.
6. **Wide and horizontally directed nostril on the cleft side**: This is brought about by a combination of vector of

Fig. 76.1 (**a**–**c**) Photographs depicting the pathologic anatomy as observed in unilateral cleft nasal deformity. (**a**) Frontal view showing the deviation of the nasal root towards the non-cleft side with asymmetrical appearing nasal tip. (**b**) Basal view depicting the deviation of the base of the columella to the non-cleft side. Also, observe the wide and horizontally directed nostril on the cleft side. Furthermore, the alar base on the cleft side is directed laterally, posteriorly and inferiorly. (**c**) Pictorial depiction of deviation of the caudal nasal septum (blue) towards the non-cleft side

orbicularis oris muscle pull and asymmetric LLC on the cleft side [4, 5].

7. **Deviation of the caudal septum to the non-cleft side:** The unopposed pull of the orbicularis oris muscle due to its improper insertion into the columellar base results in deviation of the caudal septum to the non-cleft side [3]. This force affects only the caudal septum and results in deflection of the cartilaginous and bony septum into the cleft side posteriorly. This alone or in association with hypertrophied nasal turbinates significantly narrows the opening of the nasal airway and contributes to nasal airway obstruction [6].
8. **Compromised external nasal valve:** This is the consequence of two related factors: introversion of the nasal ala and webbing of the nasal vestibule. Due to the position of the columella and alar base on the cleft side, the LLC is subjected to distortional forces that causes it to rotate posteroinferiorly and brings about introversion of the cleft side nasal ala [7]. This leads to hooding and thickening of the ala and together with surgical scarring forms an oblique fold and contributes to webbing of the nasal vestibule. This tissue bulk has an influence on the nasal airflow and significantly alters the relationship of upper lateral cartilages (ULCs) and LLCs.
9. **Weakened upper lateral cartilages (ULC) and abnormal relationship to LLCs:** On the cleft side, the ULC displays side-to-side relationship rather than the typical overlap type of relationship seen on the non-cleft side. The ULC on the cleft side is also weakened by inadequate skeletal support [8]. The consequence of both these factors is reduced support and collapse of the ULC with deep inspiration.
10. **Compromised internal nasal valve on the cleft side:** This is primarily because of septal bowing into the cleft side at the internal nasal valve together with weakened support of the ULC at the cleft side which causes the cartilage to collapse with respiration.

76.2.2 Bilateral Cleft Nasal Deformity

The bilateral cleft lip nasal deformity is grossly symmetrical and shares similar clinical characteristics as observed in unilateral cleft deformity [9, 10] (Fig. 76.2a–c). The clinical characteristics include:

1. **Under-projected and bifid nasal tip**: The lateral crus of the LLC is long, and the medial crus is short which leads to under-projection of the nasal tip. The medial crura are typically splayed, producing a poorly defined, bifid tip [11]. The nose is wide and depressed.
2. **Blunting of the alar dome with a more obtuse angle** due to posterolateral displacement of the alar domes [11].

Fig. 76.2 (**a**–**c**) Photographs depicting the pathologic anatomy as observed in bilateral cleft nasal deformity. (**a**) Frontal view demonstrating a more or less symmetrical deformity with bifid nasal tip and blunting of the alar dome. (**b**) Basal view depicting symmetrical position of the caudal nasal septum, short columella and bilateral displacement of the alar bases laterally, posteriorly and inferiorly with wide and horizontally directed nostrils bilaterally. (**c**) Pictorial depiction of the classical midline position of the caudal nasal septum

3. **Short columella with a wider base:** The columella is short or nearly absent as a consequence of decreased soft tissue and skin between the nasal tip and the upper lip [12].
4. **Alar bases are displaced laterally, posteriorly and inferiorly.** This brings about flaring of the alar bases and widening of the nostrils.
5. **Hypoplastic maxillae bilaterally.**
6. **Nostrils are wide and horizontally directed with margins buckling inwards.**
7. **Classical midline positioning of the septum.** The nasal septum is classically midline; however, in case of a slight discrepancy, the septum deviates to the less affected side [13, 14].
8. **The external nasal valve is compromised by** introversion of the LLCs and webbing of the nasal vestibules bilaterally.
9. **The ULCs are weakened and display abnormal relationship to LLCs** similar to that seen in the unilateral cleft nasal deformity.
10. **The internal nasal valve is compromised by weakened support of the ULC:** It is important to note that midline positioning of the nasal septum in bilateral cleft nasal deformity results in compromise of the internal nasal valve to a lesser significant degree as compared to the unilateral cleft nasal deformity.

76.3 Surgical Timing

The timing of cleft lip nasal repairs can be divided into primary, intermediate and secondary or definitive repairs.

76.3.1 Primary Rhinoplasty

Initially, most surgeons were sceptical with early nasal interventions at the time of cleft lip repair following demonstrations of impairment of nasal and midfacial growth in experimental studies that resulted after large submucosal resections of the nasal septum. However, studies by McComb and Coghlan [7] have dispelled this philosophy and demonstrated that early interventions seldom interfere with growth provided the lower lateral cartilage is only repositioned and not resected. Primary rhinoplasties are now increasingly accepted, and their positive effects on secondary rhinoplasties are well documented.

Primary cleft rhinoplasty is typically carried out at 3 months of age at the time of primary cheiloplasty [15]. An early intervention improves the existing cleft nasal deformity by achieving better symmetry, allowing the nose to grow in a symmetric fashion and potentially improving long-term appearance and the final outcome.

The definite goals of the procedure are highlighted in Box 76.1.

Box 76.1: Definite Goals of Primary Cleft Rhinoplasty

- To bring about approximation of the nasal floor to establish a muscle and soft tissue sill across the nasal base
- Symmetrical positioning of the abnormally positioned LLC
- Providing nasal tip support
- Repositioning of the alar base and correction of the webbed lateral alar mucosa by plicating skin and mucosa [16]

The addition of presurgical naso-alveolar moulding device is advocated by some authors in conjunction with primary surgery. The technique delivers continuous low-level pressure on the alveolar segments and is highly successful in shaping the nasal cartilage within the initial 6 weeks due to high levels of circulating maternal oestrogen that makes the cartilage increasingly elastic [17].

The technique helps in bringing the alveolar segments closer thereby narrowing the cleft gap, improving the alar base symmetry, expanding the soft tissue envelope and elongating the columella [18, 19].

76.3.2 Intermediate Rhinoplasty

Intermediate rhinoplasty is reserved for procedures that are carried out prior to completion of nasal growth, in the time interval spanning between definitive lip repair and secondary rhinoplasty. The procedures are planned on the lines of conservation with the singular aim to achieve symmetry during continued nasal growth, ultimately creating a definitive platform for a more successful definitive repair.

The primary goal of surgery is to correct the abnormal position of the LLC on the cleft side so that there is no exacerbation of the deformity following nasal growth in future. It is imperative to perform a septorhinoplasty or cartilage grafting procedures in the post-adolescence age so that the nasal growth proceeds unimpeded [11].

Intermediate rhinoplasty can be carried out at two distinct time intervals [20]. One corresponds to 4–6 years of age, and this age group coincides with the timing of lip revision if required and also helps in achieving a better nasal symmetry. Also, this is the time when the peer pressure starts to mount necessitating the need for intermediate rhinoplasty in this age group. Furthermore, any lateral vestibular webbing can be dealt with preventing the obstruction of the external nasal valve.

The other instance when an intermediate rhinoplasty can be carried out is after completion of orthodontic alignment and secondary alveolar bone grafting (8–12 years). This helps in creating a solid skeletal platform to affect a long-lasting correction of severe nasal deformities.

76.3.3 Secondary or Definitive Rhinoplasty

Secondary or definitive rhinoplasty is performed once the maxillary and nasal growth ceases, which corresponds to 14–16 years of age in females and 16–18 years of age in males [21]. The procedure has to be definitive and provides an opportunity to introduce aggressive surgical interventions like septorhinoplasty, nasal osteotomies and cartilage grafting manoeuvres without fear of jeopardising the maxillary or nasal growth.

The goals of definitive rhinoplasty are mentioned in Box 76.2.

Box 76.2: Goals of Definitive Rhinoplasty

- Create a lasting symmetry and definition of the nasal base and tip.
- Relieve nasal obstruction.
- Manage nasal scarring and webbing.
- Correct short columellar skin if present, and augment the nasal dorsum in cases of bilateral cleft nasal deformities [1].

Most CLP patients present with maxillary hypoplasia and therefore require maxillary advancement surgery in the form of either LeFort I osteotomy, total maxillary distraction or anterior maxillary distraction. The maxillary projection can be improved with these procedures without affecting the nasal dorsum adversely [22]. These procedures also allow for forward movement of LLC and improvement of the tip projection. In scenarios such as this, definitive rhinoplasty is often carried out after addressing the skeletal discrepancies.

76.4 Preoperative Evaluation

Prior to carrying out a rhinoplasty surgery, it is prudent to carry out a thorough evaluation of the nose in a meticulous manner. This when backed up with sound knowledge of nasal anatomy can bring about aesthetically pleasing results in cleft rhinoplasty.

76.4.1 History

It is imperative to address any patient concerns as related to symmetry of the lip and nose, nasal airway, etc. prior to carrying out a rhinoplasty surgery. Any previous nasal surgeries have to be documented accurately. The effects of such surgeries on the postoperative outcomes have to be explained to the patient beforehand.

76.4.2 Physical Examination

A thorough physical examination involves examining both the external appearance and the internal nasal structures.

External examination of the nose must be carried out in accordance with its position on the facial skeleton. Measurements as traced on preoperative photographs can provide a guide in the surgical planning (Fig. 76.3a–d).

Internal nasal examination proceeds in a systematic and repeatable manner and is performed using a nasal speculum to evaluate for the nasal function.

When performing the physical examination of the nose, the clinical characteristics of unilateral and bilateral cleft nasal deformities as previously described are looked up for in a systematic manner. Gunter diagrams can be a valuable aid for the purpose of preoperative planning [21].

76.4.3 Photographic Documentation

76.4.3.1 Two-Dimensional Photographs

Appropriate documentation of the deformity is made possible by taking preoperative photographs in all views, viz. frontal, basal, lateral and oblique views (Fig. 76.4a–f). These photographs serve diagnostic purpose as well as help in protecting the surgeon in cases of medico-legal implications. The photographs also help in explaining the goals of surgery adequately to the patient. Furthermore, the photographs can serve as a visual guide to the surgeon intraoperatively, helping in implementing the planned surgical goals precisely.

76.4.3.2 Three-Dimensional Imaging

This method requires a set of devices, viz. an optical system, digital communication network and a computer with a calculation program which helps in determining the shape of the three-dimensional object by transforming the image from analogue to digital form (Fig. 76.5a). The technique is reliable, can be safely employed in child patients due to its non-ionising nature and offers both qualitative and quantitative assessments, and the digital model can be employed in the clinical setting immediately. The disadvantages include the cost, long time that is required for patient preparation and data acquisition and inability to measure bony or interactive landmarks.

76.4.4 Radiographic Assessment

76.4.4.1 Cephalometric Analysis

Cephalometric analysis aids in evaluating the maxillary position and its possible implications on the patient's nose [21] (Fig. 76.5b). The need for any maxillary advancement surgery and the importance of performing it before any rhinoplasty surgery should be conveyed to the patient. Cephalometric analysis also allows for evaluation of chin position [21].

76.4.4.2 Computed Tomography (CT)/Cone Beam Computed Tomography (CBCT)

CT scans of the paranasal sinuses in axial and coronal views help in defining the deformation of the septum as well as other intra-nasal structures. CBCT is an attraction alternative to CT with regard to decreased ionising radiation to the patient and image quality for hard tissues on par with CT. No modalities other than CT/CBCT allow for evaluation of nasal septum objectively [23] (Fig. 76.5c).

76.4.5 Facial Casts

Facial casts have been employed by authors to study the nasal morphology by direct anthropometry [24] (Fig. 76.5d). The technique is found to be objective and cost-effective and

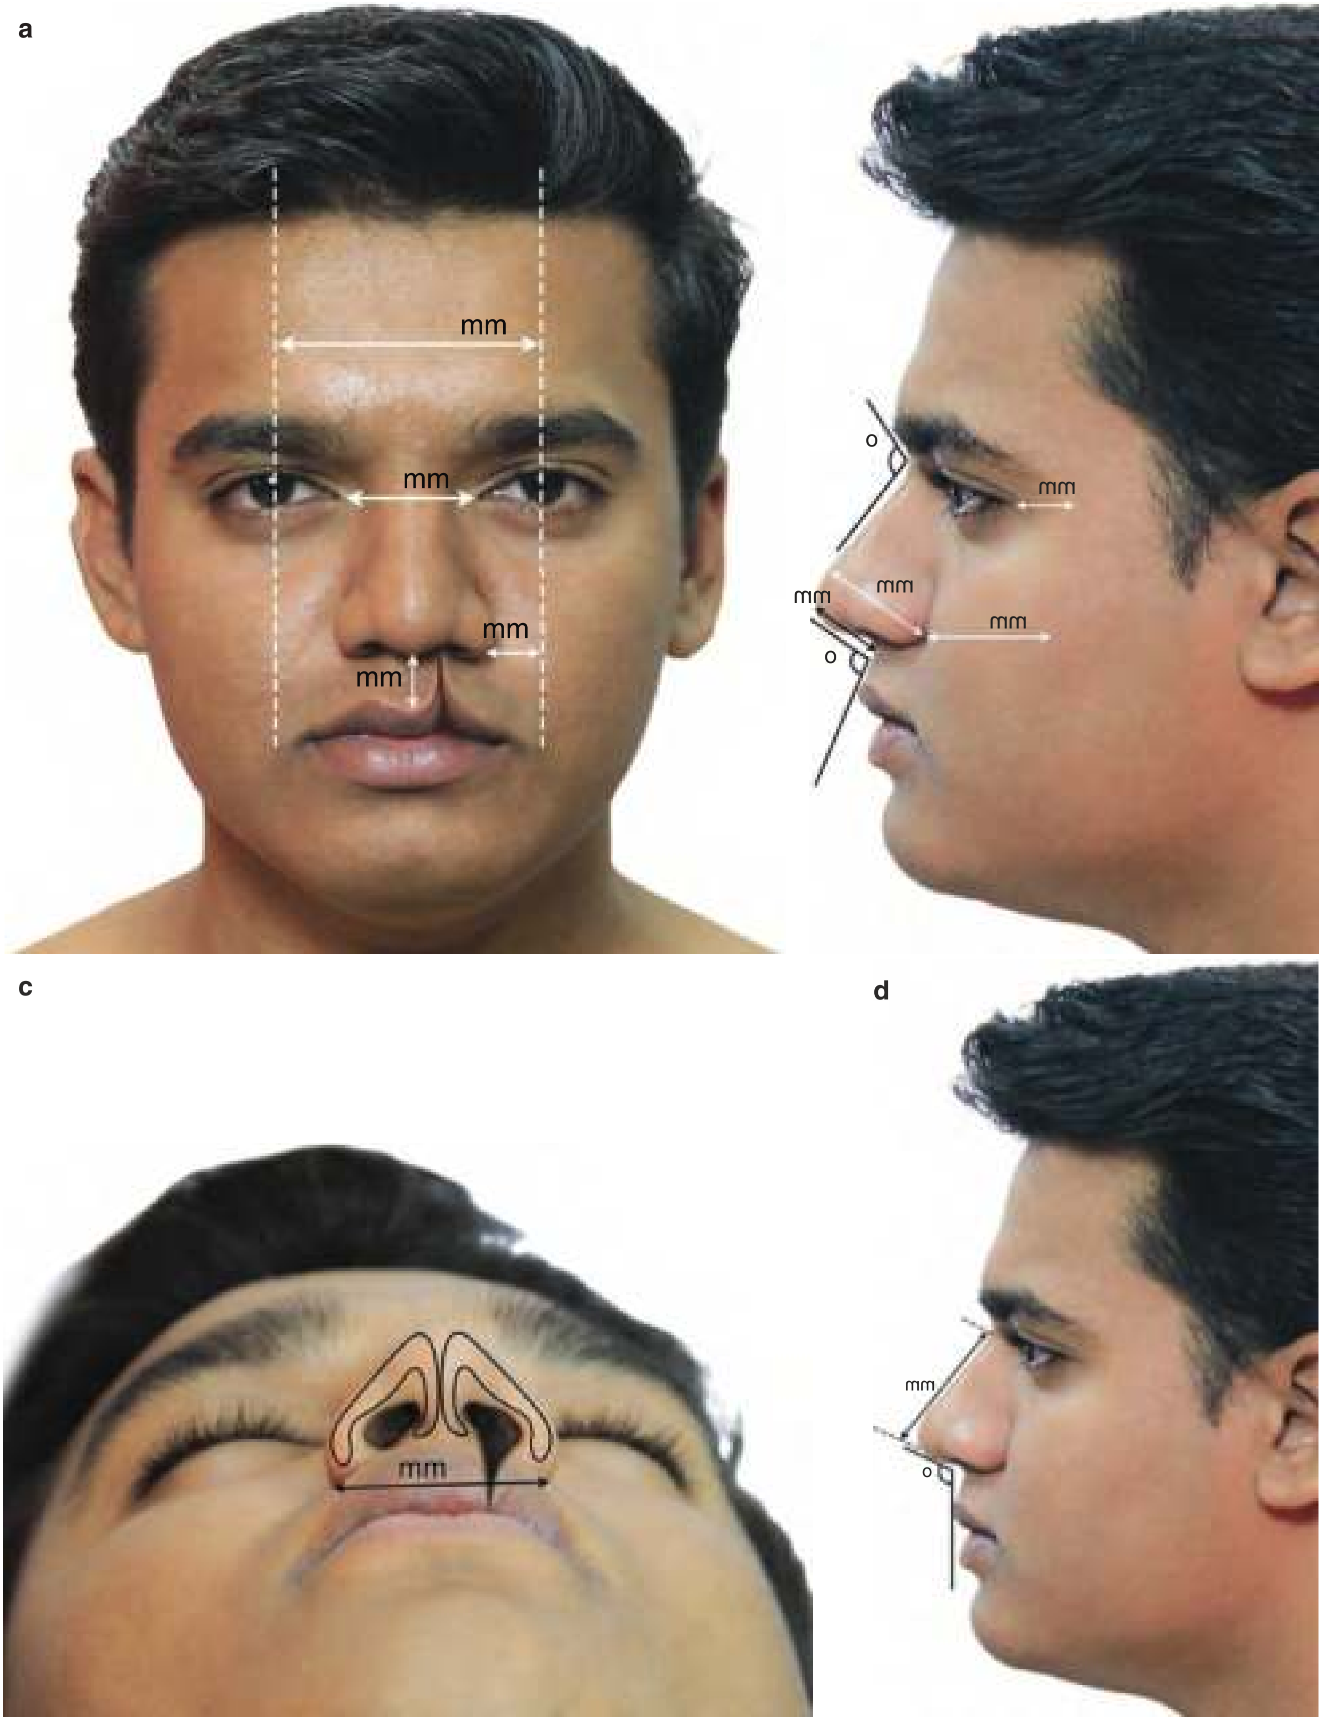

Fig. 76.3 (**a**–**d**) Important angular and linear measurements as traced from preoperative photographs can serve as a guide for preoperative surgical planning

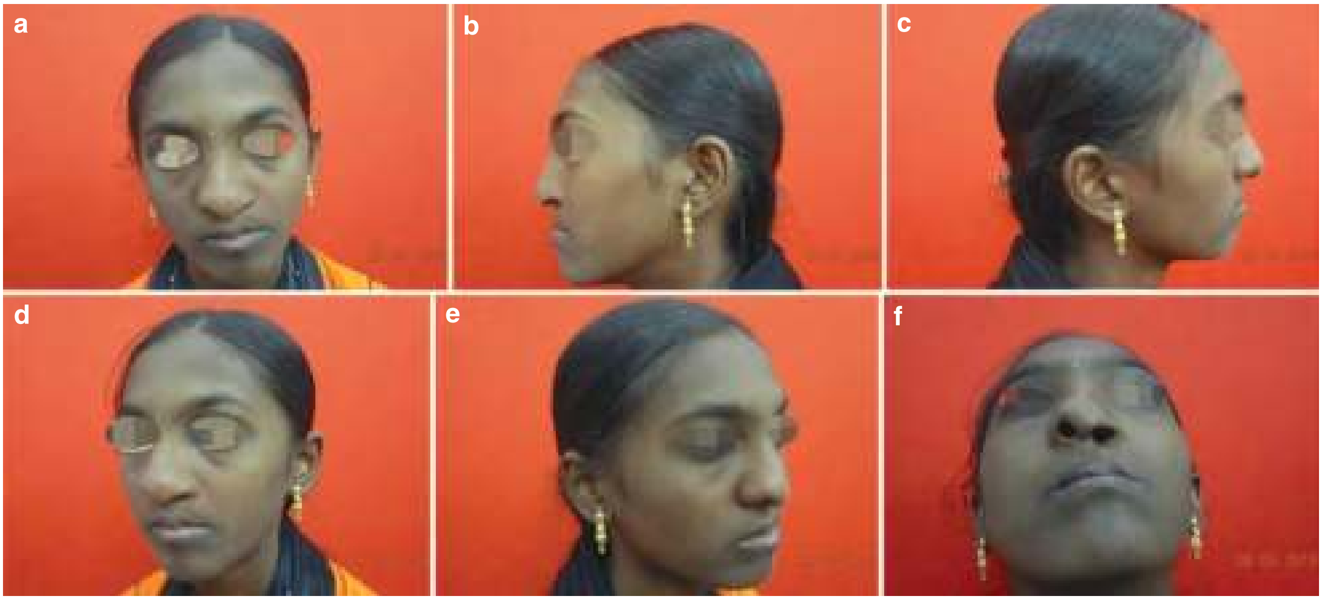

Fig. 76.4 (**a**–**f**) Standard photographic views for cleft rhinoplasty. (**a**) Frontal view. (**b**) Left lateral view. (**c**) Right lateral view. (**d**) Left lateral oblique view. (**e**) Right lateral oblique view. (**f**) Basal view

allows precise recording of selected parameters as the soft tissues are not deformed.

76.4.6 Video Recording

Some authors [25, 26] have also resorted to video recordings that make assessment of movements possible and eliminates the need for clinical photographs as these can be generated from the video records. The disadvantages include increased time and need for trained personnel with considerable cooperation from the patients.

76.4.7 Functional Assessment

Function is as important as nasal aesthetics. Functional assessment can be established using rhinomanometry; however the usefulness of such an evaluation is limited.

76.5 Surgical Correction

76.5.1 Surgical Approaches

Cleft rhinoplasty can be accomplished using either an open or closed approach.

While primary rhinoplasty can be carried out using either of the two approaches, definitive rhinoplasty is almost always accomplished using an open approach.

The open approach allows for both superior visual control and enhanced surgical exposure of all the abnormal components facilitating their anatomical reconstruction under direct vision. Furthermore, the approach facilitates nasal sculpting either by suturing or by introduction and fixation of different types of grafts. The approach also helps in saving time when compared to the closed approach. When employing the open approach, a combination of bilateral marginal incisions with an inverted V mid-columellar incision is preferred among most surgeons [27] (Fig. 76.6a, b).

Sometimes, additional skin needs to be recruited in the columella. In such cases, the typical external columellar incision can be modified. When addressing the unilateral cleft nasal deformity, columellar lengthening can be achieved with the help of an asymmetric V to Y incision on the side of the cleft. The V to Y incision is made in the midline, recruiting the skin from the upper lip into the columella in cases of bilateral cleft nasal deformity. A viable alternative incision in cases of bilateral cleft noses is an upper lip forked flaps which achieve columellar lengthening together with narrowing of the central segment [28].

Other viable options include the use of prolabium advancement flap together with an Abbe flap, composite graft of skin and auricular cartilage and skin rim rotation flap [29].

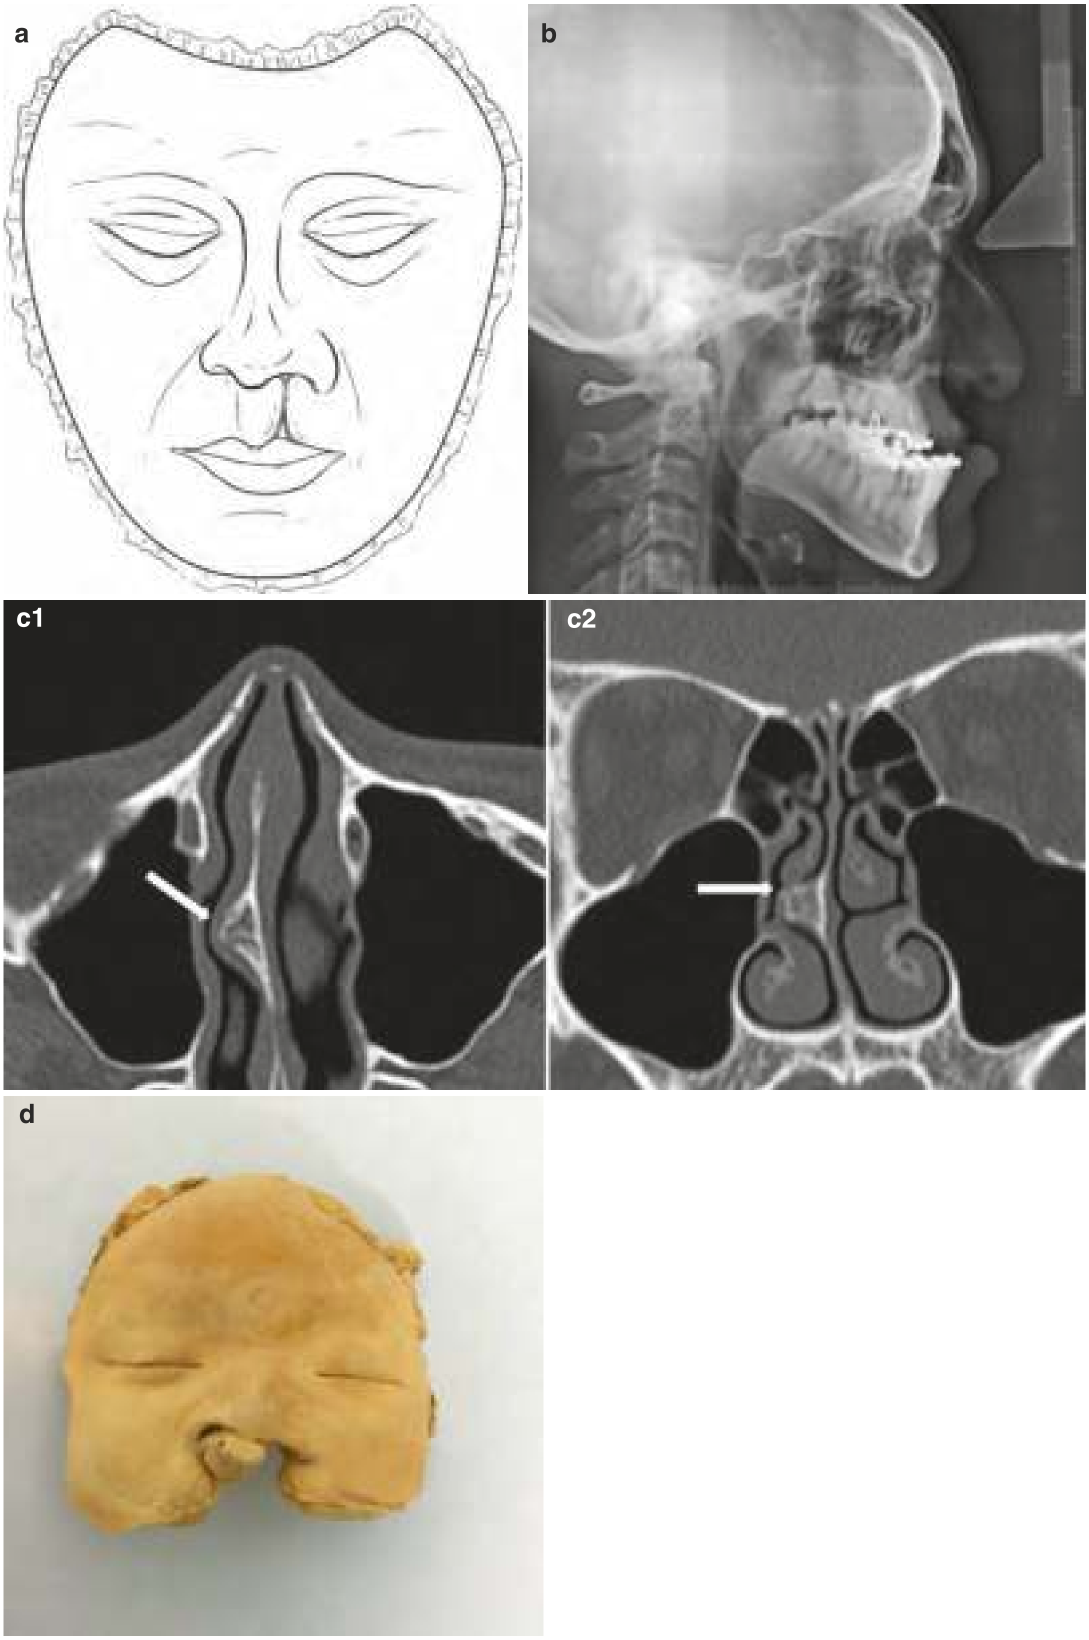

Fig. 76.5 (**a**–**d**) Tools for preoperative patient evaluation for cleft rhinoplasty. (**a**) Three-dimensional model of the face. (**b**) Lateral cephalogram for cephalometric analysis for evaluating the maxillary and chin position prior to cleft rhinoplasty. (**c**) (1 and 2): Axial and coronal CT scan views allow for evaluation of the nasal septal deviation objectively (white arrows). (**d**) Facial cast for evaluating the nasal morphology

Fig. 76.6 Open approach for cleft rhinoplasty. A combination of inverted V (**a**, **b**) transcolumellar and bilateral marginal incisions is typically employed. (**a**) Marking of the incision. (**b**) Skeletonisation of the nose using the above incision

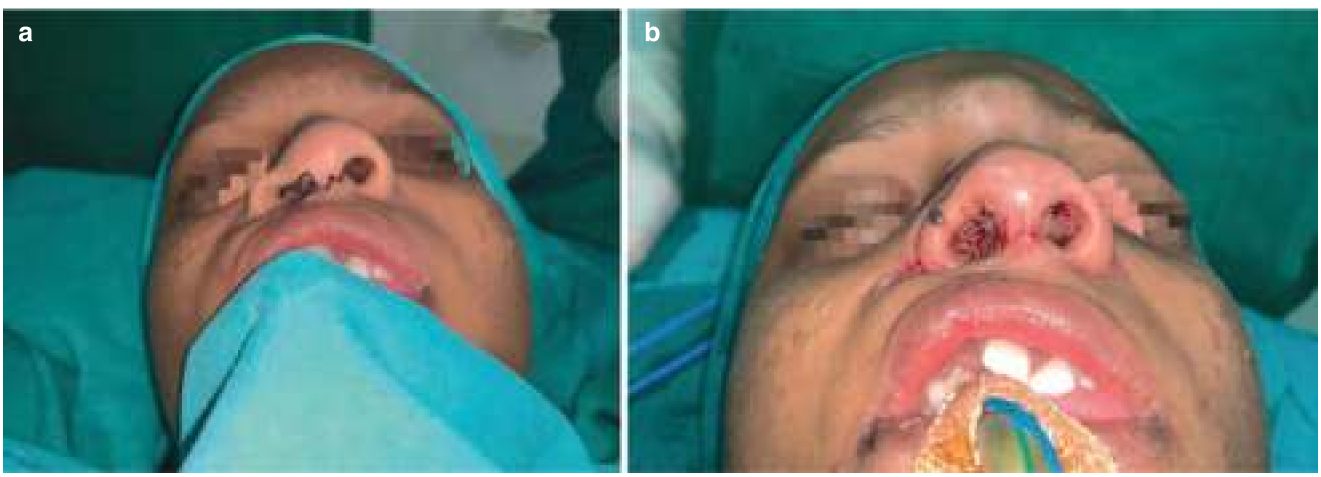

Fig. 76.7 (**a**, **b**) Tajima and Maruyama reverse U incision for correction of nostril asymmetry. (**a**) Marking of the reverse U incision on to the external nasal skin on the right side of the nostril. (**b**) Correction of nostril asymmetry following closure (also see Fig. 76.17)

Most patients with unilateral cleft nasal deformity are often disturbed with the nostril asymmetry that accompanies such a deformity. This has been addressed using a reverse U incision as described by Tajima and Maruyama in 1977 [30]. The technique involves extending the marginal incision into a rim incision at the point of the alar web. The skin of the web is incorporated with the LLC flap and vestibular skin, and the flap is suspended both medially and cephalically from the LLC to the ipsilateral ULC and the septum using sutures (Fig. 76.7a, b). This helps in recruiting the external skin of the alar web to the vestibular lining which also helps in addressing the issue of deficient vestibular skin associated with unilateral cleft noses. This incision is well accepted among surgeons for correction of nostril asymmetry.

76.6 Primary Rhinoplasty

The aim of the surgery is to attain symmetry of the nasal tip and alar base.

76.6.1 Unilateral Cleft Nasal Deformity

The literature has reported a number of techniques for achieving symmetry in unilateral cleft nasal deformities primarily [15, 31]. The salient points that are common to most of these techniques include:

- Completely freeing the soft tissue attachments of the alar base from the pyriform aperture and maxilla for symmetrical repositioning of the retro-positioned alar base on the cleft side.

- Nasal tip plasty is carried out to increase the nasal tip projection. This is made possible by utilising the incisions for lip repair. Dissecting through these incisions, the skin overlying the LLC's is dissected with the help of medial and lateral tunnels, and the cutaneous attachments of the lateral crura are separated [1] (Fig. 76.8a).
- Repairing the caudal septum by attaching it to the anterior nasal spine.
- Finally, following complete closure of the lip and repositioning of the alar base, the LLC is secured in the new position using either transnasal sutures or nasal bolsters [32]. These sutures help in recreating the cleft side dome thereby increasing the nasal tip projection and improving the tip symmetry (Fig. 76.8b).

76.6.2 Bilateral Cleft Nasal Deformity

In bilateral cleft nasal deformities, the retro-positioned alar bases are released from the nasal lining laterally and positioned symmetrically by securing the nasalis muscle to the nasal septum on both sides. The nasal muscular ring is reconstructed as performed in the unilateral cleft noses. Nasal tip surgery is not performed at this stage but is carried out at the time of intermediate rhinoplasty [21].

76.7 Intermediate Rhinoplasty

76.7.1 Unilateral Cleft Nasal Deformity

The intermediate rhinoplasty addresses two issues in unilateral cleft nose: the asymmetric position of LLC on the side of the cleft and vestibular webbing laterally (Fig. 76.9a–d).

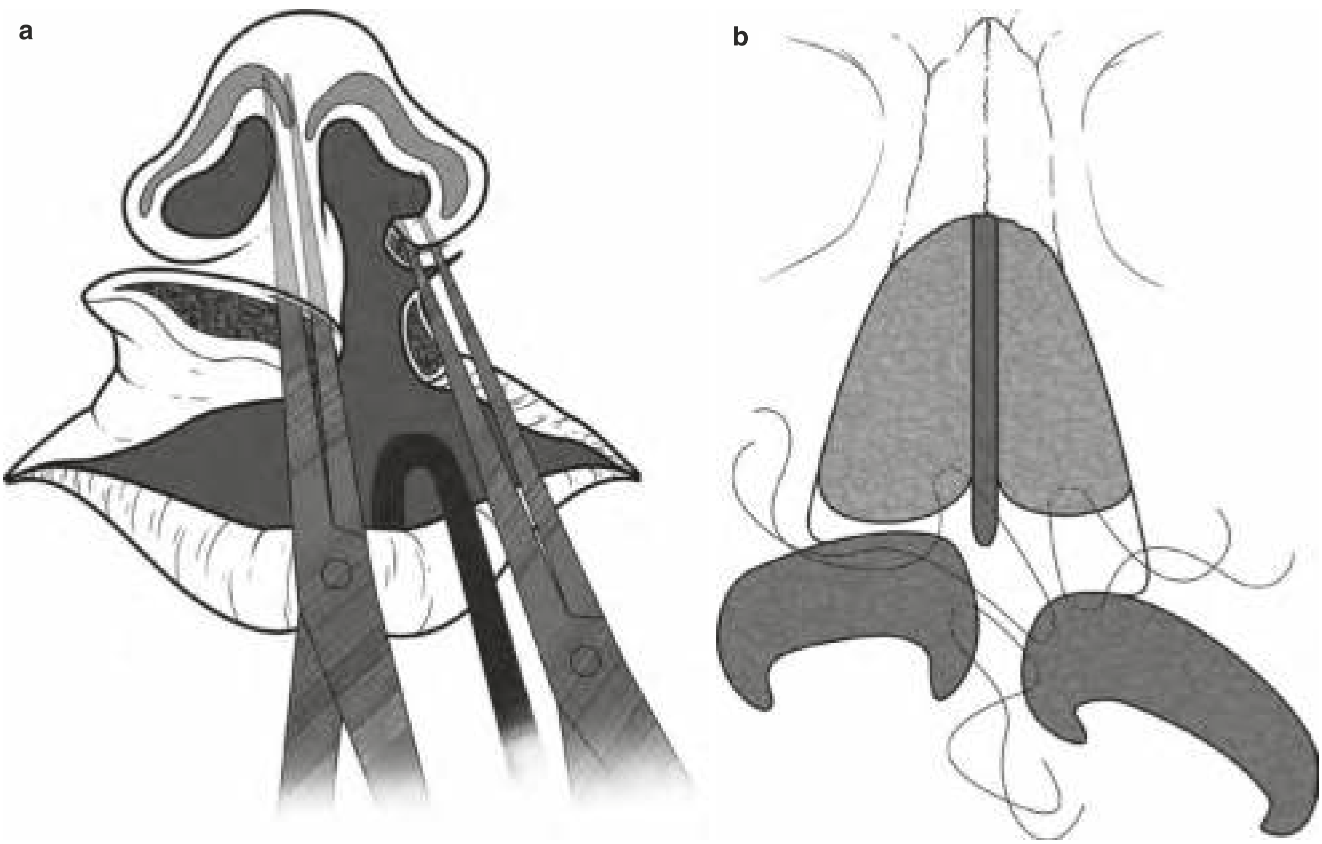

Fig. 76.8 (**a**, **b**) Schematic representation of primary rhinoplasty in a unilateral cleft lip nasal deformity case. (**a**) Dissection for access to crura utilising the incisions for lip repair. (**b**) Recreating the cleft side nasal dome using transnasal sutures for better symmetry and projection. The sutures are made to pass through the nose, vestibular lining and LLCs and through the nasal skin before being reintroduced through the nasal skin and ULC and sutured down within the nasal vestibule. It is important to reintroduce them through the same hole they exited to prevent necrosis of the nasal skin

Fig. 76.9 (**a**–**d**) A case of unilateral cleft nasal deformity in a 6-year-old child managed using intermediate rhinoplasty. (**a**) Preoperative frontal view. (**b**) Preoperative basal view showing the abnormal position of LLC on the cleft side (Left). (**c**) Postoperative frontal view. The abnormal position of the LLC on the cleft side is corrected using an open approach (inverted V transcolumellar incision) and transnasal sutures (black arrow). (**d**) Postoperative basal view showing symmetrical positioning of the LLC on the cleft side (black arrow)

In cases of asymmetric position of the LLC on the cleft side, an open approach is usually preferred that exposes the LLCs bilaterally so that the geometric differences between the two sides can be appreciated and subsequently corrected using suture techniques followed by closure along the columellar incision [33].

In cases of lateral vestibular webbing, a V/Y-type incision or a back cut can be carried out to affect the lateral nasal sidewall lengthening which will subsequently bring the LLC forward [1].

76.7.2 Bilateral Cleft Nasal Deformity

In such cases, intermediate rhinoplasty corrects the depressed LLCs as well as affects lengthening of the short columella [1, 34] (Fig. 76.10a, b). An open approach is employed for correction of the above-mentioned scenarios. Following exposure of the LLCs, the angle of divergence between the domes is decreased using transdomal suture, helping in increasing the projection of the nasal tip [34].

76.8 Secondary or Definitive Rhinoplasty (Video 76.1)

Despite an excellent primary rhinoplasty, secondary deformities coupled with scarring are bound to occur. These issues are tackled upon by definitive rhinoplasty. The surgeon's skill and his expertise will ultimately decide the success of primary cleft lip nose repair and the severity of secondary deformities. The success of definitive rhinoplasty depends on addressing every component of the deformity in a systematic manner beginning with the nasal base and ending with the alar base reduction.

76.8.1 Nasal Base

Creating a strong base for the nose represents the preliminary step in correction of either unilateral or bilateral cleft nasal deformity, the foundation for which is laid down at the time of primary cheilorhinoplasty with the approximation of the nasal floor with the lip. This is followed by addressing

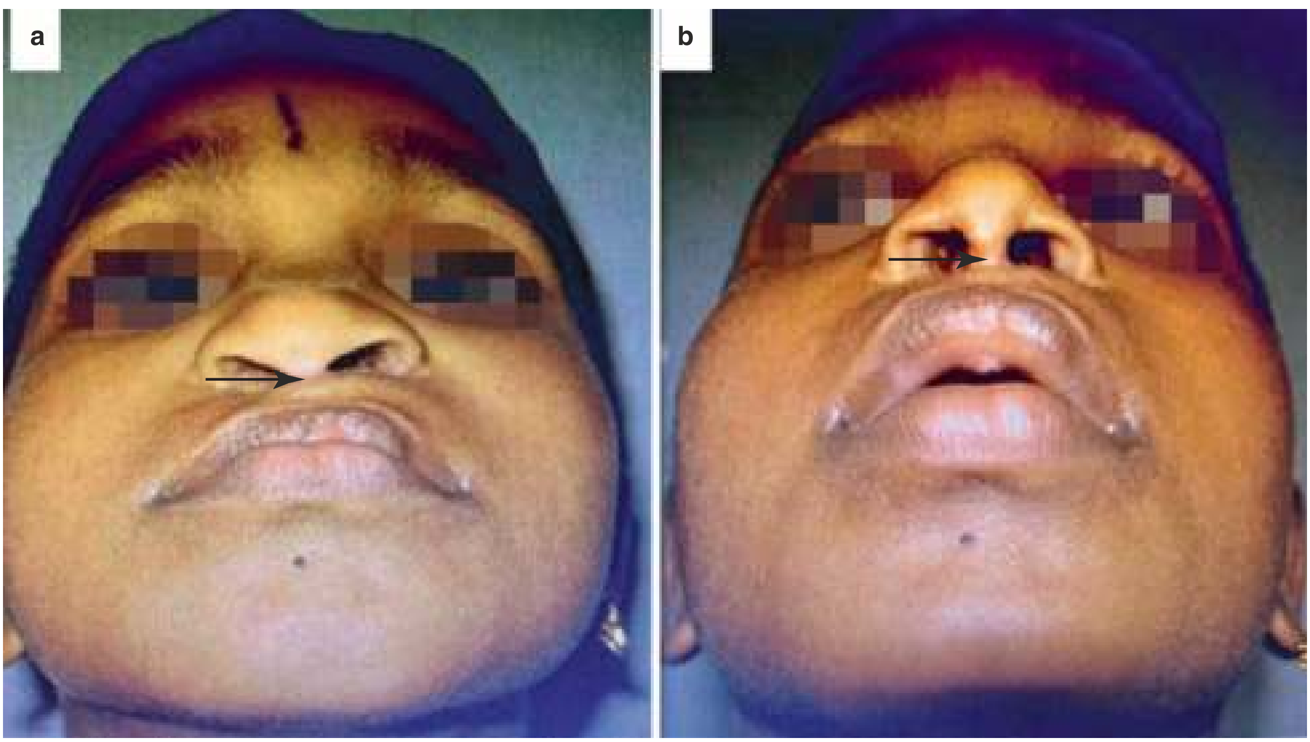

Fig. 76.10 (**a**, **b**) A case of bilateral cleft nasal deformity in a 5-year-old managed using intermediate rhinoplasty. (**a**) Preoperative basal view showing the abnormal position of the LLCs as well as short columella (black arrow). (**b**) Postoperative basal view. One can appreciate lengthening of the columella that is achieved (black arrow). The correction of LLCs is also affected bilaterally. An open approach was utilised with bilateral reverse U incision to correct the horizontal orientation of the nostrils

the skeletal deficiency in the maxilla and premaxilla and correction of the retro-positioned alar base. In some cases, the nasal sill and the nasal base might still have to be augmented at the time of secondary rhinoplasty using local tissue flaps [35].

76.8.2 Septum

The caudal septum is seen to deviate to the non-cleft side, bowing away from the anterior nasal spine with resultant nasal airway obstruction. This requires resection of this portion of the septum, maintaining at least 1 cm dorsal, and caudal septal segments in the form of a L strut to help in preserving the nasal tip and the dorsal support [21] (Fig. 76.11a–i). When doing so, more than 40% contact point must be allowed between the crest of the maxilla and L strut which helps by subjecting the septum to decreased load forces thereby preventing nasal deformities like saddle nose deformity or ptosis of the nasal tip from developing in the future. It is observed in most cases that despite resecting the deviated portion of the septum, the L strut continues to remain deviated due to residual memory that is present in the L strut. In such cases, sutures can be placed through the ULC and the septum applying force in the direction opposite of the deviation to aid in correcting the asymmetry [36]. In cases of severe septal deviation, one needs to resort to using caudal septal extension graft as struts along the dorsal margins followed by surgical repositioning of the caudal septum [37, 38] (Fig. 76.11). The resected portion of the septal cartilage can itself be used as a spreader graft. In cases where the resected septal cartilage is inadequate, one can use rib cartilage as a spreader graft. The caudal portion of the L strut is secured to the anterior nasal spine with the help of sutures. Some surgeons also prefer to make a notch in the anterior nasal spine to which the L strut can be secured. If there exists any residual memory in the septal cartilage after securing it to the nasal spine, it can be relieved by cartilage scoring with the help of a no. 15 blade.

Access to the caudal nasal septum is achieved using an open approach and by dissecting between the medial crura of the LLCs [21]. From this point onwards, a sub-perichondrial flap can be developed. Make sure that the dissection is in the proper plane. The blue appearance of the septal cartilage serves as a guide to correct plane of dissection. The mucoperichondrial flap should be cautiously raised without perforating the surrounding mucosa to provide superior coverage for a large septal extension graft especially from the rib.

76.8.3 Middle Third of the Nose

The middle third of the nose has poor support on the side of the cleft and therefore the ULCs tend to collapse resulting in internal valve dysfunction which affects the patient's ability to breathe normally. In such instances, spreader grafts placed between the septum and ULCs on either side and stabilised using sutures can help open the internal nasal valve and improve breathing [39, 40] (Fig. 76.11i).

76.8.4 Nasal Tip or LLCs

Once the caudal septum is stabilised, attention is shifted to the correction of asymmetric LLC and the nasal tip complex. Various techniques are advocated for the same.

- **Cephalic trimming:** Wide LLCs can make the nose appear asymmetric. In such cases, following surgical exposure of the LLCs via an open approach, small cephalic strips of LLCs can be excised advocating more excision on the larger side and leaving at least 5 mm for support. This manoeuvre narrows a bulbous nasal tip and improves symmetry. Cephalic trimming is followed by correction of the septal deviation by resection and replacement (Fig. 76.12a).
- **Septal extension graft:** A strong septal extension graft helps in providing support to the nasal tip and improves the tip projection by rotating an acute nasolabial angle which is the consequence of tip ptosis back to normal [22, 41]. The graft is ideally sutured in between the medial crura of LLCs and the caudal septum (Fig. 76.12b). Prior to suture stabilisation of the septal extension graft, the medial crus of LLC on the cleft side is advanced superiorly to match the vestibular dome height of the non-cleft side. This is then secured to the extension graft using mattress sutures (Fig. 76.12c). In cases where spreader grafts are used to relieve the internal nasal valve collapse, the extension graft can be secured to the spreader grafts. In such cases, the base of the nose is fortified with bolster sutures from medial crus to the septal extension graft. The strut (extension graft) is ideally placed slightly behind the medial crura to prevent the columella from either looking too wide or feeling too firm for the patient [39]. A good tip support entails extension of the septal extension graft for at least 4–5 mm beyond the septum maintaining a thickness of at least 1 mm. This also helps to resist deprojection from the resulting scar tissue that will form in this region.

Fig. 76.11 (**a-i**) 22-year-old patient with unilateral cleft lip and palate before (**a–c**) and 2 months after (**d–f**) open rhinoplasty performed to correct the severely deviated caudal septum. (**g**) Intraop picture showing batten grafting. (**h**) Resection of septal cartilage in cases of severely deviated nasal septum, maintaining an L shaped contact (black arrow) for preserving tip and dorsal support. The resected portion can be utilised as a septal extension graft (green arrow). (**i**) Spreader grafts placed between ULCs and nasal septum (black arrows)

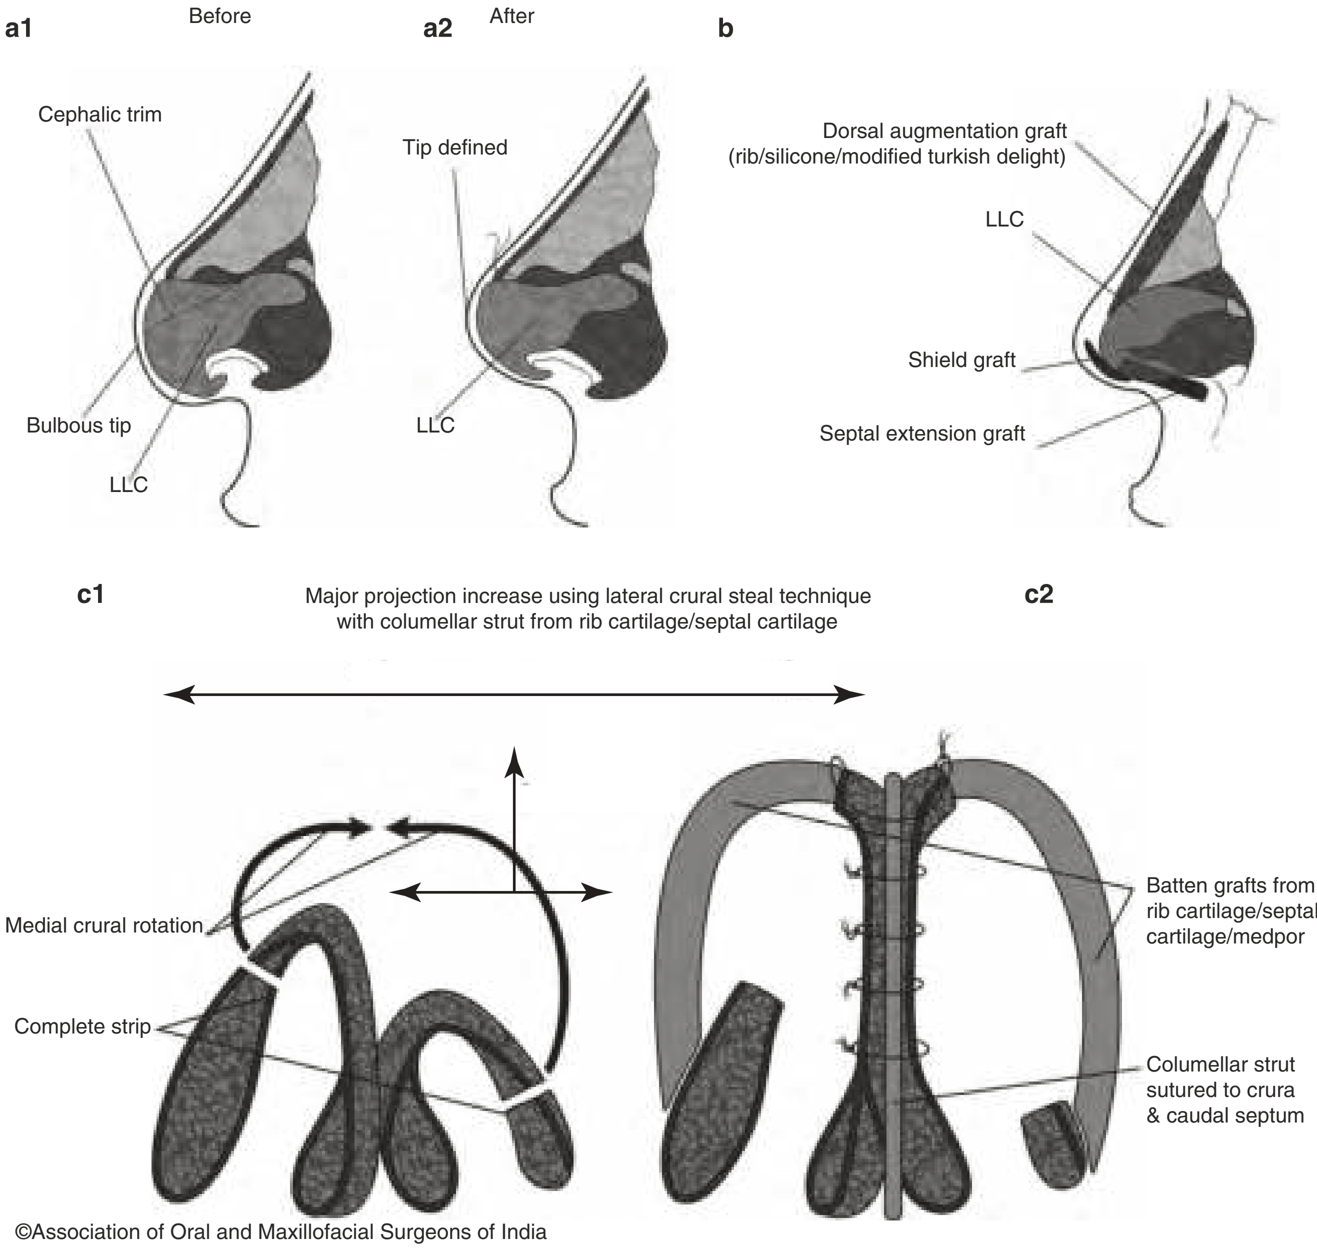

Fig. 76.12 (**a–c**) Schematic representation of techniques for correction of asymmetric LLCs and nasal tip complex. (**a1**, **a2**) Cephalic trimming (before and after). (**b**) Shield grafts, caudal septal extension grafts for improving the symmetry and projection of the nasal tip. Dorsal nasal augmentation is also been shown. (**c1**, **c2**) Lateral crural steal technique

- **Lateral crural steal or advancement flaps:** The medial crus of the LLC on the cleft side is shorter in vertical length, whereas the lateral crus is longer with a horizontal orientation as compared to the non-cleft side. In such cases, lengthening of LLC on the cleft side is achieved using the lateral crural steal technique which requires cutting of the longer part of the lateral crus of the LLC on the cleft side and shorter part of the lateral crus of LLC on the non-cleft side [39] (Fig. 76.12b). This facilitates utilisation of the longer crural flap on the side of the cleft for increasing the nasal tip projection on the cleft side thereby contributing to improved nasal tip symmetry. The lateral crura are then reconstructed using either robust cartilage struts or batten grafts in onlay or inlay fashion.
- **Shield graft:** These grafts are utilised to accentuate the tip projection further as well as improve the symmetry and tip shape (Fig. 76.12b).

In bilateral cleft nasal deformities, LLCs of either side need repositioning with tip suture techniques. In cases of weak cartilages, septal extension grafts as columellar struts as well as in onlay position need be used for ideal projection [42]. Large nasal tip can benefit from cephalic trimming of both LLCs. The goal is to decrease the angle of divergence between the domal points of the lower lateral cartilages, create a more defined nasal tip and provide a strong nasal framework for better tip projection.

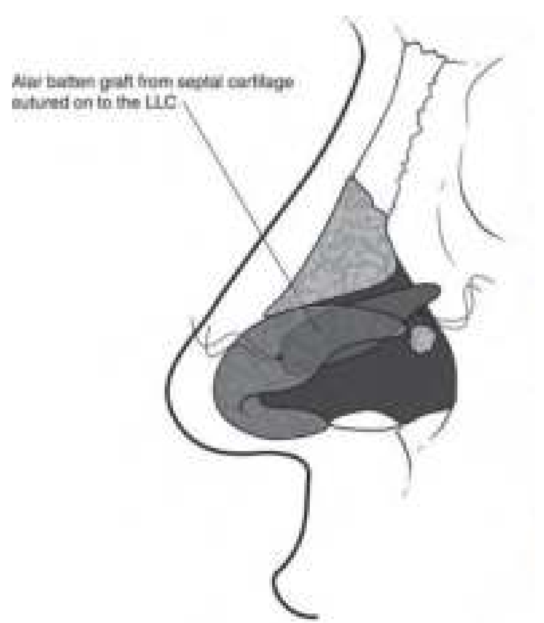

Fig. 76.13 Alar batten grafting demonstrated in a case of unilateral cleft nasal deformity. The graft fortifies the LLC and removes the concavity of the same (Refer Fig. 76.17i)

76.8.5 Alar Rim (Lateral Crus of LLC)

The LLC on the cleft side has poor skeletal support on the medial and lateral sides which makes the LLC concave with an introverted contour to the ala [43]. This concavity can be managed with different techniques, viz. suture techniques using horizontal mattress sutures, underlay alar batten grafts, onlay grafts and autocartilage flaps [44]. The lateral crus of LLC can also be dissected from the underlying vestibular skin, removed, flipped and resutured in a convex fashion.

Alar batten grafts either are placed below the residual lateral crus as underlay graft or can be placed above it as an onlay graft. This graft strengthens the lateral crus of the LLC and removes the concavity of LLC [39] (Fig. 76.13). Suture techniques such as horizontal mattress sutures also strengthen and flatten the lateral crus of the LLC. Lastly, the cephalic margin of the LLC can be made into an advancement flap which can be advanced to provide support to the remaining LLC. Each of these techniques provides support to the lateral crus of the LLC and fortifies the external nasal valve.

76.8.6 Nasal Dorsum and Nasal Osteotomies

The following issues are observed when addressing this area in definitive rhinoplasty.

- **Flat and under-projected dorsum deviating away from the cleft:** The authors' preferred technique for addressing this issue is by using a dorsal onlay graft from rib or modified Turkish delight. In modified Turkish delight technique, the authors use morselised Medpor mixed with autogenous blood and wrapped in Surgicel to affect dorsal nasal augmentation [45] (Figs. 76.12b and 76.14a–d). This cancels out the need to carry out harvesting of the rib cartilage and there eliminates the donor site complications associated with the same. Although silicone implant can also be used for this purpose, there is increased possibility of infection, graft migration or displacement or possible extrusion. It should be noted that the dorsal nasal pocket dissected should just accommodate the implant so that the implant fits snugly without much displacement or migration.
- **Dorsal humps:** The dorsal hump usually peaks at the region of the rhinion where the nasal bones and ULC join.

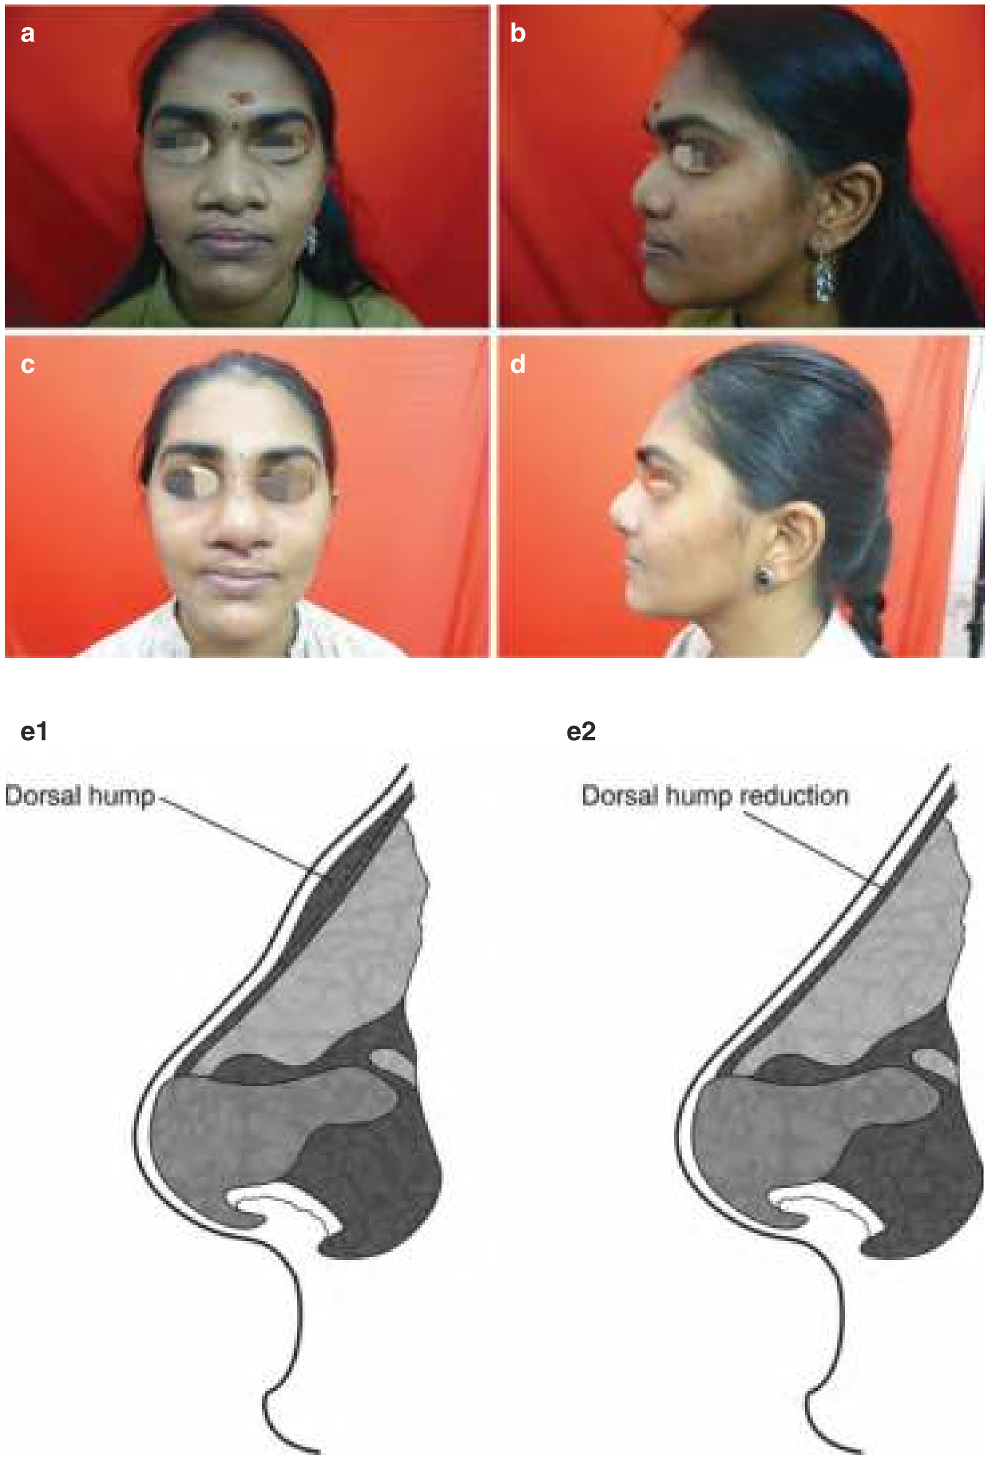

Fig. 76.14 Addressing the nasal dorsum and nasal osteotomies. A case of flat and under-projected dorsum managed using modified Turkish delight technique. (**a**, **b**) Pre op frontal and lateral. (**c**, **d**) Post op frontal and lateral. (**e1**, **e2**) Schematic representation of dorsal hump reduction. (**f**, **g**) Schematic and clinical lateral nasal osteotomies

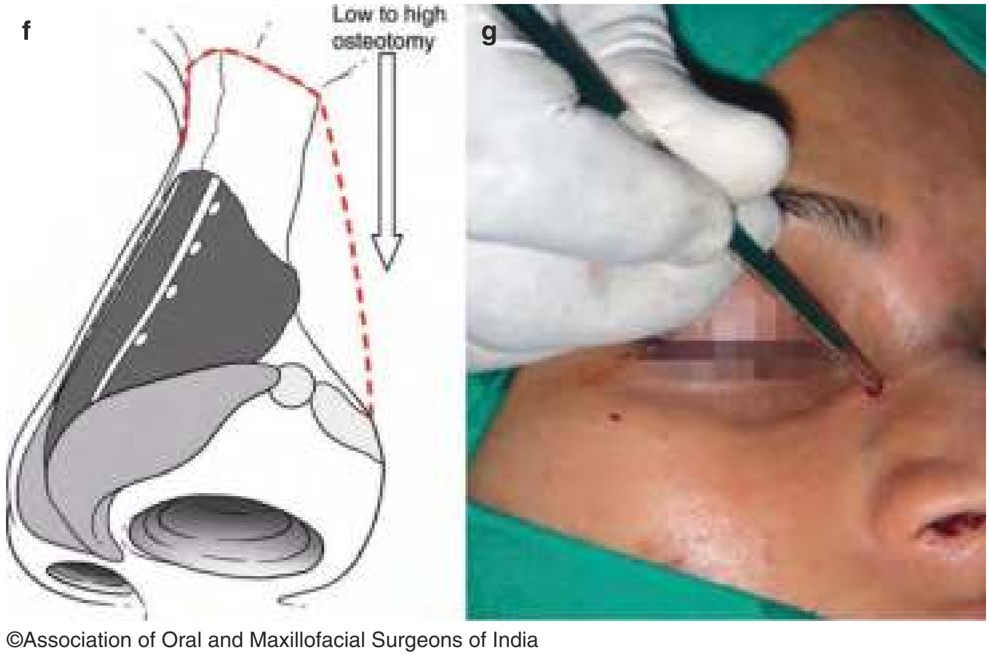

Fig. 76.14 (continued)

Dorsal hump should be addressed in conjunction with other aspects of the nose, or else an open roof deformity will be the consequence. The correction is carried out by reduction of the bone by rasping and the ULC using either scissors or number 15 blades (Fig. 76.14e).

- **Thick and wide nasal bones with deviation towards the non-cleft side with wide dorsum:** Such cases require either lateral or paramedian osteotomies to narrow the dorsal width and bring about symmetry. The authors' preferred technique for lateral osteotomies is by introducing a 2–3 mm osteotome transcutaneously to create micro punctures along the planned osteotomy going from low to high [42] (Fig. 76.14f, g). The same can also be carried out by introducing the osteotome transnasally. If this does not affect narrowing of the dorsum adequately, then the authors resort to paramedian osteotomies to create an open roof deformity followed by in-fracturing the nasal bones. This manoeuvre almost always requires placement of spreader grafts to prevent collapse of the internal nasal valve.

76.8.7 Piriform Rim and Pre-maxilla Augmentation

Cleft noses whether unilateral or bilateral present with skeletal deficiency in the region of the premaxilla and piriform rim which brings about posteroinferior displacement of the nose. If this area is left unattended, the final result is bound to be asymmetric despite addressing all the other aspects of rhinoplasty well [39]. This area can be augmented using a portion of the rib graft and securing it with a screw (Fig. 76.15). This allows for improving the anterior projection. Other options include the use of silicone implant, cortical one or fat grafting [21].

76.8.8 Nasal Alae

The nasal alae in cleft noses as discussed previously are usually displaced in a lateral and inferior direction. Correcting the abnormal orientation of the nasal alae represents the concluding steps in definitive rhinoplasty. This is usually achieved using two techniques, viz. V to Y advancement and Weir procedure (alar resection) along the alar facial groove [46–48]. These two procedures need to be supplemented with augmentation of the piriform rim as well as vertical enlargement of the nostril on the cleft side in order to achieve true symmetry. Vertical enlargement of the nostril can be achieved using skin grafts or composite grafts just inside the ala. Superior results are possible despite not addressing the nostril except from the basal view which will make the vertical height discrepancy of the nostril evident. Weir procedure is used in cases of excess skin laterally and allows for symmetrical correction of the alar base on the cleft side nostril which is usually longer and elongated (Fig. 76.15a–g). It also provides access for carrying out augmentation of the piriform rim using grafts. Nostril retainers are often sutured in place for the purpose of helping in moulding and maintaining the nasal sill.

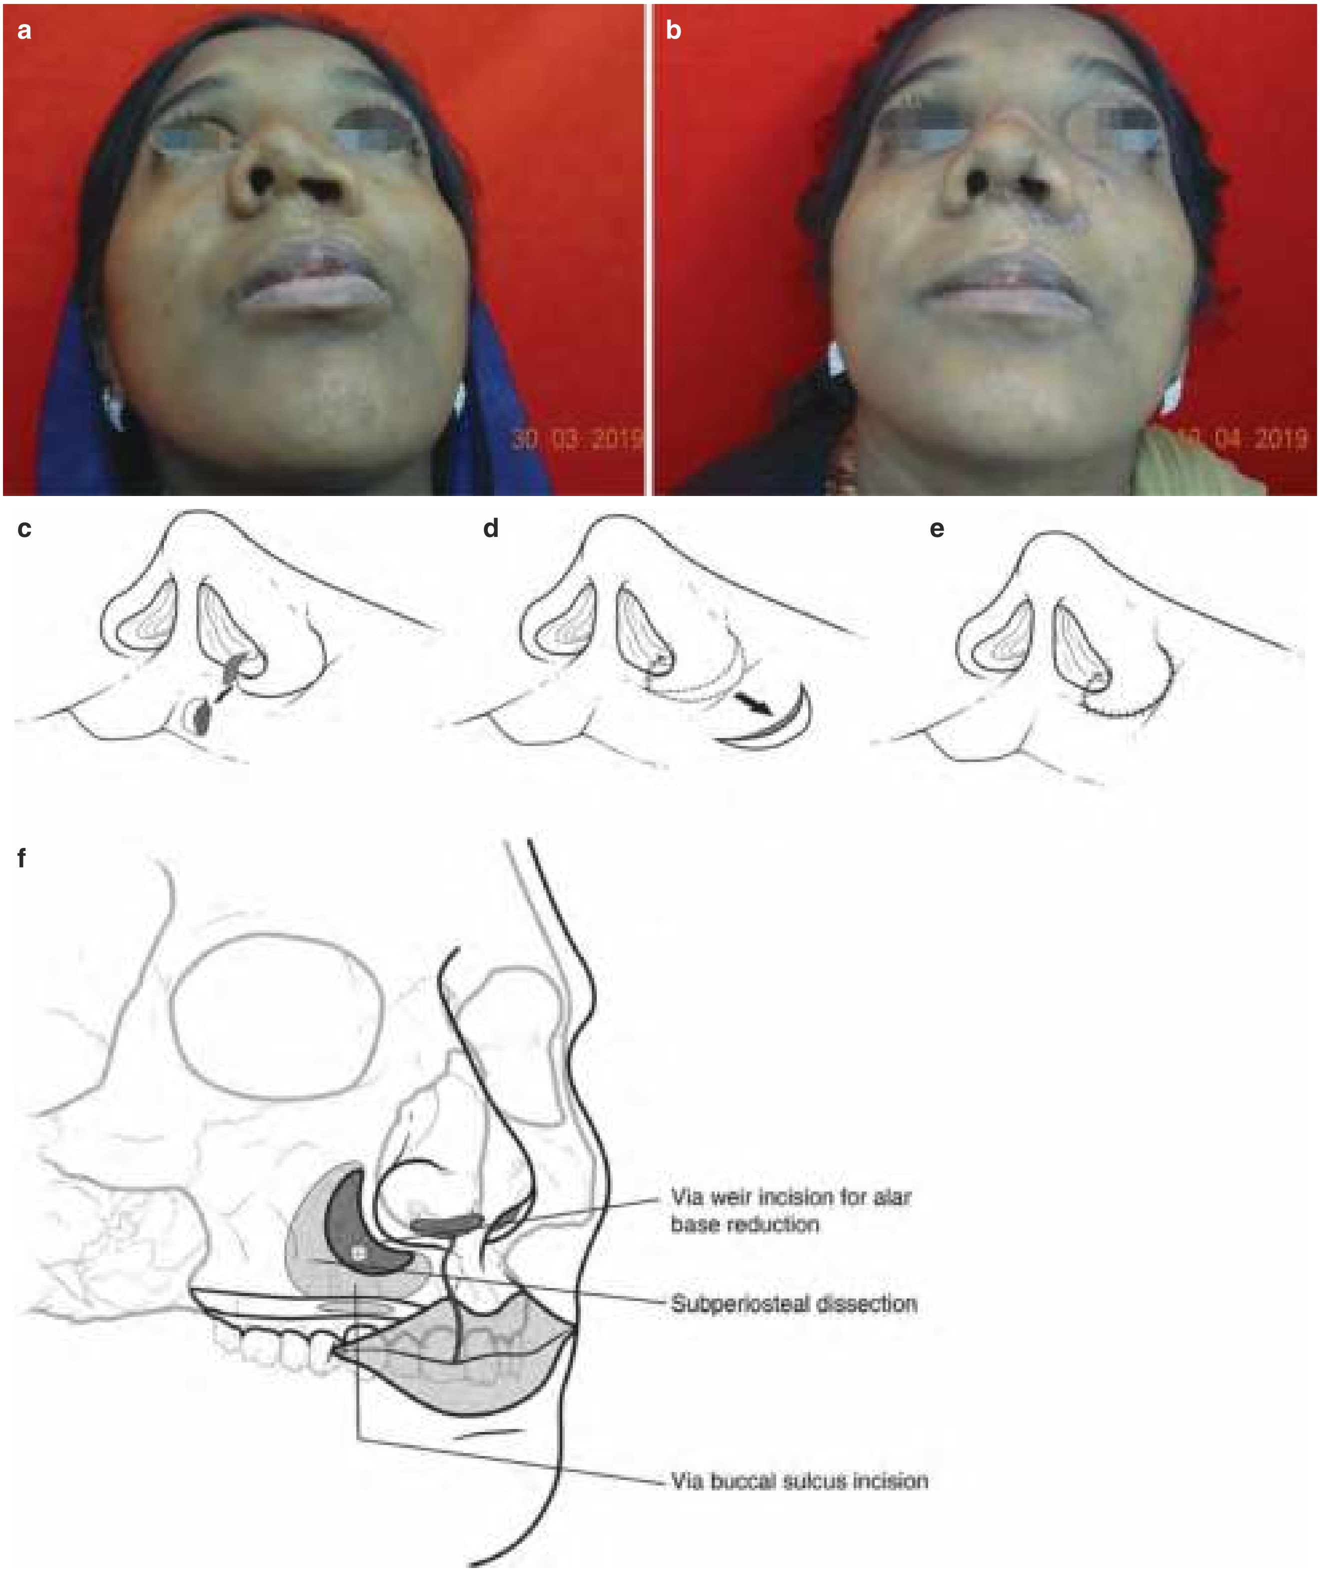

Fig. 76.15 (**a**–**f**) Piriform rim augmentation and alar base reduction using Weir procedure. (**a**, **b**) Pre op and post op basal views. (**c**) Alar base resection. (**d**) Peri alar resection. (**e**) Closure. (**f**) Piriform rim augmentation

76.9 Use of Grafts in Definitive Rhinoplasty

Grafts are pivotal to the long-standing success of definitive rhinoplasty in terms of nasal aesthetics and function. Autologous tissue is the norm and always preferred over synthetic substitutes like Medpor and silicone which presents with higher incidences of infection, displacement as well as possible extrusion. Among the autologous options available, cartilage (harvested from septum, auricle or rib) and bone (harvested from cranium, rib or iliac crest) are widely used.

Cartilage grafts harvested from the septum have the advantage of being located in the same surgical field, requiring no additional incisions and therefore preventing any additional donor site morbidity. Furthermore, simultaneous correction of septal deviations is possible with the use of this graft. The disadvantages include minimal amounts of cartilage available for grafting and presence of residual memory subjecting it to deformation. When the amount of available septal cartilage is inadequate, auricular cartilage can be the source of grafting. It may offer a large area for graft harvesting, and usually does not induce local sequelae. When larger amount of cartilage is needed especially for the purpose of dorsal augmentation, rib cartilage is an excellent source especially from the right seventh, eighth or ninth rib. This cartilage is present in abundance, is quite sturdy and robust, resists deformation by scar contracture, is easy to shape and also provides superior support for optimising the nasal projection [39]. The disadvantages include graft warpage, increased operating time, visible external scar, post-operative pain and risk of pneumothorax. Another disadvantage is ossification of cartilage in older patients [39].

Cartilage grafts are classically divided into contouring grafts and structural grafts.

76.9.1 Contouring Grafts

These grafts are added to the native osteocartilaginous nose in the coronal plane to improve upon the existing nasal aesthetics. Two most common sites for placement of these grafts are the dorsum and the infratip regions of the nose which help in optimising the tip projection. These grafts are stabilised using either resorbable or non-resorbable sutures or glue. Examples of contouring cartilage graft include dorsal onlay graft or shield-type tip graft.

- **Dorsal onlay graft**: It is used for dorsal nasal augmentation. The rib cartilage is the obvious choice. We have also utilised the modified Turkish delight (diced Medpor mixed with autologous blood and wrapped in Surgicel) for the same purpose with reasonable success.
- **Shield-type tip graft:** Onlay shield grafts help in defining the nasal tip better, optimise the tip projection as well as provide support and hide any minor tip asymmetries.

76.9.2 Reconstructive Grafts

These grafts strengthen the cartilaginous framework of the nose which improves upon the existing nasal function. These grafts are placed in the sagittal plane and display long-term stability especially when an open approach is used to secure the same. They allow structural and functional reconstruction of the nasal tip in cases of definitive rhinoplasty. Examples include spreader grafts, alar batten grafts, columellar strut grafts, etc.

- **Spreader graft:** Spreader grafts serve to open the internal nasal valve and improve nasal breathing. Options for harvest include the septal or rib cartilages. The graft can also be made to extend more caudally making it to function like a strut for improved nasal tip support as well as to straighten and stabilise the septum. Severe septal deviation can be also corrected by placing the grafts along the dorsal septum while reattaching the caudal strut to the nasal spine between the medial crura by suture fixation.
- **Alar batten graft:** Batten grafts serve to strengthen the lateral crura of the LLC. The curved portion of the rib cartilage can be used to the advantage for harvesting these grafts. They are stabilised to the LLC and the strut to mimic the natural convex form of the external nasal valve and provide structural support. These grafts are critical for the correcting alar retraction whenever present.
- **Columellar strut graft or septal extension graft:** Such a graft provides support to the nasal base and can be a platform upon which the nasal tip can be suture stabilised. It can be harvested from the septal cartilage or from the interior of the rib cartilage.

76.10 Treatment Strategy for Unilateral and Bilateral Cleft Nasal Deformities

Nakamura N has devised a treatment strategy for both unilateral and bilateral cleft noses that addresses each anatomical and pathological abnormality that is seen in either scenarios [49].

76.10.1 Unilateral Cleft Nasal Deformity

The pathologic abnormalities that have been previously mentioned are best explained by Nakamura N by comparing the unilateral cleft nose to a house that is been built on a slope. The mid-pole of the house can be thought to be nasal septum, whereas the roof is the LLC and skin, the lateral pole is the vestibule and the base of the house is the maxillary bone. As the house is present on the slope, the mid-pole and the roof incline towards the downward side. In such cases, a straight house can be built on the slope by up righting the centre pole in the centre of the pillar with expansion of the lateral pole and by lifting the roof upward [49] (Fig 76.16a).

Nakamura N's treatment strategy addresses each anatomical and pathological abnormality that causes the main deformities in unilateral cleft nasal deformity listed in Table 76.1. The author's steps in definitive rhinoplasty consist of an open approach; septoplasty; repositioning of the lower lateral cartilage; medial and upward advancement of the lip and nose components, the nasal vestibular tissues, the nasal ala, nasalis muscle and the upper part of the lip including orbicular oris muscle; and nasal vestibular expansion with or without bone graft [50].

76.10.2 Bilateral Cleft Nasal Deformity

The pathologic abnormalities that have been previously mentioned are best explained by Nakamura N by likening the bilateral cleft nose to a house that is compressed by stress. In such cases, normal form of the nose can be created by extending the centre pole at the centre, advancing the roof upwards and extension of the lateral poles on each side (Fig. 76.16b). It is very critical to relieve the stress which in other words means relieving the pull on the nasal tip due to columellar skin shortage [49].

The treatment strategy devised by Nakamura N is based on the principle that the ideal technique of definitive rhinoplasty should minimise damage to either or both the upper and lower lip tissue. This strategy also addresses each anatomical and pathological abnormality that causes the main deformities of the bilateral cleft lip-nose as shown in Table 76.2. Therefore, the author's secondary correction involves open rhinoplasty, repositioning of the lower lateral cartilages, a caudal septal extension graft, medial and upward advancement of the lip and nose components, nasal vestibular expansion and columella lengthening using a nostril rim rotation flap, if necessary [51].

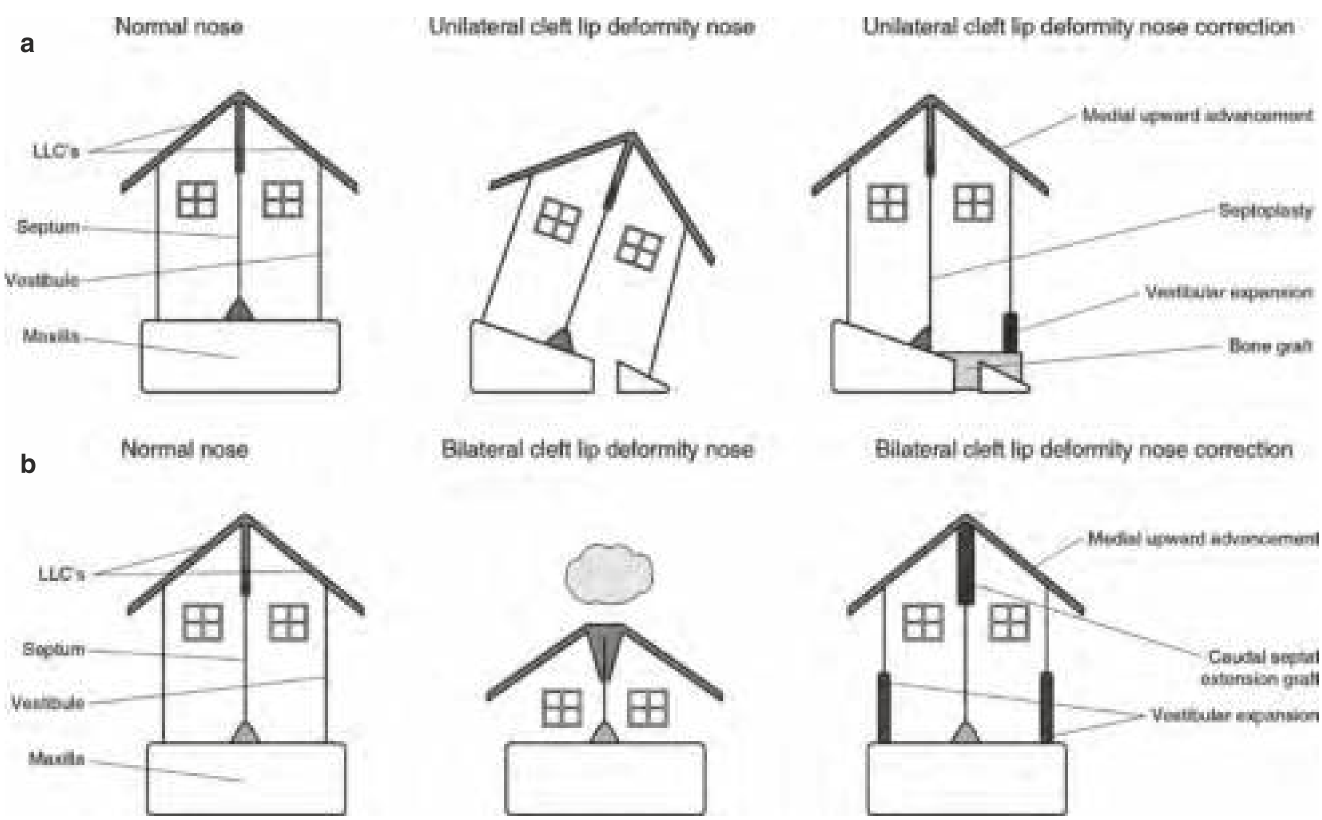

Fig. 76.16 (**a**, **b**) Simplifying cleft nasal anatomy by Nakamura N. (**a**) Unilateral cleft nasal anatomy. (**b**) Bilateral cleft nasal anatomy

Table 76.1 Treatment strategy for unilateral cleft nasal deformity

Nasal deformities	Anatomical pathological abnormalities	Secondary correction
Deviated columella	• Deviation of maxillary midline • Deviated septal cartilage	• Dissection around anterior nasal spine • Reposition of the inferior base of septal cartilage if necessary
Depressed and deviated nasal tip	• Distally and downwardly dislocated LLC on the cleft side • Growth disturbances of septal cartilage	• Freeing and repositioning of LLC by overlapping on ULC • Caudal septal extension graft
Wide and snub nasal ala on the cleft side	• Retro-positioned anterior maxillary wall • Dislocation of the attachment of nasalis muscle	• Secondary bone graft if necessary • Supra-periosteal dissection around piriform margin • Reposition of the nasalis muscle by medial upward advancement of nasolabial components
Flat and V shaped nostril	• Webbing of the rim skin • Shortage of nasalis vestibular lining • Disconnection of orbicularis oris muscle	• Bilaterally symmetric reverse U incision • Expansion of the nasal vestibule • Overlapped suturing of orbicularis oris muscle

Nakamura N et al., J Oral Maxillofac Surg 2010; 68: 2248 [50]

Table 76.2 Treatment strategy for bilateral cleft nasal deformity

Nasal deformities	Anatomical pathological abnormalities	Secondary correction
Short columella	• Shortage of columellar skin • Tightness of subcutaneous tissue in the columella	• Bilateral reverse U incision • Nostril rim rotation flap if necessary • V-Y elongation of fibrous tissue
Flat and flared nasal tip	• Growth disturbance of septal cartilage • Lateral and downward dislocation of LLC • Thin skin envelope of nasal tip	• Caudal septal extension graft. • Freeing and reposition of LLC by overlapping on ULC • Molding of fibrous tissue on nasal tip
Wide and snub nasal ala	• Dislocation of the attachment of nasalis muscle	• Supra-periosteal dissection around piriform margin • Reposition of the nasalis muscle by medial upward advancement of nasal alar component
Flat and V shaped nostril	• Webbing of the rim skin • Shortage of nasalis vestibular lining • Disconnection of orbicularis oris muscle	• Bilateral reverse U incision • Free mucosal graft in the nasal vestibule • Reposition of orbicularis oris muscle

Nakamura N et al, J Cranio Maxillofac Surg 2011; 39: 305 [51]

76.11 Outcomes in Cleft Rhinoplasty

Over the past few years, there has been an increased emphasis on the functional rather than aesthetic outcomes in cleft rhinoplasty [52]. Techniques like primary cleft rhinoplasty and naso-alveolar moulding have also been laden with complications. Although several studies have compared the different techniques of rhinoplasty to determine which technique offers the best surgical outcome, these studies lack standardised objective measurements to draw any meaningful conclusions.

The data regarding functional outcomes in cleft rhinoplasty is also sparse. In one of the prospective studies with 68 cleft patients, the authors evaluated aesthetic and respiratory outcomes at two intervals, viz. pre- and 6 months postoperatively using an active anterior rhinomanometry, rhinoresistometry and acoustic rhinometry [53]. The study showed significant improvement in many parameters. The authors concluded that while aesthetic improvement of the cleft nose is a goal, which can be achieved with regularity, nasal respiration still seems to be a challenge in cleft patients. This study highlights the need of recording functional data to study about the effects of surgery.

The outcome that is clearly documented in literature is the high satisfaction rates in patients undergoing surgery for cleft nose deformity. A study incorporating 35 patients with cleft nasal deformity was carried out by Sandor and Ylikontiola [54]. An open approach of rhinoplasty followed by alar base relocation and asymmetric nasal tip augmentation with auricular cartilage grafts was carried out in all patients. The patients' level of satisfaction was recorded in the form of a survey and interview 2 years post-surgery. A visual analogue scale (VAS) numbered 0–10 was also used by the patients to grade outcome compared to preoperative appearance at four anatomic sites. The study demonstrated highest improvements in VAS score for the tip, followed by alar position and dorsum and symmetry of nostrils. They noted that all patients were willing to undergo such procedure for a second time, if necessary. Two more studies have also reported high patient satisfaction rates for patients undergoing surgery for cleft nasal deformities [55, 56].

76.12 Further Revisions in Cleft Rhinoplasty

Although secondary cleft rhinoplasty is considered the ultimate revision rhinoplasty, in certain cases like those involving asymmetries or scarring, the patient's overall functional and aesthetic outcome may be compromised necessitating further revisions. It is important to remember that the principles that are followed in revision rhinoplasties are similar to those followed in primary and secondary rhinoplasties. The emphasis should be on early recognition after the definitive rhinoplasty so that revision is possible before scarring sets in.

76.13 Complications

The complications noted in cleft rhinoplasty are similar to those noted in the traditional open rhinoplasty in non-cleft patients. As cartilage grafts are employed, there exists a possibility of infection. Over the long term, the grafts, whether autologous, allogenous or alloplastic, can demonstrate failure. There is no difference in the risk of bleeding between cleft rhinoplasty and traditional rhinoplasty. All patients should be made aware of possible need for secondary rhinoplasty, need for revision either major or minor, existence of nostril asymmetry, visible scars, necrosis of the skin, nasal system dysfunction and morbidity associated with the donor site. One can fail to create the nasal contour as desired as well as fail in creating a normal looking appearance, and these are very common findings in cleft rhinoplasty.

76.14 Conclusion

Cleft rhinoplasty as a surgical procedure is often complex and complicated due to multiple surgical procedures that the patient needs over the years. Despite all the challenges that the procedure offers, the final surgical outcome could serve as a life changer for the patient in terms of aesthetics, function as well as symmetry. One should stick to the concepts of restoring symmetry and definition to the nasal tip and alar base, realigning and re-establishing the patency of nasal airway and preventing scarring and webbing from jeopardising the outcome. All cases have to be thoroughly planned preoperatively using the right assessment tools, and the surgery should be executed to near perfection. An increased emphasis should be placed on carrying out a primary rhinoplasty procedure keeping in mind that a definitive rhinoplasty will almost always be required to fine-tune the results.

76.15 Case Scenarios

Case 1 Figure 76.17 represents a case of right unilateral cleft nasal rhinoplasty in a 20-year-old female managed with definitive rhinoplasty. The patient presented with the chief complaint of crooked nose and difficulty in breathing from the right nostril. The patient was subjected to thorough clinical examination of both the external and internal nasal anatomy. The following features of the cleft nose were noted: deviated nasal dorsum away from the cleft in frontal view and horizontally oriented right nostril in basal view with deviated base of columella to the left. Deviated caudal septum was also noted with difficulty in breathing in the right nostril. Concavity of the right LLC was also observed in the basal view. In the lateral view, tip ptosis was observed. The patient was subjected to open rhinoplasty approach using inverted V transcolumellar incision with incorporation of the reverse U incision on the right side to correct the right nostril asymmetry. Following skeletonisation of the nose, dissection was carried between the medial crura of LLCs to expose the caudal septum which was resected to correct the septal deviation. *The authors would like to stress on the importance of addressing the nasal septum almost always in all cases when performing a definitive rhinoplasty in a unilateral cleft nasal deformity*. Substantial amount of septal cartilage was harvested to be used as a caudal extension graft to correct septal deviation as well as to improve tip projection. The cartilage was also utilised as an alar batten graft sutured to the lateral crura of LLC of the right side to correct the concavity of the right LLC. Bilateral spreader grafts were sutured between the ULC and the septum to improve the nasal breathing by improving the internal nasal valve function. Lateral crural steal was performed on the right side to maximise the projection of the nose, and further tip projection was achieved using

Fig. 76.17 (continued)

Fig. 76.17 (continued)

interdomal sutures. The deviated nasal dorsum away from the cleft was corrected using transcutaneous lateral osteotomies bilaterally in a low to high fashion. Lastly, right alar base reduction using a Weir procedure was carried out to achieve symmetry between the two alar bases. Closure of the incision was carried out using 4-0 Vicryl Rapide sutures. Comparison of the pre- and 4 weeks postoperative photographs demonstrate significant improvement in the nasal aesthetics. The patient is very satisfied with the overall result and has no complains of difficulty in breathing.

Case 2 Figure 76.18a–k represents a case of bilateral cleft nasal deformity in a 6-year-old male managed with intermediate rhinoplasty. On clinical examination, all the features characteristic of bilateral cleft nasal deformity was evident some of which included wide dorsum with bifid nasal tip, horizontally oriented nostrils, tip ptosis and short columella with a wide base. The septum was classically midline. Intermediate rhinoplasty was planned via an open approach in this case. An inverted V transcolumellar incision with bilateral reverse U incisions was planned to correct the horizontal orientation of the nostrils. The goal of the surgery was to primarily affect symmetric positioning of LLCs as well as to increase the length of the columella. Following exposure, dissection of the LLCs was carried out. A columellar strut from medpor was utilised which served to increase the tip projection. Symmetric positioning of LLC's was affected and sutured in place using horizontal mattress sutures. Transdomal sutures were also added to correct the bifid tip and decrease the angle of divergence between the alar domes. A modified Turkish delight graft was utilised for the purpose of dorsal nasal augmentation, and closure was affected with vicryl rapide sutures. It is important to note that any septal procedures were avoided to prevent growth disturbances. The pre- and 2 months postoperative photographs reveal a dramatic improvement and achievement of the preoperative goals.

Part XX

Craniofacial Anomalies

Rare Facial Clefts

77

Srinivas Gosla Reddy and Avni Pandey Acharya

77.1 Introduction

Since ages, congenital deformities were considered evil and wizard, and infants were abandoned to die in isolation. Jean Yperman (1295–1351) valued the congenital origin of the clefts. He additionally characterized the different types of the condition and set out the standards for their treatment. Fabricius ab Aquapendente (1537–1619) and William His of college of Leipzig independently researched and published embryological premise of clefts [1].

Laroche was the first to separate between common cleft lip or harelip and clefts of the cheek. Further qualification was made in 1864 by Pelvet, who isolated oblique clefts including the nose from the other cheek clefts, and drawing on Ahlfeld's work, in 1887 Morian gathered 29 cases from the writing, contributing 7 instances of his own. Morian perceived three unique groups of oblique facial clefts. From that point forward, astounding audits have been composed by Griinberg in 1913, Boo-Chai in 1970, Paul Tessier in 1976 [2] and Millard in 1977 [3].

Craniofacial cleft by definition is "a fissure of the soft tissues that corresponds as a general rule with a cleft of the bony structures." [1] The greatest research on craniofacial clefts was finished by Tessier and is credited for the formation of the craniofacial surgery for establishing the framework of the advanced craniofacial surgery by fundamentally breaking down facial clefts and portraying facial osteotomies [4].

Craniofacial clefts are significant clefts affecting the face, cranium, or both. These clefts cause distortion of the face and cranium with lacks or abundances of tissue that cleave anatomic planes in a straight fashion [2]. Craniofacial clefts exist in changing degrees of seriousness, and practically every one of them happens along the anticipated embryologic lines. These clefts can be either complete or incomplete and can seem alone or in relationship with other facial clefts. Seriousness of craniofacial clefts fluctuates extensively, running from a scarcely distinguishable indent on the lip or on the nose or a scar-like structure on the cheek to an extensive partition of all layers of facial structures. Notwithstanding one parted sort can show on one side of the face, while an alternate kind is available on the other side [2, 3].

Craniofacial clefts need comprehensive rehabilitation. Past the physical consequences for the patient, they have monstrous mental and financial impacts on both patient and family, prompting disturbance of psychosocial working and diminished nature of life [4, 5].

Cleft repair is a necessary part of the modern craniomaxillo-facial surgical spectrum and remains a challenge on account of inadequate and contorted tissue (minor to major) at the site of the deformity [6]. The outcomes are additionally impacted by the short and long haul aesthetic (soft tissue and facial skeletal appearance) [7] and useful (occlusal and discourse) outcomes [8]. What's more, the kind of careful fix, the specialist's abilities and the compliance of the patient likewise, affects the stylish [9] and utilitarian [10]outcomes. The real test isn't just understanding the hereditary qualities [11], in addition to plan the standard conventions for the surgery in these phenomenal kinds of clefts [12].

77.2 Incidence

Craniofacial clefts are a lot rarer than the simple cleft lip/palate deformity [13]. The precise occurrence of craniofacial clefts has not been exactly documented in view of their rarity. However, the reported frequency of craniofacial clefts is 1.5–6.0 per 100,000 live births [14]. The occurrence of uncommon craniofacial clefts contrasted with ordinary cleft lip and palate may vary from 9.5 to 34 for every 1000 [15].

Disclosure: Authors have no financial conflicts to disclose.

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_77

Lateral or transverse clefts of the lip are very uncommon and have commonly archived to have a rate of 0.3% of 1.0% of all of the facial cleft deformity spectrum (Boo-Chai 1969; Hawkins et al. 1973; Bauer et al. 1982; Verheyden 1988; Gleizal et al. 2007), or of 0.02% of live births (Kuriyama et al. 2008) [16]. Median clefts of the lower lip are very rare and only 68 cases have been accounted for till date [17].

77.3 Embryology

Successful treatment of innate craniofacial defects depends on an intensive comprehension of the embryologic procedures prompting their development [18]. There are various interesting highlights that plainly recognize craniofacial improvement from the advancement of different tissues in the body.

One of these novel highlights is the double starting point of craniofacial tissues: the skeletal framework and the vast majority of the connective tissues, including veins, begin from a gathering of cells called the cranial neural crest, while the musculature and some parts of the skull begin from mesoderm.

A second one of a kind component is the unit of intricate, complementary tissue interactions between the neuroectoderm, the mesenchyme, and facial ectoderm that drive ordinary advancement.

A third novel element is the extravagantly arranged morphogenetic developments—brought about by both uninvolved cell removal and dynamic cell movement—that characterize head advancement. Any procedure that upsets the rate, the planning, or the degree of these complex cell conduct can result in a craniofacial birth imperfection.

77.3.1 The Initiation of Craniofacial Development

77.3.1.1 Establishment and Fusion of the Facial Prominences (Figs. 77.1 and 72.3)

The basic morphology of the face is established between the 4th and 10th week of human development. The face is formed as a result of fusion of the midline frontonasal prominence and three paired prominences, the maxillary, lateral nasal, and mandibular prominences. Each of these prominences is filled with cranial neural crest cells that originated at different positions along the neural tube.

77.3.1.2 The Frontonasal Prominence

The frontonasal prominence gives rise to the forehead, midline of the nose, the philtrum, the middle portion of the upper lip, and the primary palate. Interruptions in frontonasal growth often result in a bilateral cleft lip, where the primary palate frequently "everts." In the mildest cases, clefts involving frontonasal prominence-derived structures may be limited to a notch in the vermillion border of the lip. In more severe cases, frontonasal clefts involve all of the tissues of the lip, and these cases may most likely occur because of a failure of fusion between the frontonasal and maxillary prominences.

77.3.1.3 The Lateral Nasal Prominences

The lateral nasal prominences give rise to the alae of the nose. Clefts that involve the side of the nose often result from a failure in the fusion between the lateral nasal prominences and either the frontonasal or the maxillary processes.

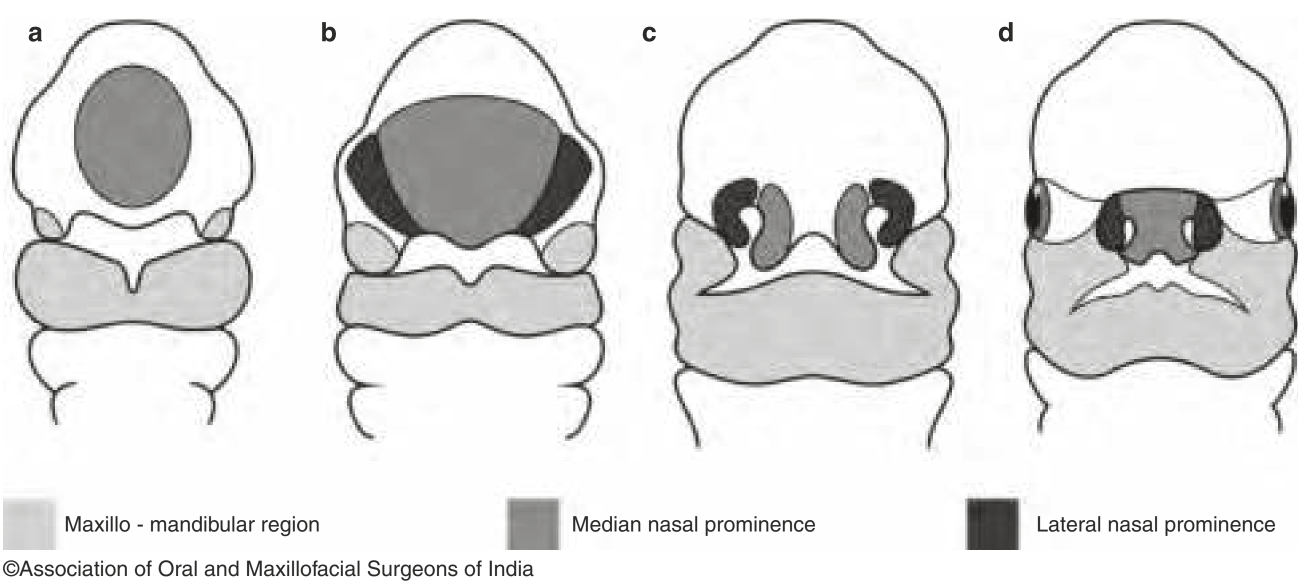

Fig. 77.1 (**a**–**d**) Embryological representation of fusion of nasal prominences

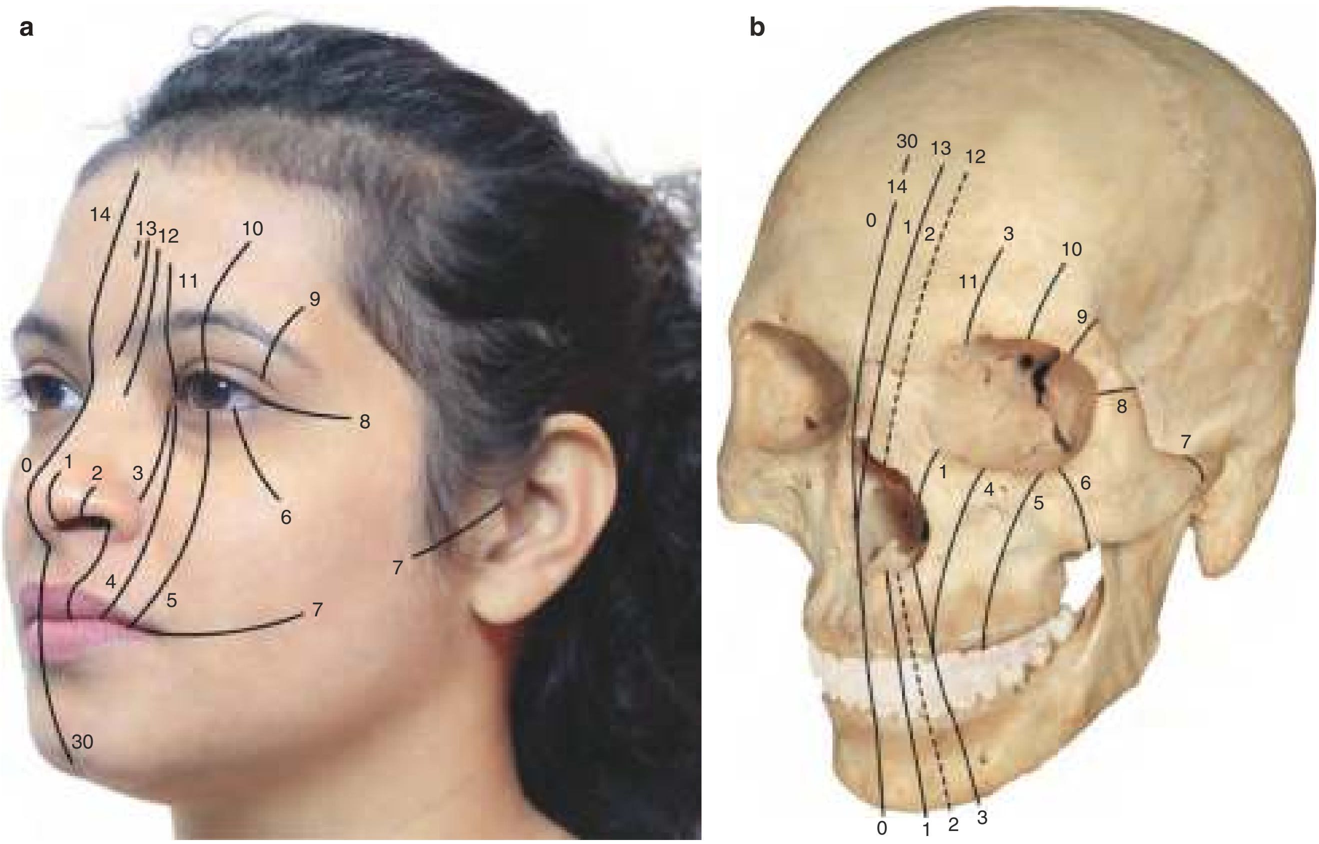

©Association of Oral and Maxillofacial Surgeons of India

Fig. 77.2 (**a**)Tessier classification for soft tissue clefting. (**b**) Tessier classification for bony clefting

77.3.1.4 The Maxillary Prominences

The maxillary prominences develop into the upper jaw, the facial halves, the upper lips, and the secondary palate. The nasal passage is divided from the pharynx by the secondary palate, which is formed from the neural crest cells. The palatal shelves first drop vertically and then rotate into a horizontal plane on the dorsal side of the tongue before fusing. The epithelium of the palatal shelves sloughs off, with only the basal layer of epithelium remaining to cover the later palate.

77.3.1.5 The Mandibular Prominences

This develops into the lower jaw and lower lip. Clefts of the lower jaw are very rare, presenting with a wide variety of phenotypes, ranging from a vermillion notch on the lip to a complete cleft involving the anterior mandible, chin, tongue, and lower lip and occasionally involving midline structures of the neck up to the manubrium sterni [19].

77.4 Etiology and Pathogenesis

Development of the head and face contains a standout among the most mind-boggling events among embryonic advancement. Disturbance of this firmly controlled course can result in a facial cleft where the facial primordia fail to meet and form the suitable structures [20]. The definite instrument of the cause of facial clefts is obscure, yet they are accepted to have a multifactorial etiology including a mix of natural and hereditary causes during embryonic development [21, 22]. In India affiliation and healthful inadequacies in pregnant mothers are the main cause of clefts [23].

The discussion is as yet in contention between the supporters of Meckel who trusted that clefts were brought about by a developmental arrest and Geoffroy St. Hilaire (1832) who felt that amniotic groups were responsible [15].

Fogh-Andersen previously characterized hereditary factors in clefting, which have been affirmed by segregation analysis [23]. Research in molecular genetics have identified genes responsible for rare facial clefts which may be syndromic and also for complex non-syndromic variants [24].

The non-syndromic types of orofacial clefts are likely due to secondary gene-environment interactions [25]. Non-syndromic cleft is a heterogeneous disease entity with candidate clefting loci on chromosomes [1, 2, 4, 6, 11, 14, 17, 19].

Four general classes of natural "cleftogens" have been distinguished to date, as follows [26]:

Radiation. Huge dosages of radiation have been associated with microcephaly.

Infections. The offspring of mothers with toxoplasmosis, rubella, or cytomegalovirus diseases display expanded frequencies of facial clefts.

Maternal idiosyncrasies. Mothers of children with CLP display an increased rate of phenylketonuria. The oculo-auriculovertebral range has been seen with strange recurrence among neonates with mothers who are diabetic. Numerous examinations have proposed maternal factors, for example, age, weight, and general well-being, as potential reasons for distortions.

Chemicals. Nutrient deficiencies are related with expanded rates of CLP, which might be decreased with vitamin supplementation for expectant mothers. Vitamin A, its subsidiaries, and related compounds, for example, isotretinoin, have been involved in the developments of facial clefts and hemifacial microsomia [26].

Any maternal liquor consumption during pregnancy increases the frequency of orofacial clefting [27]. The impact of maternal smoking also may be responsible [28]. Multiple studies have demonstrated that folate deficiency is related with clefts. Pre-birth folic acid supplementation has shown to diminish this hazard. At present, folic acid supplementation is the main empirical safeguard to diminish the frequency of facial clefting [2].

77.5 Classification

An all-round grouping plan that completely envelops, precisely depicts, and coordinates all the different types of orofacial and craniofacial clefts does not exist [2]. Soemmering (1791), Morian in 1886, Degenhardt (1961), the American Association of Cleft Palate Rehabilitation (AACPR) (1962), and Boo-Chai have made huge contributions in building up a classification [29–32].

77.5.1 Tessier Classification

In 1976, Paul Tessier depicted an anatomical order framework in which a number is doled out to every abnormality based on its position with respect to the sagittal midline [33].

This framework has moved towards global acknowledgment and allows reliable correspondence among clinicians [34].

This classification involves the orbit as the principle reference point. Fifteen areas of clefting have been demonstrated with discussion of their soft tissue and hard tissue involvement [33] (Fig. 77.2a, b).

The numbered clefts relate the soft tissue features to underlying bony involvement.

These have been verified by operative findings and more recently preoperative 3D CT assessments [35]. The clefts are radially distributed around the orbit with the midline 0 cleft named as median facial dysrhaphia [33].

77.5.1.1 Number Zero

The no. 0 cleft is the most widely recognized of the craniofacial clefts [36]. No. 0 and 14 is also called as midline craniofacial dysrhaphia. Clinically, this cleft shows up as an absence of conclusion of the front neuropore [33].

It shows two variants: a true and false middle congenital cleft, with or without related hypo- or hypertelorism [36]. Developmental cause of Tessier no. 0 isn't evident; however, it is realized that midline facial deformities can be followed to a period relating to the third week of gestation [36]. The cleft expresses as a duplication of the crista galli in frontal bone ("skull bifidum" and middle encephalocele), and as nasal septal duplication, and cleft through the columella, maxilla, and lip [33]. This form of cleft may have either a deficiency or abundance of tissue: with tissue agenesis and holoprosencephaly toward one side and frontonasal hyperplasia and inordinate tissue (the hyperplasias) at the opposing end. Midway inconsistencies with normal tissue volume possess the center segment of the spectrum [37].

Features of true midline congenital fissure:

1. Split upper lip with renal duplication
2. Bifid nose with wide columella and a wide furrow in the nasal dorsum
3. Duplication of the nasal septum
4. Overprojected nose due to fibromuscular connection of the alar ligaments and the frontal bone
5. Hypertelorism
6. Low placed cribriform plate of the ethmoid bone
7. Occasional midline encephalocele [38]

Features of the pseudo midline congenital fissure include:

1. Hypotelorism
2. Absence of the philtrum of the lip, premaxilla, nasal septum, columella, and the crista galli [33]
3. Clefting along the entire length of the upper lip
4. Hypoplastic nasal septum
5. Holoprosencephaly
6. Hypoplastic ethmoid bones [37]
7. Widened body of the sphenoid bone with separation of the pterygoid plate [35]

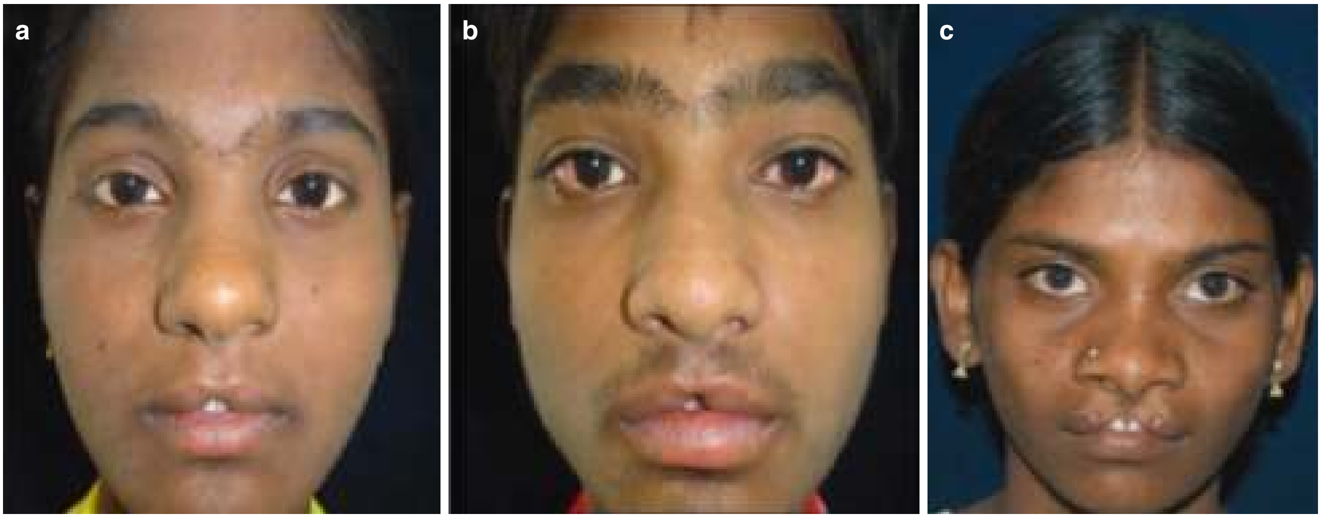

Fig. 77.3 (**a**–**c**) Clinical subclassification of Tessier number 0. (**a**) Type I—Involving only vermillion not involving the white roll. (**b**) Type II—Involving vermillion and white roll. (**c**) Type III—Involving vermillion, white roll, and philtrum

Fig. 77.4 (**a**–**c**) Clinical subclassification of Tessier no. 0. (**a**) Type IV—Involving vermillion, white roll, philtrum, columella. (**b**) Type V—Involving columella and tip, supratip, and dorsum of the nose. (**c1, c2**) Type VI—Involving columella, tips, supratip, dorsum of the nose and frontonasal area

Millard [39] classified a middle split of the lip as any vertical cleft through the focal point of the upper lip, paying little heed to the degree (Fig. 77.3a–c). Middle clefts have been isolated into two gatherings by Millard and Williams [39]. The principal bunching includes agenesis of the frontonasal procedure, and the second gathering is portrayed as separated to the middle component. The last is related with different degrees of nasal bifurcation and cranial malformations including hypertelorism [40–42] (Fig. 77.4a–c).

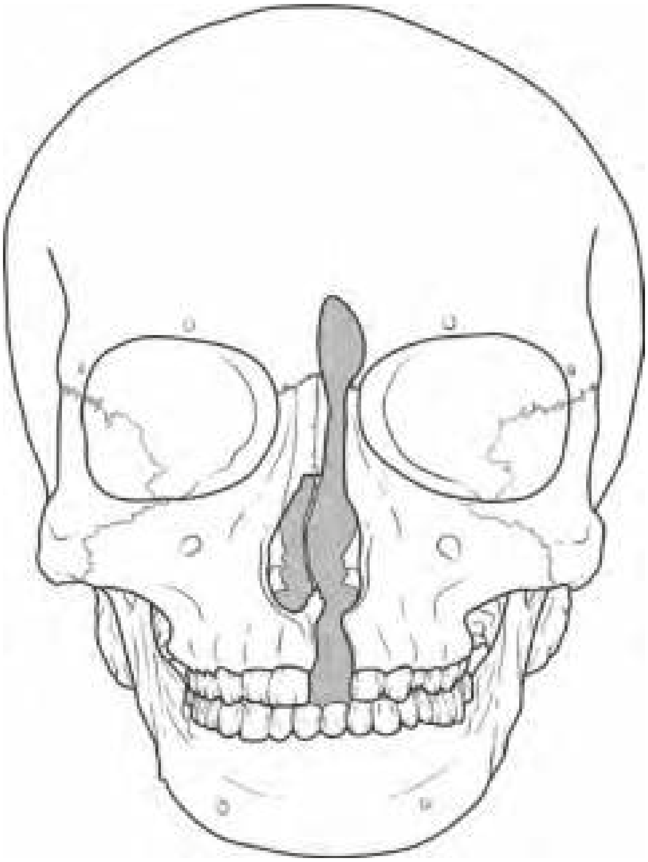
77.5.1.2 Number 1 Cleft

The number 1 cleft is also called as a paramedian cleft. Skeletally it passes through the frontal bone affecting the olfactory groove along the ethmoid producing hypertelorism (Fig. 77.5). It also widens the area between the nasal bone and the frontal process of maxilla. The soft tissue component involves the dome of the nose and may involve the alveolus and the lip. It may have a cranial counterpart in No 13 cleft. [33]

Soft Tissue Characteristics:

Soft tissue characteristics of No 1 cleft include:

1. Alar clefting that produces deviation of the nose to the opposite
2. Vertical ridges and furrows on the nasal dorsum
3. Vertical orbital dystopia and telecanthus
4. Tongue-shaped frontal hairline which is indicative of no. 13 cleft [35]



©Association of Oral and Maxillofacial Surgeons of India

Fig. 77.5 Tessier 1

Skeletal Involvement:
Skeletal features are as follows:

1. Clefting of the maxilla extending posteriorly as a total cleft of the hard palate.
2. Hypoplastic maxilla.
3. Nasal dorsum is deviated.
4. Asymmetry of the pterygoid plates and increased prominence of the lesser wing of the sphenoid bone.
5. Mild plagiocephaly may also be an associated feature [35].

77.5.1.3 Number 2 Cleft
Tessier no. 2 clefts are found parallel to the midline Tessier No. 0 clefts [33]. The deformation of the middle third of the nostril rim is a characteristic feature of the Tessier 2 cleft. This produces widening of the nasal bridge and flattening of the lateral side of the nose (Fig. 77.6a–e).

Skeletal features of Tessier 2 clefts are as follows:

1. Alveolar dysplasia from the lateral incisor to the pyriform aperture.
2. Palatal cleft may or may not be seen.
3. Deviated nasal septum.
4. A bony indentation is seen near the naso-maxillary suture [35].
5. Dysplasia of the lateral ethmoid region with orbital hypertelorism [43].
6. Cranial base asymmetry.
7. Dislodged medial canthus with intact lacrimal duct [44].

77.5.1.4 Number 3 Cleft
No. 3 is the oculo-nasal cleft (Morian I). This is also called "medial" orbito-maxillary cleft which passes through the lacrimal segment of the lower eyelid. This paranasal cleft occurs obliquely involving the lacrimal groove [33]. The patient may have microphthalmia [35] but anophthalmia is rare [45] (Figs. 77.7a–c and 77.8a–c).

Soft Tissue Characteristics [35, 46]
The important soft tissue features of the Tessier 3 cleft are:

1. Soft tissue hypoplasia of the face in the vertical direction [35]
2. Clefting of the alar base involving the nasolabial groove
3. Alveolar cleft with cleft of the lip
4. Displacement of the medial canthal apparatus and the lacrimal punctum of the lower eyelid
5. No patency of the lacrimal duct into the nose
6. Normal globe with orbital dystopia

Skeletal involvement include the following features:

1. Absence of the frontal process of the maxilla and medial wall of the maxillary sinus [33]
2. Deviated nasal septum
3. Cleft lip and palate
4. Continuity of the nasal cavity into the maxilla with no bony lateral nasal wall [35]
5. Hypoplastic maxilla
6. Narrowing of the ethmoid body and sinus on the affected side [35]
7. May be associated with a cranial cleft No 10 or 11 [33]

77.5.1.5 Number 4 Cleft
The No 4 Tessier cleft is a rare, complex, and gruesome craniofacial malformation [47]. No. 4 is the oculofacial separated I (Morian II). This is a "focal" orbito-maxillary cleft [33].

It may range from a unilateral notch paramedially to large bilateral tissue defects extending from the mouth to the eyes with huge bony fissures [47] (Fig. 77.9a–f).

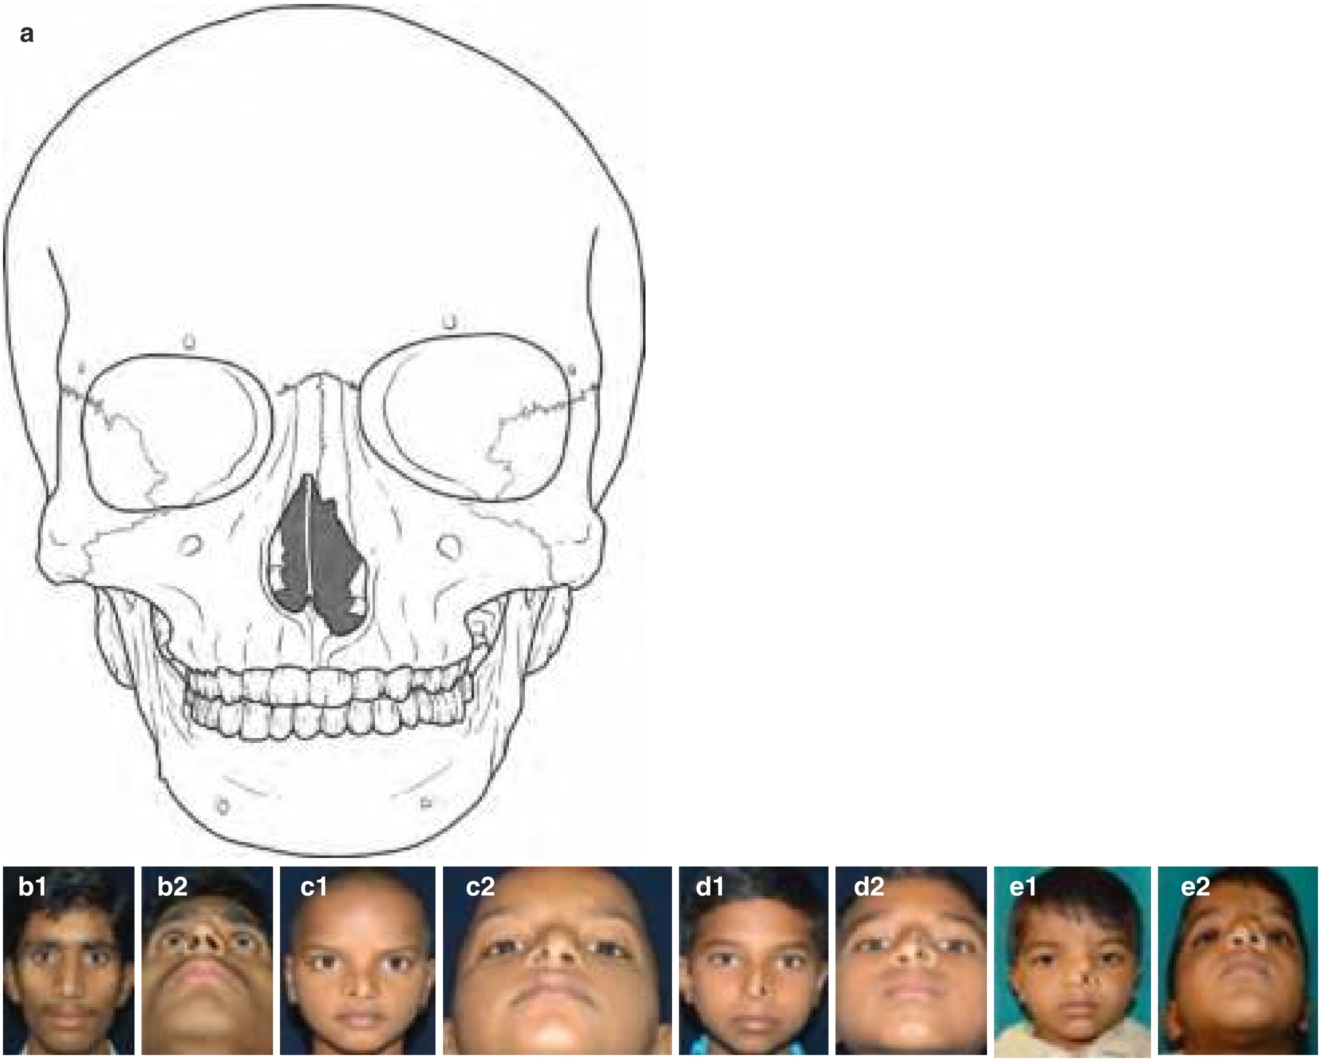


Fig. 77.6 (**a**–**e**) Tessier 2 clefts ranging from microform defect to more severe

Soft tissue characteristics include:

1. Clefting extending halfway between the philtral crest and the labial commissure
2. Extreme degree of vertical tissue deficiency extending from the labial cleft to the ocular separation in the lower eyelid [35]
3. Decreased oro-ocular distance
4. Microphthalmia with exposure keratitis secondary to eyelid deficiency [47]
5. Dystopia and inferior placement of the involved globe

Skeletal characteristics are enumerated below:

1. Bony cleft starting caudally between the lateral incisor and the canine proceeding cephalically medial to the infra-orbital foramen onto the orbital floor.
2. Prolapse of the orbital contents into the maxillary sinus due to the orbital defect.
3. Naso-lacrimal duct is intact, but the inferior lacrimal canaliculi may be hypoplastic or absent [47].
4. This may be associated with a cranial cleft no 12.

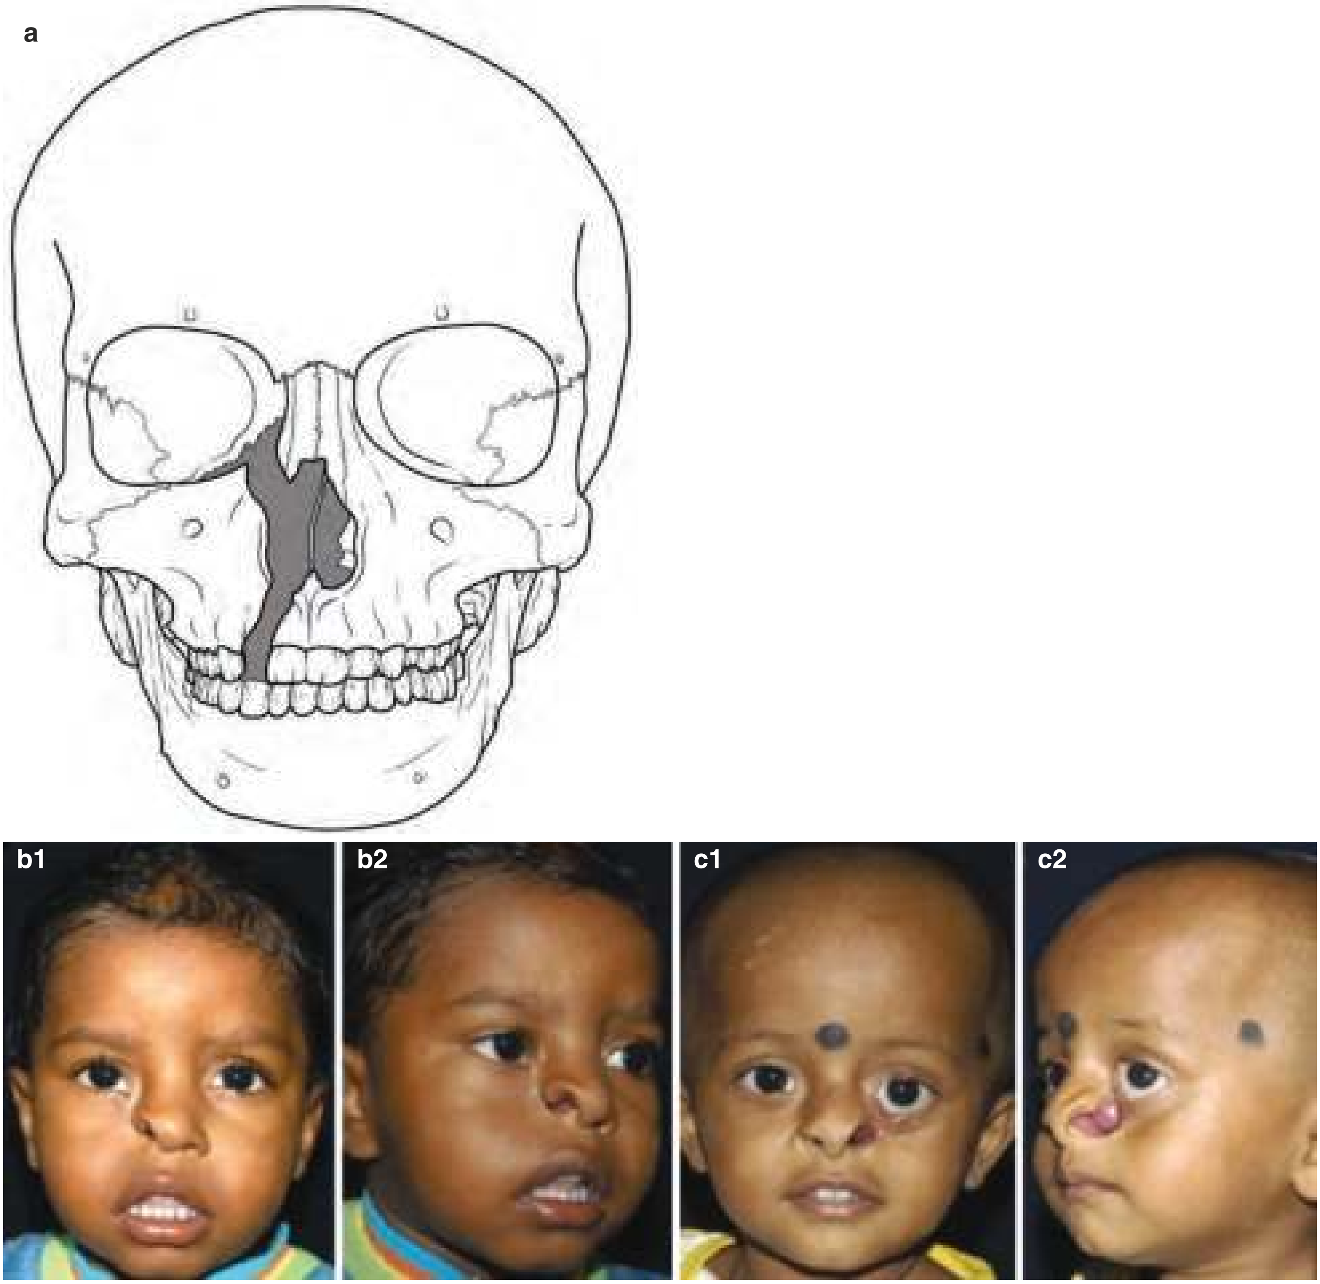

Fig. 77.7 (**a**–**c**) Tessier 3 cleft with ocular involvement

77.5.1.6 Number 5 Cleft

The Tessier No 5 cleft is a very uncommon malformation and is also referred as the oculofacial cleft II (Morian III). This lateral orbito-maxillary cleft gets through the medial third of the lower eyelid [33] (Fig. 77.10a, b).

Soft tissue involvement demonstrates:

1. Clefting immediately medial to the commissure which courses along the cheek lateral to the ala of the nose, ending in the lateral half of the lower eyelid.
2. The globes are usually normal but may occasionally show microphthalmia [35].

Skeletal involvement:

1. The alveolar cleft starts lateral to and travels lateral to the infra-orbital foramen and ends in the lateral part of the orbital floor. There may be associated hypoplasia of the maxillary sinus [48].

Fig. 77.8 (a–c) Tessier 3. (a) With bilateral involvement (b) without ocular involvement (c) with oral involvement

2. Vertical orbital dystopia due to prolapse of the orbital contents.
3. Thickened lateral orbital wall and abnormal greater wing of the sphenoid bone.
4. Cranial base may be generally normal [35].

77.5.1.7 Number 6 Cleft

This is otherwise called as zygomaticomaxillary cleft which may form an incomplete variant of the Treacher Collins syndrome (Fig. 77.11a, b). It was named as maxillozygomatic dysplasia by Van der Meulen [33, 49].

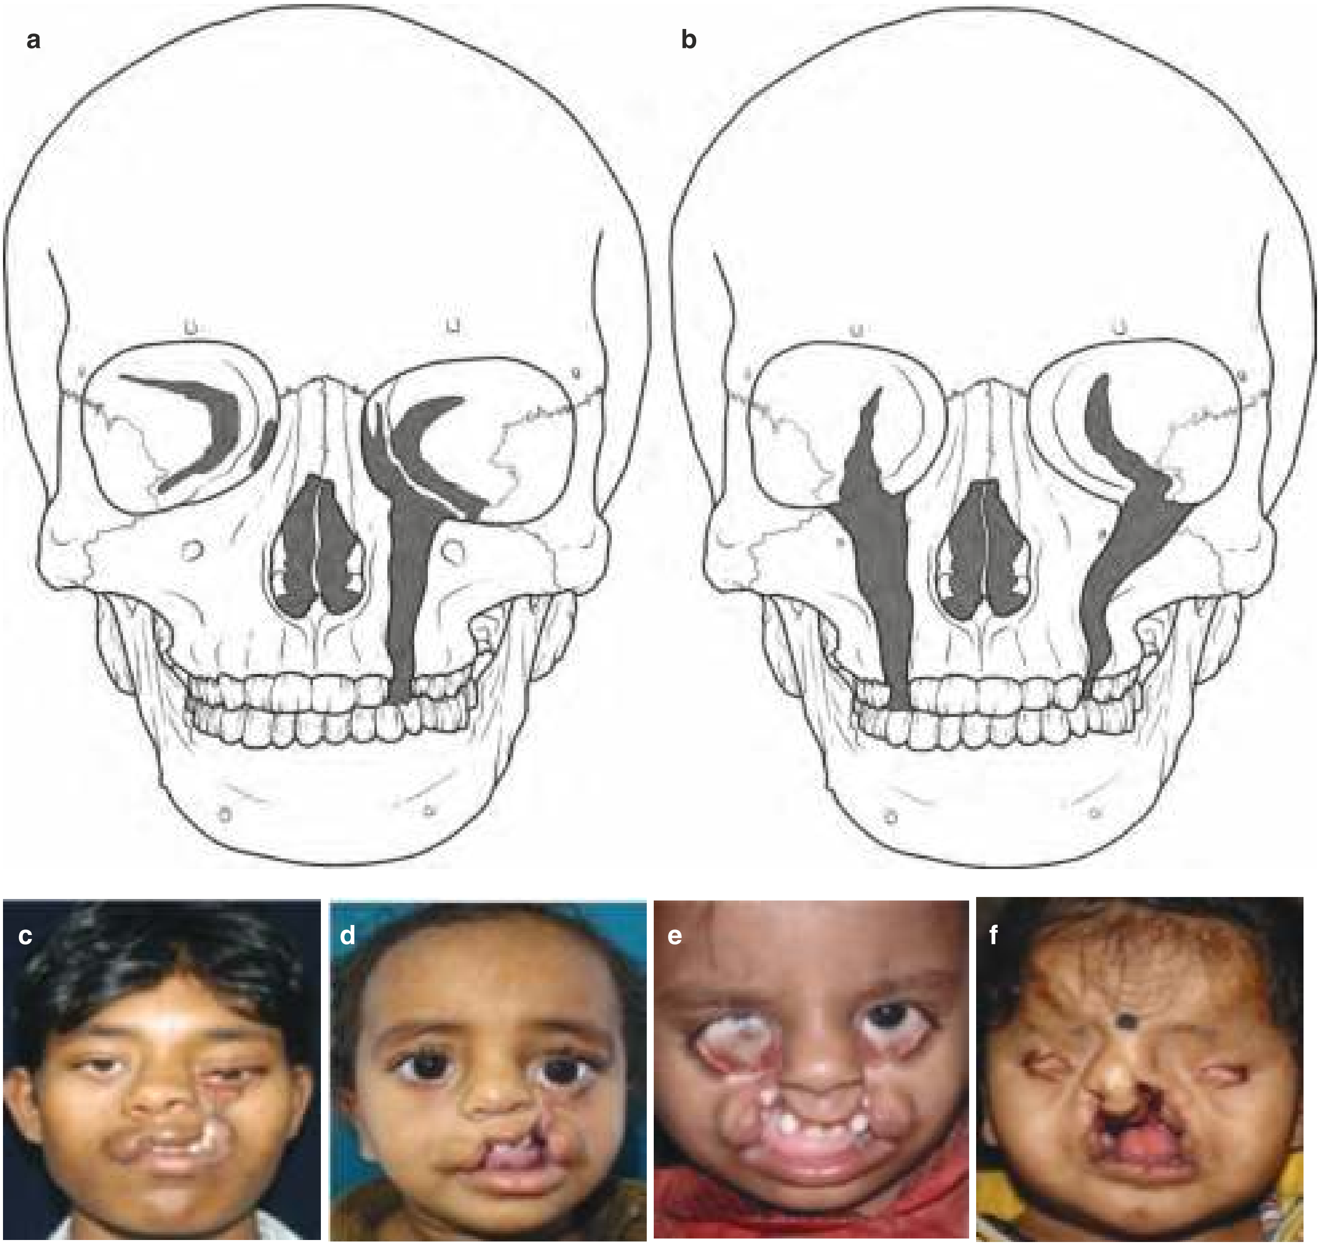

Fig. 77.9 (**a**–**f**) Tessier 4. (**a**, **b**) Skeletal Tessier 4. (**c**, **d**) Unilateral Tessier 4. (**e**, **f**) Bilateral Tessier 4

Soft tissue involvement of the No 6 cleft is detailed below:

1. Vertical cleft furrow extending from the oral commissure to the lateral aspect of the lower eyelid.
2. This also involves the zygomatic eminence pulling the lateral aspect of the palpebral fissure down with inferior displacement of the lateral canthus [33].
3. This gives the appearance of an anti-mongoloid slant and lower lid ectropion.
4. Colobomas may be seen in the lateral lower eyelid region [33].

Skeletal involvement is as follows:

1. A bony split is seen along the zygomaticomaxillary suture separating the maxilla and the zygoma [33].
2. Usually there is no alveolar cleft.
3. The maxilla may be shorter antero-posteriorly.
4. The cleft enters the orbit at the lateral orbital floor.
5. The zygoma is hypoplastic with change in the cheek contour.
6. The anterior cranial fossa is narrow but sphenoid is normal [35].

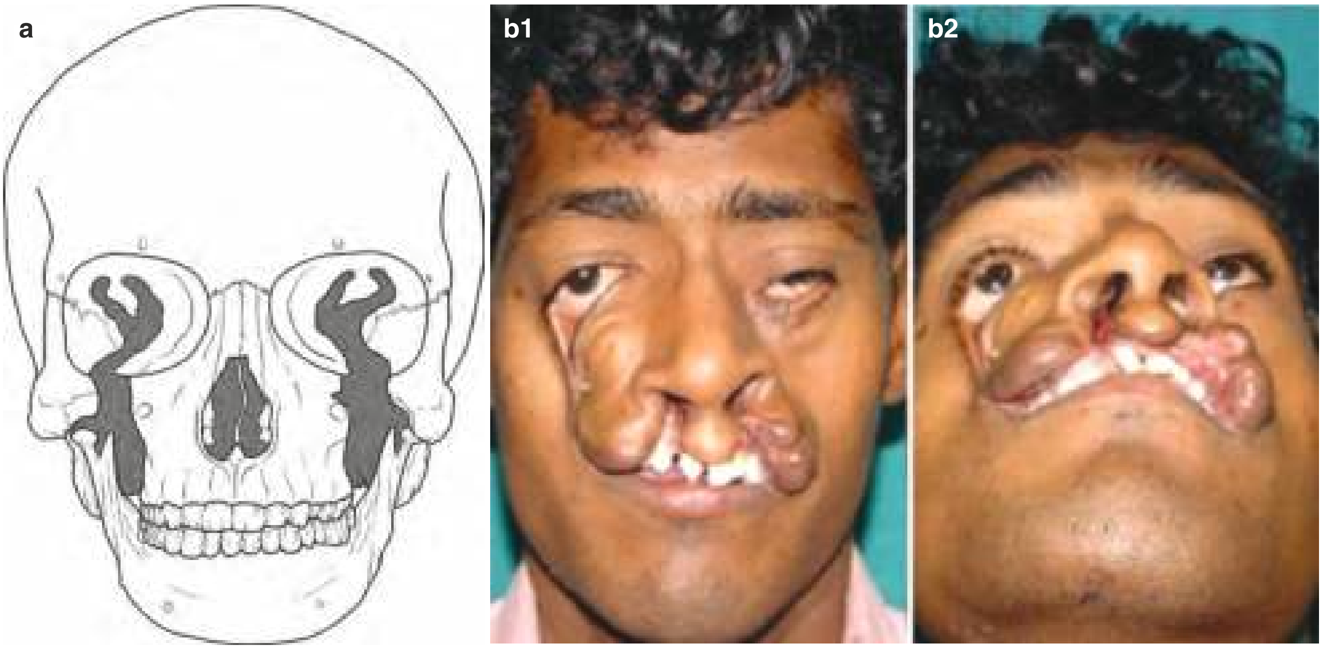

Fig. 77.10 (**a**, **b**) Tessier 5

Fig. 77.11 (**a**, **b**) Tessier 6. Skeletal Tessier 6. (**a**) Unilateral Tessier 6. (**b**) Bilateral Tessier 6

77.5.1.8 Number 7 Cleft

This is a temporo-zygomatic cleft and is the most well-known of all the craniofacial clefts [35] (Figs. 77.12 and 77.13a–d). It may occur along with hemifacial microsomia.

Soft tissue features include:

1. Soft tissue clefting from the oral commissure to the pre-auricular hairline.
2. It may range from a mild broadening of the oral commissure with pre-auricular skin tags to a complete fissure ending in a microtic ear [35].
3. There may be deficiency of the ipsilateral tongue, soft palate, and muscles of mastication.
4. There may be absence of the parotid gland and duct.
5. There may be external and middle ear abnormalities [50–52].
6. Abnormal pre-auricular hair form in hemifacial microsomia and Treacher Collins disorder [35].

Skeletal qualities include [35, 53, 54]:

1. Skeletal cleft involves the pterygo-maxillary junction.
2. Hypoplasia of the posterior maxilla, mandibular ramus, coronoid, and condylar process with occlusal canting [33].

Fig. 77.12 Tessier 7

Fig. 77.13 (**a**–**d**) Subclassification of Tessier 7. (**a**) Oro-aural Tessier 7. (**b**) Bilateral Tessier 7. (**c**) Tessier 7 with cleft lip. (**d**) Tessier with ear tag

3. Hypoplasia of the zygoma with displacement and deformation. In extreme cases the arch may manifest as a little stump alone.
4. There may be true orbital dystopia in severe cases.
5. There may be a tilt of the cranial base [35].

77.5.1.9 Number 8 Cleft (Fig. 77.2)

This fronto-zygomatic cleft situated at the lateral canthus forms the equator of the Tessier craniofacial cleft sphere. It is a part of the zygomatico-frontal dysplasias [49]. The number 8 cleft seldom occurs in isolation and usually occurs as a part of other craniofacial clefts. It corresponds to the cranial occurrence of the No 6 cleft. In bilateral occurrences it is associated with numbers 6 and 7. This shows features similar to the Treacher-Collins and the Goldenhar's disorder with the former showing more skeletal deformities and the latter soft tissue ones [55].

Soft tissue features include [56, 57]:

1. Cleft extends from the lateral canthus to the temporal region.
2. They may present with dermatoceles and colobomas with absence of the lateral canthal apparatus.
3. Abnormal hair patterns may be present between the temporal area and the lateral canthus.
4. Globe may show eye bulbar dermoids.

Skeletal involvement includes [58, 59]:

1. Bony clefting at the fronto-zygomatic suture [58].
2. Features of the Goldenhar's or Treacher-Collins syndromes may be seen with the zygoma being hypoplastic or missing along with the lateral orbital wall [59].
3. The palpebral fissure shows a lateral descent due to the absence of the zygoma.

77.5.1.10 Number 9 Cleft

No. 9 is a form of the upper "lateral" orbital cleft. The clefting is seen in the lateral third of the upper eyelid and the lateral supra-orbital angle (Fig. 77.14). It is the cranial extension of the number 5 facial cleft [52]. There may be a deficient greater sphenoid wing in this type [60].

Soft tissue involvement shows:

1. Anomalies of the lateral third of the upper eyelid and the eyebrow.
2. Distortion of the lateral canthus.
3. Severe cases show microphthalmia.
4. The superolateral bony deficiency in the orbit may be the cause of lateral displacement of the globes.
5. Anterior displacement of the temporal hairline with temporal projection.
6. Palsy of the 7th cranial nerve with temporal and eyelid signs may be common.

Skeletal involvement:

1. Cleft extending through the superolateral aspect of the orbit.
2. The greater wing of the sphenoid may be distorted affecting morphology of the orbital wall.

Fig. 77.14 Tessier number 9

3. Hypoplasia of the pterygoid plates.
4. Decrease in the antero-posterior dimensions of the anterior cranial fossa [35].

77.5.1.11 Number 10 Cleft

No. 10 is an upper "central" orbital cleft with the cleft happening in the middle third of

the supra-orbital edge, lateral to the supra-orbital nerve (Fig. 77.15a, b) [33]. This is the cranial counterpart of the No 4 cleft. Both present with similar ocular deformities and may show colobomata of the iris [33].

This cleft causes a large defect in the frontal bone [46].

Soft tissue features include:

1. Elongated palpebral fissure
2. Amblyopia with inferior and laterally displaced eye [35]
3. Eyebrow which is deficient medially and is more dispersed laterally [46]
4. Occurrence of frontal encephalocele involving the middle third of the frontal bone and the orbital roof [35]

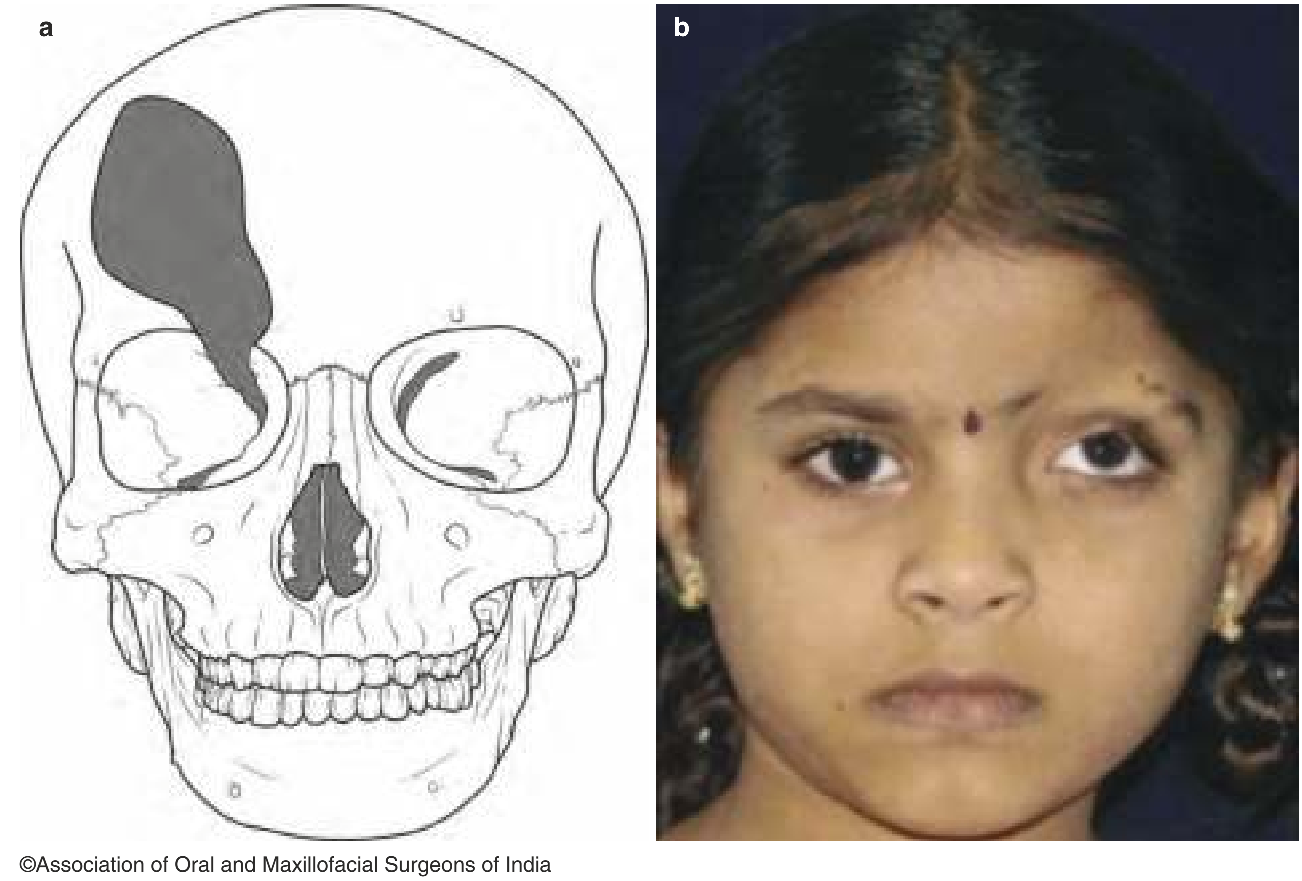

Fig. 77.15 (**a**, **b**) Tessier number 10

Skeletal involvement:

1. Cleft defect on the lateral aspect of the supra-orbital rim which may involve an encephalocele.
2. Orbital deformity with a latero-inferior rotation.
3. Orbital hypertelorism may be a feature in severe cases with distortion of the anterior cranial base [35].

77.5.1.12 Number 11 Cleft (Fig. 77.2)

No. 11 is the upper "medial" orbital cleft. This shows coloboma of the medial third of the upper eyelid, with stretching of the eyebrow [33]. This cleft is often associated with the facial cleft No 3 [35]. Van der Meulen incorporated this deformity in his frontal dysplasia group [49].

Soft tissue involvement includes:

1. Coloboma of the upper eyelid in the medial third
2. Disturbance in the upper eyebrow with a tilt toward the frontal hairline
3. Tongue-like projection of the frontal hairline [35]

Skeletal involvement:

1. Frontal bone defect medial to the supra-orbital nerve and lateral to the ethmoid and lacrimal bones
2. Bony defect of the medial orbit
3. Fronto-ethmoid encephalocele with resultant orbital dystopia
4. Deficiency of the lacrimal bone with associated lacrimal stenosis [46]

77.5.1.13 Number 12 Cleft

The No 12 cleft shows deficiencies in the ethmoid labyrinth and the glabella [46]. This cleft is usually found medial to the medial canthus [35] (Fig. 77.16).

Soft tissue characteristics include:

1. Soft tissue dehiscence medial to the medial canthal apparatus [33]
2. Lateral displacement of the medial canthus with aplasia of the medial eyebrow

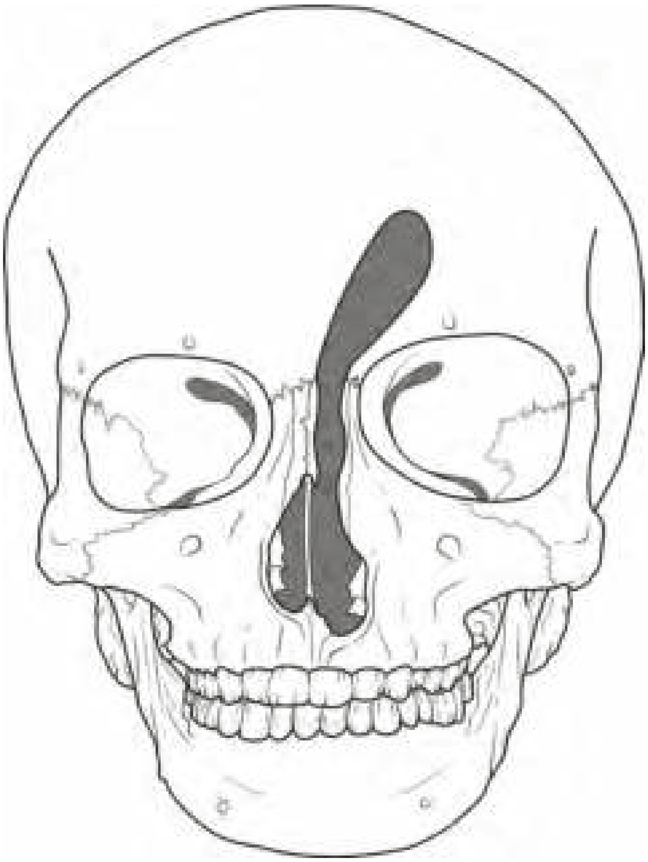

Fig. 77.16 Tessier number 12

3. Presence of a V-shaped frontal hairline in the paramedial region of the forehead [35]

Skeletal involvement:

1. There is a flattened widening of the affected bone.
2. May present with grades of hypertelorism or telecanthus.
3. Normal sphenoids with mild hyper-pneumatization of the frontal sinus.
4. Obtuse fronto-nasal angle.
5. Low incidence of associated encephaloceles.

77.5.1.14 Number 13 Cleft

The number 13 cleft is the cranial counterpart of the paramedian facial cleft 1.

It is situated between the nasal bone and the frontal process of the maxilla passing through the frontal bones and along the olfactory groove [36] (Fig. 77.17).

Soft tissue characteristics include the following:

1. This occurs medial to the eyebrow which remains undivided [36].
2. The cleft produces a paramedian widows peak [35].
3. The cleft may descend and pass through the intersection of the nasal skin and alar skin and results in an alar cartilage cleft [46].

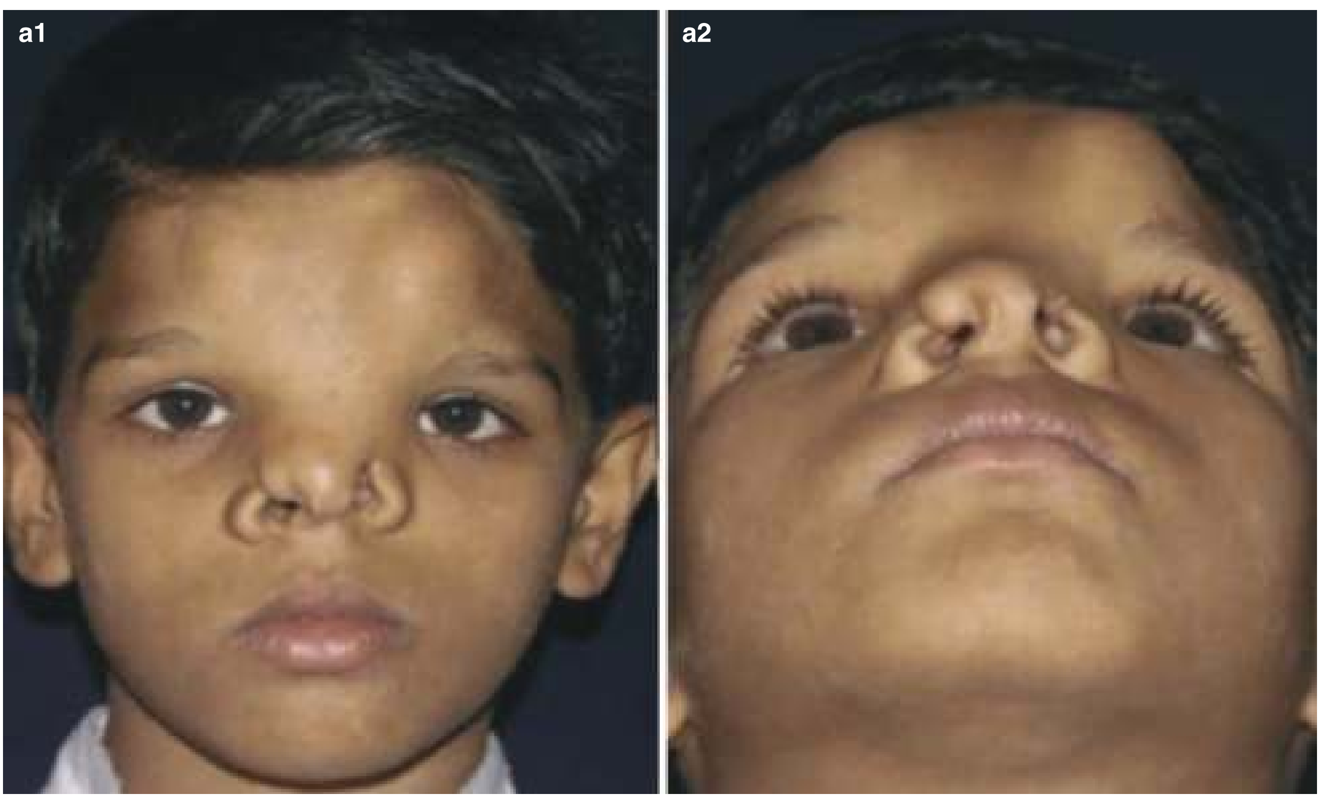

Fig. 77.17 Tessier number 13

Skeletal involvement:

1. Deformities of the medial aspect of the cribriform plate [46].
2. There may be olfactory groove widening with associated widening of the cribriform plate and the ethmoid sinus with resultant hypertelorism.
3. Paramedian frontal encephalocele may cause inferior displacement of the cribriform plate with orbital dystopia.
4. Unilateral and bilateral types of the number 13 cleft exist with bilateral demonstrating the most extreme forms of hypertelorism [4].

77.5.1.15 Number 14 Cleft

No. 14 is the cranial congener of the cleft no. 0, which is the median craniofacial dysrhaphia. The terms frontonasal and frontonasoethmoid dysplasia were utilized by Van der Meulen for this group of deformities [49] (Fig. 77.18a–g).

Soft tissue characteristics:

1. Severe lateral displacement of the medial canthal apparatus bilaterally.
2. Glabellar flattening.
3. The periorbita including the eyelids and eyebrows is generally normal.

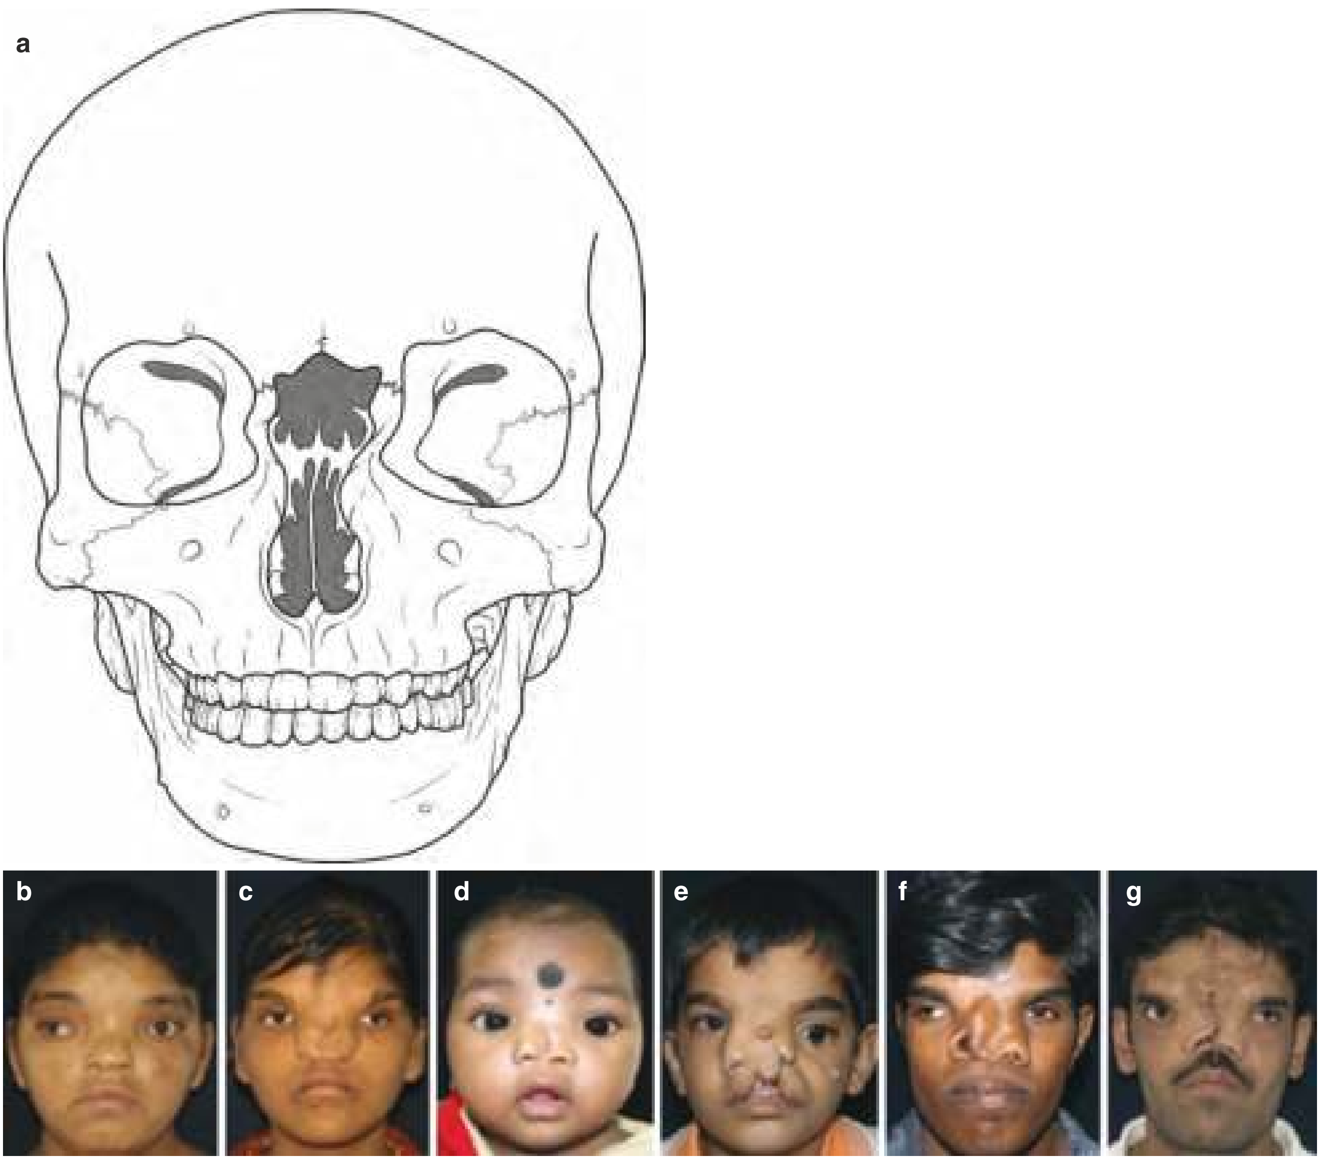

Fig. 77.18 (**a–g**) Tessier number 14 with variable degree of nasal duplication and hypertelorism

4. Midline projection of the frontal hairline [35].
5. There is distortion of the nasal capsule and the developing forebrain stays in a lower position.

Skeletal characteristics:

1. Severe hypertelorism.
2. Frontal encephalocele may be seen herniating through the midline frontal bone defect.
3. Caudal flattening of the frontal bone is flattened with flattened glabellar region
4. Absence of frontal sinus pneumatization.
5. The crista galli and the perpendicular plate of the ethmoid are bifid, and there is an expanded separation between the olfactory grooves [35].
6. The crista galli and ethmoids are widened with caudal dislodgement.
7. There may be a shortening of the middle cranial fossa.
8. The anterior cranial fossa is tilted upward, producing a harlequin eye disfigurement on plain radiographs [35].

77.5.1.16 Number 30 Cleft

Tessier 30 cleft otherwise known as lower midline facial cleft or median mandibular cleft is a rarity (Fig. 77.19). Median cleft of the lower jaw was first described in 1819 by Couronne [30].

It is generally constrained to a deformity in the soft tissue of the lower lip.

In its severe form, it may groove or split the mandibular symphysis and at times involve the midline structures of the neck including the hyoid bone, the thyroid, and even the strap muscles. The anterior part of the tongue may be bifid, showing ankyloglossia [54], with one case of absence of tongue being reported [55].

Fig. 77.19 Tessier no 30

77.6 Treatment of Craniofacial Clefts

Surgery for facial deformities involves the best balance of art and science. The restoration of the malformed anatomy requires artistic creativity, while the science lies in the reestablishment of impaired function [57].

From a careful perspective, even microform clefts might deform. Contingent upon the level of distortion, an arranged strategy has been viewed as the treatment of choice [58]. Due to their multifaceted nature; the individual level of cleft involves successful reconstruction and the rehabilitation in practically every one of the cases request multistep and multi-proficient procedure [59]. Besides cautious examination, imaging methods are important to evaluate the individual level of skeletal inclusion. For correct determination current imaging frameworks seen in systems, for example, CT, MRI, and 3D CT, permit better preoperative comprehension of the issue and planning of the surgeries. Analysis ought to be founded on a classification relying upon the site and types of defects (morphology) which helps in foundation of a legitimate treatment plan [60] (Figs. 77.20, 77.21, and 77.22a–e).

Institutionalized treatment plans are not constantly conceivable in light of the assortment of craniofacial clefts and dimensions of seriousness. Be that as it may, core values are useful in deciding the best possible planning and stages for restorative surgery [30]. The Australian Craniofacial Unit Treatment Protocol, which is a pioneering center with international acclaim, has recommended the following:

- Early repair of the soft tissue defects and preventing exposure keratitis
- Orthodontic intervention interceptive orthodontics and speech therapy for the school-going years (4–10 years)
- Reconstruction of the orbital floor, orthognathic surgery, and rhinoplasty to be done after growth completion [30]

77.6.1 Tessier No. 0–14 Cleft

Literature reveals that the midline Tessier 0 and 14 clefts are among the most common encountered [5], while the combination of 0 and 14 is the most common combination of non-isolated clefts [61].

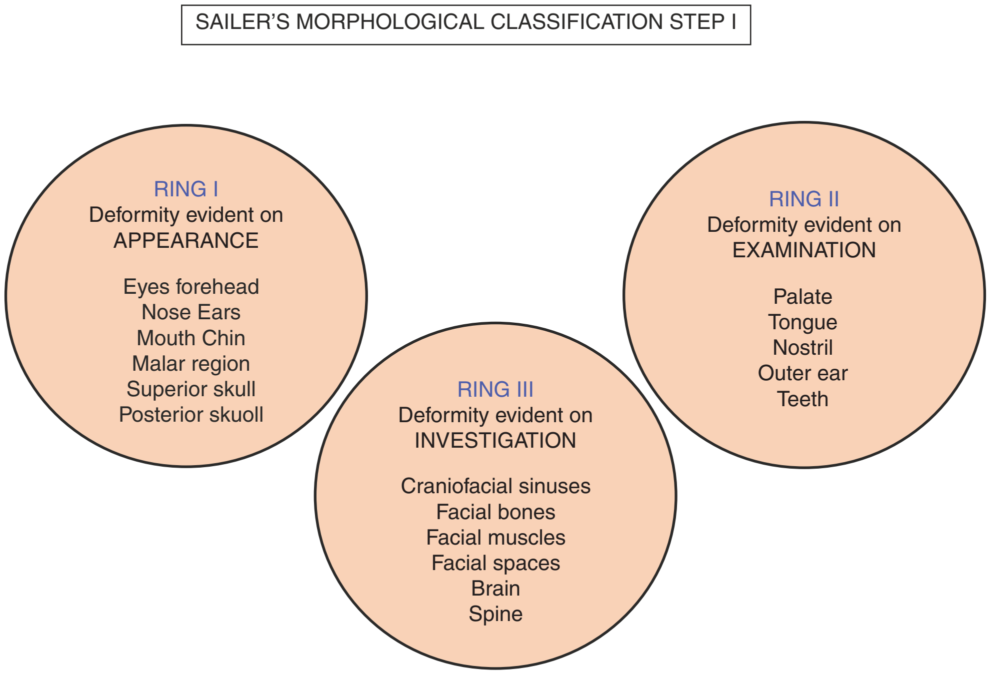

Fig. 77.20 Sailer's morphological classification step I

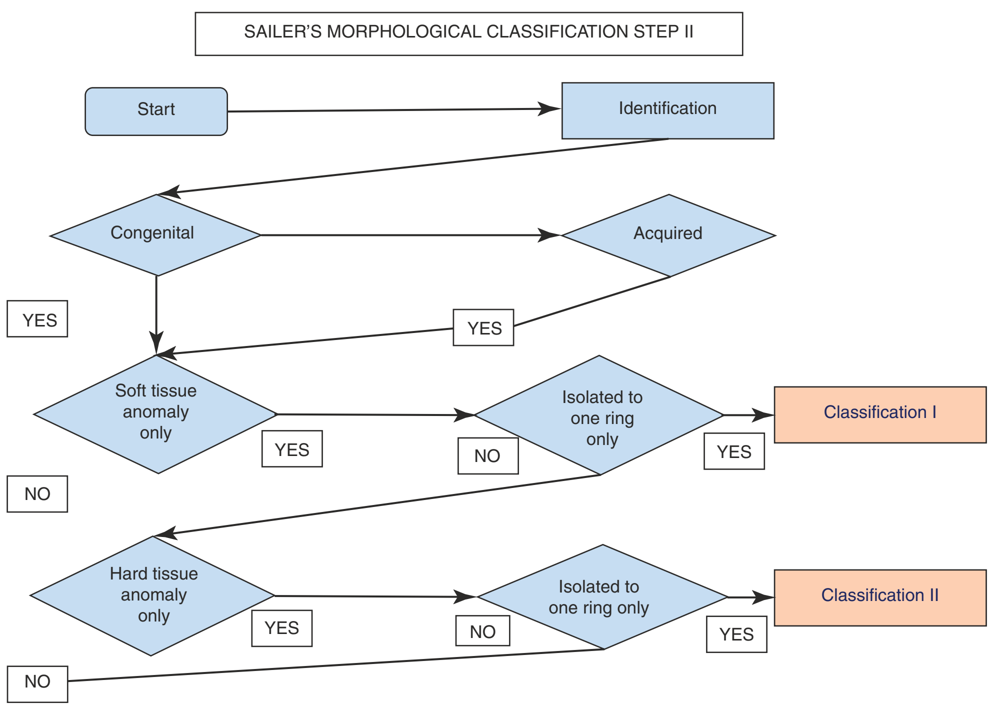
Fig. 77.21 Sailer's morphological classification step II



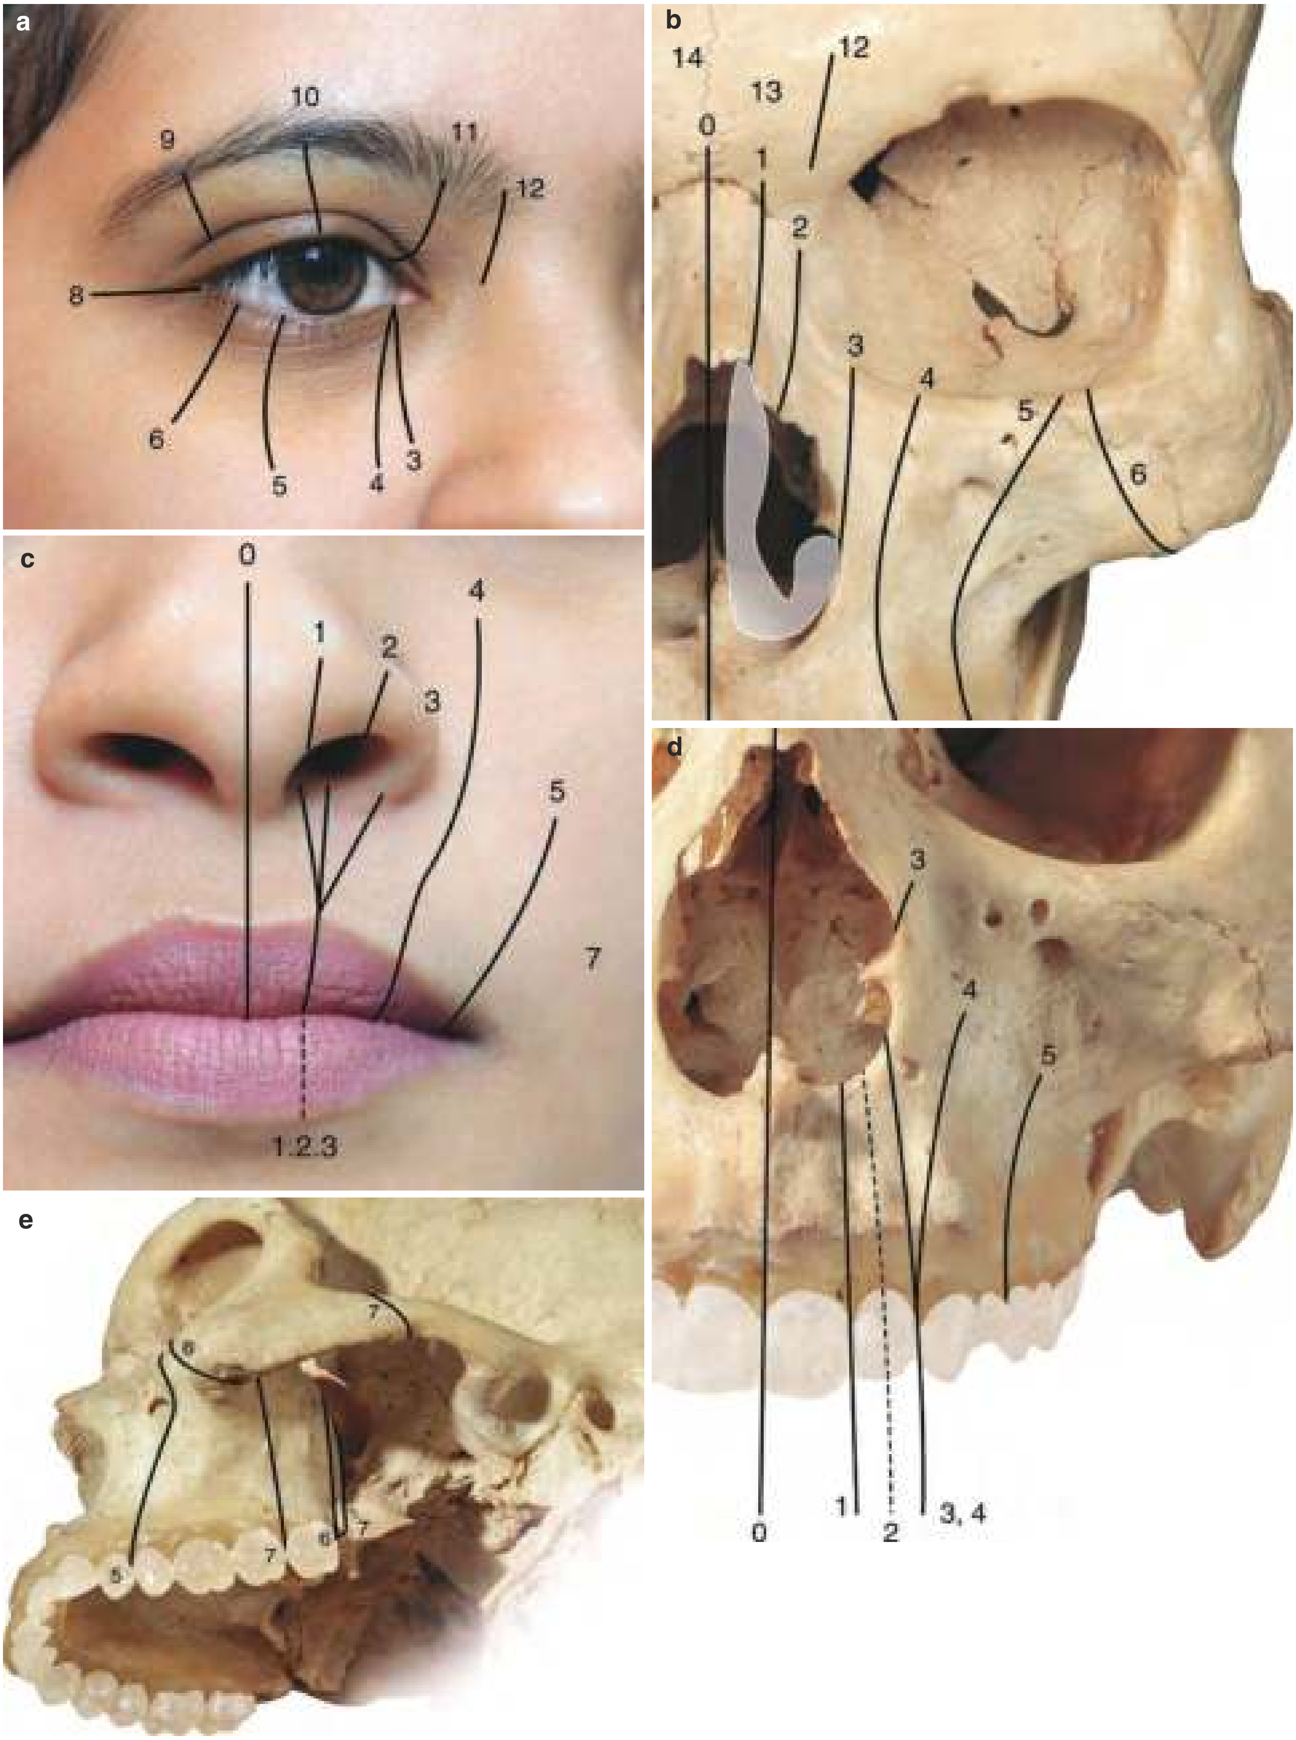


Fig. 77.22 (**a**–**e**) Anatomical classification of facial, craniocalvarial clefting

The most commonly adapted protocol for Tessier no. 0–14 is modified from surgical protocol for midline Tessier 0–14 craniofacial clefts (David 2006) (Fig. 77.23).

> As per Sailer's morphological classification, Tessier 0–14 clefts involve:
>
> (i) The medial orbital zone
> (ii) The zone of the maxilla, oral cavity, and lips
> (iii) The zone of the nose

Treatment is generally formulated based on the degree of involvement of these zones (Figs. 77.20 and 77.21).

77.6.2 The Orbital Zone and Skull Bone Defect

77.6.2.1 Resection of Encephalocele

An encephalocele is a herniation of a part of the cerebral matter through a deformity in the skull. This may contain meninges (meningocele), or meninges, cerebrum, and ventricle (meningoencephalocystocele) [61].

Tessier no. 0–14 is most generally connected with fronto-ethmoidal gathering of encephaloceles group which can be subdivided into nasofrontal, nasoethmoidal, and nasoorbital types.

The objectives of repair involve:

1. Meticulous repair of skin deformities. This helps prevent contamination and desiccation of brain tissue.
2. Water-tight dural repair with removal or invagination of the non-functional brain tissue which is present extra-cranially.
3. Complete craniofacial reconstruction of skeletal components. Care taken to prevent appearance of a long nose [62].

77.6.3 Orbital Hypertelorism

Hypertelorism is the most common indication for major craniofacial correction in a Tessier 0–14. Treatment strategies are varied and range from medialization of the medial wall of the orbits to total repositioning of the orbital and facial bipartition [63]. Hypertelorism is a physical finding in many craniofacial malformations, which is characterized by an increase in interorbital distance. It may be a part of a syndrome but it is not a syndrome by itself.

In 1924, Greig called orbital hypertelorism as "ox-eyed" and also coined the term "ocular hypertelorism" [64]. The more accurate term of "orbital hypertelorism" to denote true lateralization of the orbital complex was coined by Tessier in 1972 [65]. Tessier classified hypertelorism into three degrees based on the interorbital distance [65, 66] (Fig. 77.24).

77.6.3.1 En Bloc Osteotomies (Fig. 77.25a–d)

Radical mobilization of the orbits to correct increased interorbital distance is one of the most challenging procedures in craniofacial surgery [67].

Paul Tessier was the first to perform orbital mobilization using a trans-cranial approach [53]. This surgical intervention was planned to eliminate undue risk to the

Fig. 77.23 Surgical protocol for midline Tessier 0–14 craniofacial clefts

Adapted Surgical Protocol for Midline 0–14 Tessjer Craniofacial Clefts (David, 2006) [16, 17]

Birth to 1 year
- Preserve the essential functions of the airway, feeding, sight, and; hearing
- Repair any encephaloceles
- Craniosynostosis correction by fronto-orbital advancement at 3–6 months

5 years
- Orbital box osteotomy once the tooth buds can be reliably preserved
- As an alternative, a medial faciotomy (facial bipartition) can be performed slightly later
- Possible use of tissue expanders beneath the zygomatic periosteum in extreme hypertelorism
- Temporary nasad reconstruction, as this will not be repeated later

5 to 10 years
- Orthodontic management is commenced when enough permanent teeth are present
- Alveolar bone grafting is carried out to correcti the more extensive defects in the maxilla that may to present

10 years until the completion of growth
- Maintenance of the orthodonitic therapy with retainers
- Further preservation of the eyes and hearing if required

Completion of growth
- Orthodontic preparation for midface surgery
- Midface surgery performed at any level, with or without bone grafting/mandibuloar surgery depending on need
- After establishment of the facial platform, platform, definitive nasal reconstruction is performed
- Further secondary surgery is performed if necessary

HYPERTELORISM

optic nerve [65]. Converse described in 1968 preservation of the olfactory nerves by performing subcranial U-shaped osteotomy [68]. Schmid described the extra-cranial circumferential orbital osteotomies for medializing the orbits [68], while Jacques van der Meulen described the facial bipartition in 1983 [69]. Medialization of the medial orbital walls and hemifacial rotation do not interrupt midfacial growth and thus were performed before age 5 in the majority of patients. Orbital translocation causes growth disturbances and thus is to be performed after attaining skeletal maturity [63].

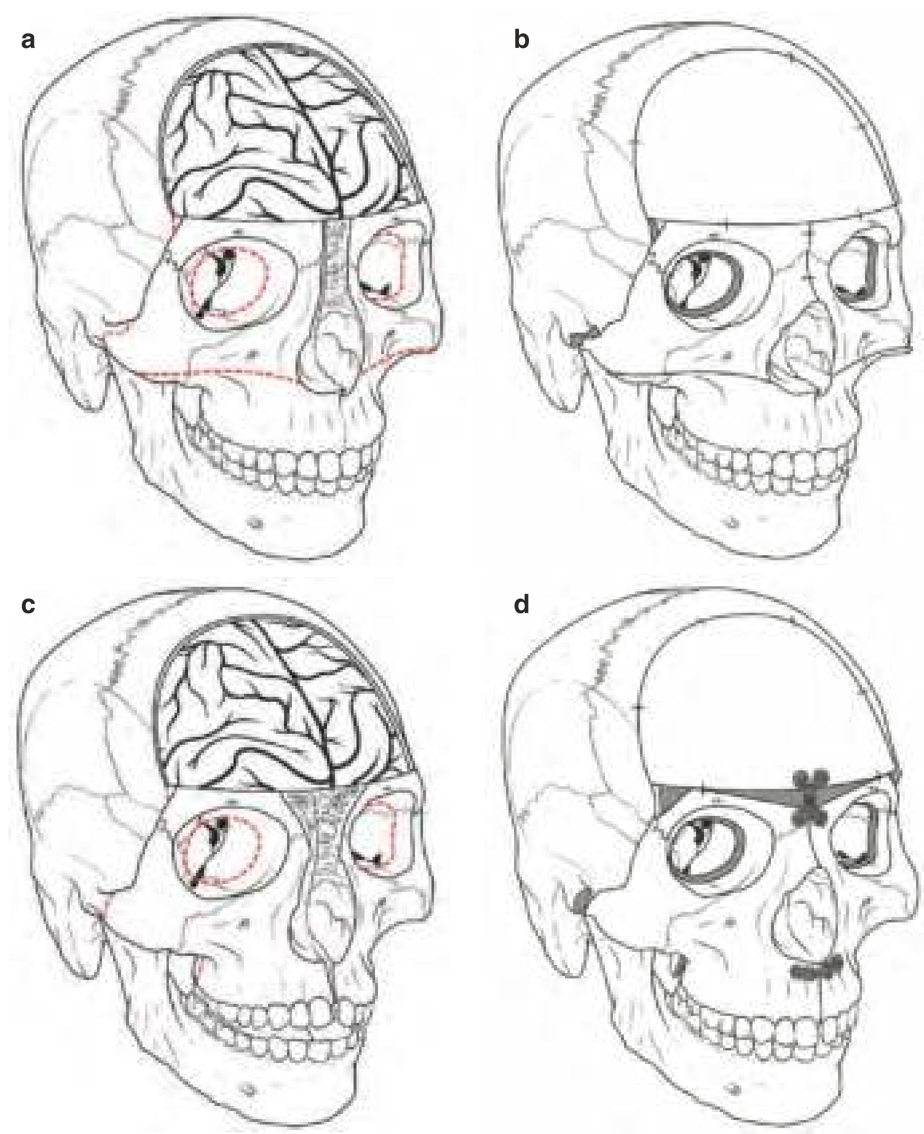

Fig. 77.25 En bloc osteotomies (**a–d**)

Fig. 77.26 Stereolithographic models—simulation

Pre-op Evaluation

Pre-op evaluation for orbital hypertelorism includes the following:

- External facial measurements
- Dental casts
- Posteroanterior x-ray cephalometry [70]
- Modern aids like computed tomographic scan
- Three-dimensional imaging and stereolithographic models [71] (Fig. 77.26)

Facial Bipartition

The facial bipartition procedure involves the mobilization and rotation of the entire midface in a monobloc fashion (Fig. 77.27a, b). The osteotomy involves the supra-orbital rims first. It is then continued along the lateral orbital walls in a similar fashion to the LeFort 3 osteotomy and is dropped caudally to involve the dentate segment also in the mobilized segment. The intra-orbital circumferential osteotomies are performed using a combined trans-cranial and trans-facial approach once the hemifacial segments are mobilized, the intervening ethmoids are resected creating space for the upper face to be rotated medially. This causes the maxillary dentate segment and the palate to have a lateral rotation increasing the transverse dimension of the face and correcting the palatal crossbite of the upper posterior teeth. This procedure can also be combined with an advancement of the midface complex by combining it with a LeFort 3 type modification [72].

77.6.3.2 Box Osteotomy (Fig. 77.28a–d)

Correction of orbital hypertelorism done using a box osteotomy may include corrections of associated nasal deformities. Bone and cartilage grafts may be necessary to provide nasal framework. Skin grafts may be required for nasal coverage and may be accomplished by local flaps. The box osteotomy is generally preferred when the dental occlusion is normal.

Van den Elzen et al. (2011) advocated waiting until after age 10 (after eruption of permanent dentition) to perform orbital box osteotomy. Monasterio and Taylor [61] supported the use of orbital translocation after skeletal maturity and have stated that early intervention retards midfacial growth. Tessier (1973) noted that neuro-ophthalmological benefit was increased by correcting hypertelorism at 3 years and psychosocial benefit was heightened by operating at 6 years, before schooling begins, or after 12 years to preserve the dentition. Marchac et al. (1999) also described the use of box osteotomies after 12 years of age.

77.6.3.3 Spectacle Osteotomy (Fig. 77.29a–e)

The spectacle osteotomy is done by performing the transfrontal craniotomy and preservation of frontal bandeau along with trimming of the bone in the periorbital region and around the pyriform aperture with *medialization* of the orbits.

A lateral canthopexy is an integral part of this procedure [48]. The medial canthi should be recognized and anchored using trans-nasal wires. At times this is performed with a miniplate anchor for orienting the wires in the right direction [72]. The plate is secured to the thick nasal bone, and the lower hole is kept at the level of the lacrimal crest. The canthi are independently fixed to these holes bilaterally utilizing steel wires (Also refer Chap. 79 on craniofacial syndromes) [73].

77.6.3.4 Soft Tissue Management

The midline cleft lip notch can be successfully treated by holding fast to three noteworthy standards (Fig. 77.30a, b):

1. Excision of the constrictive band on the lip
2. Approximation of the split orbicularis oris muscle at the midline
3. Mucosal lengthening using "Z"-plasties [36, 42, 74–76]

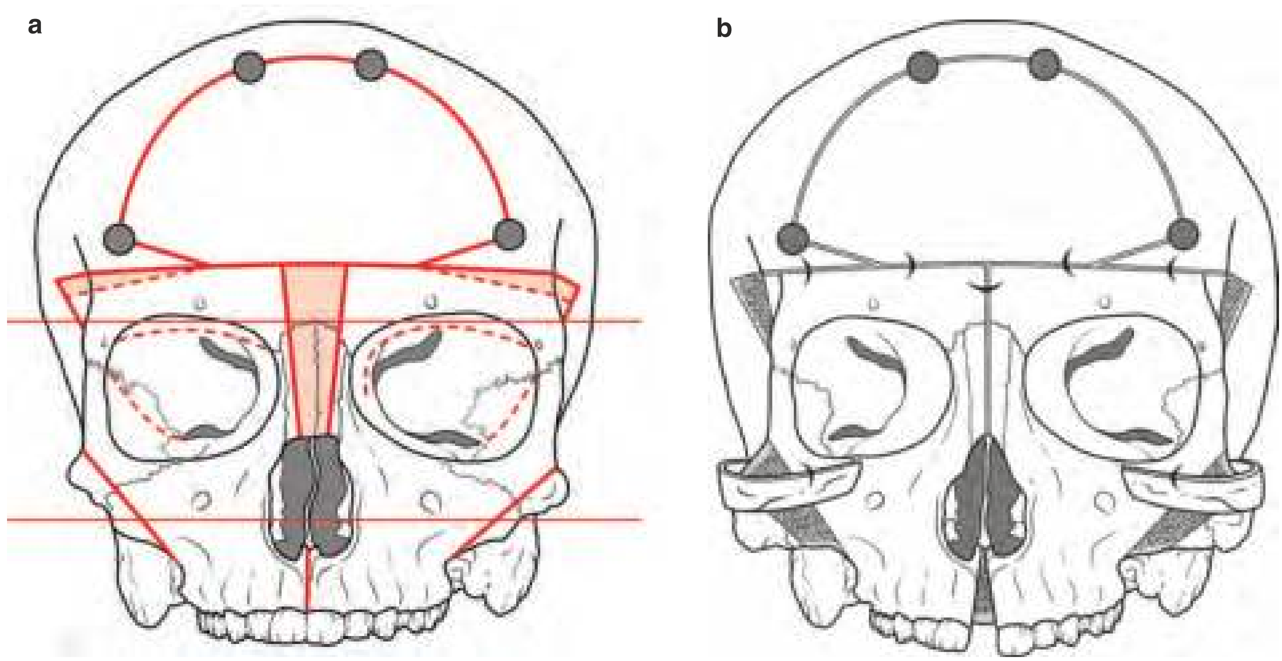

Fig. 77.27 (**a**, **b**) Facial bipartition

Fig. 77.28 (**a**–**d**) Box osteotomy—skin incision for the intracranial correction of the orbital hypertelorism consists of bicoronal incision, transfrontal craniotomy sparing the frontal bar, periorbital osteotomy, block bone removed near pyriform area, calvarial bone graft, miniplate fixation and closure

Fig. 77.30 (**a**, **b**) Reconstruction of Cupid's bow and philtrum

Fig. 77.31 (**a**, **b**) Resection of the excess skin of the nasal dorsum and closing in the midline

In managing the 0–14 cleft, the clinician should be able to diagnose if it is a true or a pseudo occurrence. In cases of a true midline cleft, care should be taken to reconstitute the important components of the lip, external nose, and nasal septum. Resection of excess skin also needs to be planned and performed [36] (Figs. 77.31a, b and 77.32a, b).

Nasal Clefts

Nasal clefts include Tessier no. 2 and Tessier no. 3 clefts.

Principles of surgical management (Fig. 77.33). Because of their rarity and extreme variability, it is not surprising that *standardized* methods of correction have not been established for patients with nasal clefts. Therefore, each case

must be approached on an individual basis using the basic principles of nasal reconstruction as a foundation.

The fundamental principles and techniques of nasal reconstruction are to assess what is present, what is missing, utilization of available tissue, and importing required tissue as indicated by the deformity.

Inventory of Nasal Components

Each component of the nose, skin, lining, and support (bony and cartilaginous), must be evaluated in a quantitative and qualitative manner. The quality and quantity of external skin and nasal lining are evaluated for deficiency or excess. The integrity of the cartilaginous framework, nasal septum, has to be assessed.

Staged Reconstruction

Patients with complex craniofacial clefts frequently require multiple staged reconstructive procedures. Planning of these procedures must be tailor-made to each patient. Surgical stages must be planned and executed with all subsequent surgical sessions clearly in mind.

Replace Like with Like

Whenever possible absent or deformed tissue should be replaced with identical or similar autogenous material.

Bony defects may be present along the cleft from the alveolus to the orbit. It is essential to reestablish a stable anatomic bony base to ensure adequate support for the soft tissue reconstruction of the nose and orbit. Autogenous split calvarial, rib, and iliac graft are the general preferences.

Cartilage

Free cartilage grafts alone may often suffice to correct small deficiencies of the alar rim, nasal rim, nasal dorsum, or tip. Larger defects of the upper and lower lateral cartilages can be replaced using conchal or septal cartilage grafts. Thin bone from the perpendicular plate of the ethmoid can be used to replace upper lateral cartilage.

Small composite chondro-cutaneous grafts from the concha can be used to replace small defects if additional lining is needed. For larger cartilage defects in the area of the upper laterals, septal hinge flaps can be used. Reconstruction of lower lateral cartilage can be accomplished using conchal cartilages or chondromucosal grafts from nasal septum.

Nasal Lining

Adequate lining to the nose is critical to achieve a functional and predictable aesthetic result. This is also essential to reestablish vascularity to the underlying tissue and to minimize contracture of the soft tissues. Local turnover flaps are useful for small defects, while larger defects may require vascularized tissue transfer.

Skin

Small nasal clefts are amenable with local tissue transfer in the form of rotation flaps from the lateral nasal area. Onus in simple nasal clefts is given to the reestablishment of the alar rim contour [68]. The use of z-plasty techniques and composite grafts helps in achieving additional symmetry [77].

Downward rotation of the cephalically displaced alar rim is the first step in this process. This may require the use of a back cut to rotate the alar margin caudally. The triangular defect produced by the alar rotation is then filled by a transposition flap from adjacent areas having excess skin [78, 79].

Descriptions of a nasal dorsal rotation flap (Figs. 77.34a–d and 77.35a, b) for a Tessier 2 cleft and a brow-eyelid-nasal transposition flap for a Tessier 3 are predictable techniques [80].

Fig. 77.34 (**a**–**d**) Design for bilateral Tessier no. 3 cleft—nasal dorsum rotational flap

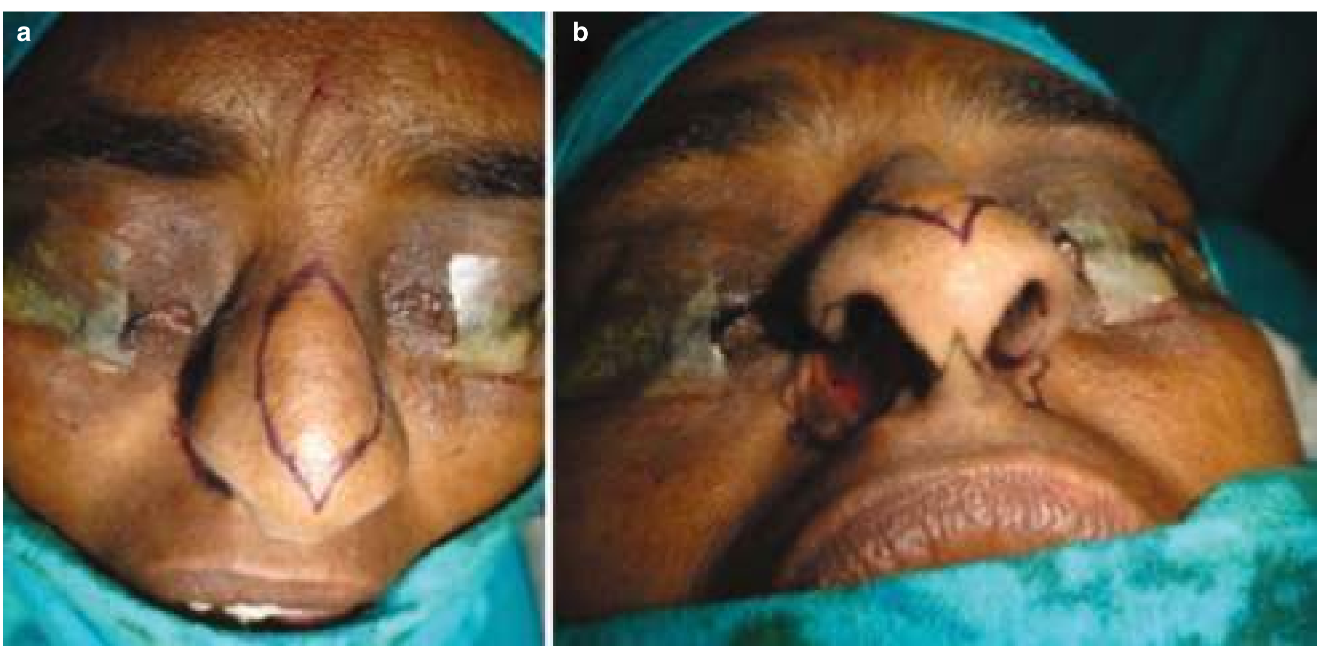

Fig. 77.35 (**a**, **b**) Nasal dorsum rotational flap

The nasal dorsum rotational flap design to correct Tessier no. 2 clefts improves alar symmetry at the cost of reduced nostril size. A notch on the affected ala is a major problem to handle in this technique [80, 81].

The forehead-eyelid-nasal transposition flap (Fig. 77.36) technique involves the use of an inter-eyebrow-forehead flap which is pedicled on the tissue of the nasal bridge. The rotation achieved by the flap gives both the alar and nostril symmetry while reducing the need for revision [80].

Reestablish Nasal/Facial Aesthetics

Optimal reconstruction of the nose should be based on the principle of aesthetic subunits as described by Gonzalez-Ulloa and Castillo (1954) and refined by Burget and Menick (1985). Superior results are better achieved by replacing the entire subunit of the nose rather than simply patching the defect. The achievement of the nasal proportions should be in conjunction with facial proportions though there are many aesthetic and surgical limitations because of associated severe craniofacial deformities. Definitive nasal reconstruction may need to be delayed or staged as explained, until optimal canthal, orbital, and maxillary relationships are obtained.

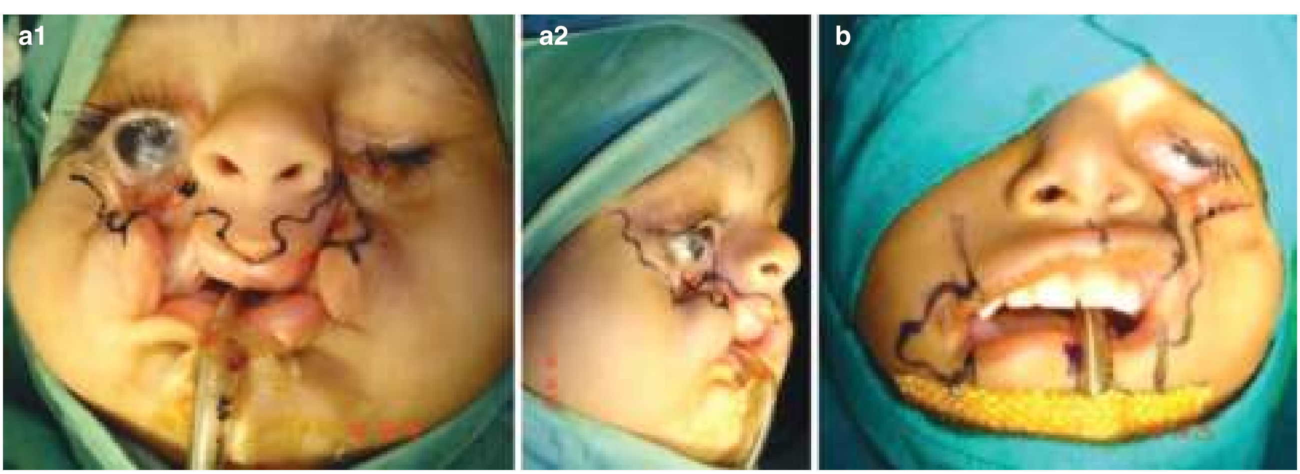
Fig. 77.36 Forehead-eyelid-nasal transposition flap

77.6.4 Tessier No. 4 (Fig. 77.37a, b)

Tessier no. 4 cleft is a rare, complex malformation which has severe implications on both the soft tissue and skeletal structures of the face. As a general rule, priority needs to be given for reconstructing the soft tissue envelop, and the skeletal repair should in the form of osteotomies or bone grafting procedures need to be deferred until the school-going years. This is due to the fact that early intervention to the bony skeleton may hinder the development of the midface and associated (Resnick and Kawamoto 1990; Kawamoto and Patel 1998) [76].

An important clinical indication that necessitates emergency intervention is exposure keratitis of the cornea and resultant blindness. This depends on the gravity of the cleft deformity. In narrow cases of Tessier 4 cleft, the clefting is more toward the medial side of the orbit which retains a large bony component of the lateral orbit. This lends support to the globe and enables reasonable competence of the upper eyelid to cover the cornea. In such instances the early surgical intervention may be avoided [82]. On the other hand in severe cases, there is total absence of the orbital floor causing the globe to sink downward with the cornea facing upward due to a lax supporting structure. This prevents the upper



©Association of Oral and Maxillofacial Surgeons of India

Fig. 77.37 (**a**) Incision for bilateral Tessier no. 4 (**b**) unilateral tessier 4 on left side with tessier 7 on right side eyelid from being able to protect the cornea, with the resultant problem of exposure keratitis and permanent corneal damage. Such instances produce an emergency, and a repair of the orbital support system is mandated. In cases where an early intervention is not possible due to medical and anesthetic implications, emergency intervention at least in the form of a tarsorrhaphy is performed within 2–4 days of birth.

While treating severe deformities like the Tessier no. 3 and Tessier no. 4 clefts, a "split method" of management can be utilized to handle the anatomical regions individually as given below [83].

The affected regions were divided into three segments:

1. Lid segment
2. Lip segment
3. Nasomalar segment

77.6.4.1 Managing the Lid Segment

An ectropion like deformity is commonly present. This can be managed using conventional techniques. They include (a) a back-cut release of the lower eyelid to cheek junction and medial advancement of the lower eyelid with medial canthopexy, (b) lower lid resection with inferior layered tarsal strip, or augmentation of the tarsal plate with spacer grafts. However in cases where there is inadequate tissue locally, tissue must be imported into the lower eyelid for optimal results [83]. Some of the commonly used flaps for this include the median forehead flap and the nasolabial flap. However, free vascularized tissue transfer techniques also may be adopted [84].

Numerous techniques have been described for the management of the Tessier 4 cleft. But most of them result due to the interdigitating scars produce a sub-optimal outcome [33] (Tessier 1976; Kawamoto 1990). Longaker et al. (1997) proposed the superiorly based nasolabial flap that was transposed to the lower eyelid. Though this technique had an advantage cosmetically, it had that limitation that it was useful only for mild forms of the cleft. The cheek advancement technique described by Van der Meulen [4] had the advantages of being useful even for wider clefts and favorable scars along aesthetic facial subunits. Van der Meulen likewise depicted that it was significant for improving the scarring caused by anchoring the cheek flap firmly to the pyriform aperture [85]. However, despite the options available, it is better to understand that a single flap may be insufficient at times to reconstruct the eyelid [86]. To overcome these challenges, the use of tissue expanders and free vascularized transfers have also been advocated [87, 88].

The Veau III method of bilateral lip repair can be used for correcting the lip component. The last area to be addressed is the naso-malar junction [89].

77.6.5 Tessier No. 5–9 Cleft (Fig. 77.38a, b)

The primary outcomes that are needed for the correction of these clefts include:

- Lower eyelid reconstruction
- Lateral canthal repositioning
- Repair of the labio-maxillary cleft
- Skeletal continuity restoration (this includes the orbital floor) using bone grafts

The principles to be borne in mind in the management of the Tessier 5–9 spectrum have been modified by different surgeons: Tessier (1971) advocated early correction of orbital dystopia – prior to 1 year of age. In all forms of facial clefts that affect the ocular region, priority is given to the preservation of vision by early interventions to prevent exposure keratitis of the cornea. Pre-surgical care includes use of ophthalmic ointments or temporary tarsorrhaphy procedures [48, 89]. Kara and Öçsel (2001) have reported the use of multiple z-plasties for the soft tissue reconstruction as early as 8th day after birth.

77.6.6 Tessier No. 7

Lateral facial cleft or Tessier no. 7 cleft is generally unilateral in presentation, though may also occur bilaterally. The bilateral form produces more gross clinical appearance with the face being amphibious in nature with an expanded mouth and infero-laterally placed commissures.

The condition is often related to syndromes of the first and second branchial arches. The cleft involves the skin, mucosa, and muscles of the oral sphincter (i.e., the orbicularis oris and the buccinator) [89]. In rare instances the cleft may involve the masseter [90]. This is a condition which may be concurrent with a lot of other deformities mandating a very thorough investigation in any patient exhibiting the classical feature of macrostomia [89].

Fig. 77.38 (**a**, **b**) Tessier no 5–9 management

The surgical objectives for the management of the lateral facial cleft have been detailed as follows [90] (Fig. 77.39a–d):

1. Reconstituting the oral sphincter by reconstructing the orbicularis oris and the buccinator
2. Identification and reattachment of the other muscles of facial expression and the masseter in cases
3. Reconstruction of a natural and symmetrical commissure bilaterally
4. Attaining lip symmetry
5. Closure of the defect in layers with the mucosa, muscle, subcutaneous layer and skin [91]

Numerous procedures for the repair of macrostomia have been described in literature; [16, 17, 92, 93, 96, 97] Onizuka 1965; Boo-Chai 1969; Mansfield and Herbert 1972; Skoog 1974; Talukder 1980; Kaplan 1981; Bauer et al. 1982; Fukuda and Takeda 1985; Verheyden 1988; Yoshimura et al. 1992; Torkut and Coskunfirat 1997; Ono and Tateshita 1999.

Maximal care is exercised on the repair of the involved muscles with an overlapping technique [94, 95]. In severe cases other muscles of facial expression like the buccinator and the risorius also need to be repaired (Ono and Tateshita) [93]. This ensures normalization of both form and function of the perioral region [94].

The skin repair consists of two parts: repair of the cheek wall and commissuroplasty. Commissuroplasty denotes the reconstruction of the skin mucosa junction at the corner of the lips. Care is taken to design the repair in such a way that there is no associated contracture in the post-surgical period. There are various descriptions for the commissural repair. The triangular flap repair of Ono and Tateshita [93]. This procedure produced better aesthetics due to the triangular design of the flaps. Kawai et al. in 1998 described an inferiorly based triangular flap taken close to the lower lip to minimize the re-expansion of the commissure in the long term.

Eguchi et al. used the vermillion square flap method for commissuroplasty [96].

Other popular techniques described for the skin repair of the lateral lip element include to direct linear suturing, Z-plasty [94], and W-plasty [96]. The purpose of a Z-plasty is to break the long linear scar. But it is seen that the use of multiple Z-plasty or W-plasty procedures violates the relaxed skin tension lines. Therefore, a single Z-plasty with vertical limb lying in the nasolabial crease is preferred [90].

77.6.6.1 Bone Grafts

The establishment of normal contour of the soft tissues is never complete without the much needed skeletal support system. The skeletal reconstruction of craniofacial clefts essentially needs the use of bone grafts to fill and bridge both minor and major defects. The consolidation and take of the bone graft in the recipient site happens in two important steps: (i) the bony union of the joints between the grafted bone and the native bone and (ii) graft remodeling and creeping substitution [97]. Bone grafting can be performed at any age and is generally combined with soft tissue reconstruction [97].

Repairs performed in the early years of life can be accomplished with bone stock from the rib or iliac crest. However, the quality of the bone supplied by the ilium is better suited for this work. The cortico-cancellous graft material can be placed as such or carried over titanium cribs. It is important to note that the general consensus for the use of non-vascularized grafts is for defects less than 6 cm [98].

- Iliac crest grafts are the most favored with a good stock of available cortico-cancellous bone. Generally the anterior iliac crest is preferred as the posterior iliac crest requires a change of position to prone and may not accommodate simultaneous work from two teams. Donor site morbidity rate for anterior iliac crest grafts is around 23% and much less for posterior iliac crest. Complications include post-operative pain, iliac or acetabular fractures or instability, persistent hematoma, herniation of abdominal contents, vascular injury, lateral femoral cutaneous nerve injury, and contour defects along the iliac crest [17].

- Occasionally the use of alloplastic materials like Medpor may also be used (Fig. 77.40).
- Calvarial bone is another preferred site and can be freely available when the surgery involves cranial procedures and trans-cranial approaches. It has the lowest rate of resorption among all the bone grafts making it a preferred choice for facial and orbital reconstruction (Fig. 77.41a, b). The parietal calvarium can safely provide up to 8 × 10 cm of the bone for harvesting [99]. The temporo-parietal region provides more curved bone suitable for orbital or malar reconstruction. Generally the grafting is performed in strips so that there are no gross fractures and later the strips are joined together to reconstruct larger defects. Calvarium is harvested in three main forms: partial-thickness outer cortex, full-thickness outer cortex, and bicortical grafts. Partial-thickness outer cortex grafts are ideally harvested from children between 4 and 8 years of age, using an osteotome to produce a curling sheet of the bone.
- Calvarial grafts are safe in adults and are the standard indication when simultaneous craniotomy is performed. A bicortical graft is harvested and the graft is split. The inner cortex is used for reconstruction, while the outer cortex is replaced to fill the donor site defect and contour.
- Complications of calvarial grafting include contour defects of the donor site, graft fractures, and rarely dural tears while harvesting bicortical grafts. Dural tears mandate a thorough and formal dural repair to prevent further complications. Intra-cranial hemorrhage is a very rare complication during this procedure but has been documented [100].
- Grafts of ample volume can also be harvested from the anterior tibia both in the form of cancellous bone or in the form of cortical strip from the anterior tibial plateau.
- Rib bone or costochondral grafts can be harvested from ribs 5 to 7 which may be used as full-thickness or split rib grafts. Costochondral grafts are extensively used in the reconstruction of ascending mandibular ramus and condylar defects. Site-specific complications include postoperative pain, injury to the pleura with associated pneumothorax, hemothorax, or pneumohemothorax. Occasionally it may cause exaggerated facial asymmetry due to overgrowth.

Fig. 77.42 Distraction osteogenesis in the correction of asymmetry

Defects which are larger and demand more complex reconstruction may not be amenable to bone grafting alone and may require well-designed osteotomy techniques [82, 101] or at times, even distraction osteogenesis (introduced by McCarthy and co-workers) [102] to form better contour of the involved skeletal framework and improve function (Refer Chap. 87 on Distraction osteogenesis) (Fig. 77.42).

77.7 Conclusion

The uncommonness of craniofacial clefts has made the accumulation and complete anatomic documentation of this extensive arrangement troublesome. Preoperative and postoperative CT examinations with 3D reproductions will improve the understanding of these complex deformities. The test of managing these monstrous deformities still challenges the skill and experience of many a craniofacial surgeon [35].

This is an effort to bring a comprehensive account on the varied presentation and management techniques employed in the management of craniofacial clefts of the head and face. We also emphasize the utilization of the brilliant and time-tested diagnostic and surgical principles detailed here to establish new protocols for the comprehensive management of these deformities. Moreover we also advocate that more standardization along with structured investigation and planning methods should be utilized to come to sensible yet efficient treatment models that can be utilized by all for the treatment of this unfortunate set of people.

78 Hemifacial Microsomia (HFM) and Treacher Collins Syndrome

Manikandhan Ramanathan

78.1 Introduction

Hemifacial microsomia (HFM) is a three-dimensional congenital deformity of the craniofacial region characterized by abnormal and underdevelopment of the first and second pharyngeal arches. Due to involvement of multiple structures, this disorder has a broad spectrum of involvement with diverse clinical features [1].

The highly variable phenotypes have probably led to variation in its nomenclature as well, alternatives used being craniofacial microsomia (CFM), otomandibular dysostosis, facio-auriculo-vertebral spectrum, oculo-auriculo-vertebral spectrum, first and second branchial arch syndrome, otomandibular-facial dysmorphogenesis, and lateral facial dysplasia [2].

This disorder is characteristically unilateral; however, incidence of bilateral cases is 10–15%. Although this disorder was described first by Carl Ferdinand von Arlt, a German physician in 1881, "hemifacial microsomia" got its name from Gorlin and Pindborg in the early 1960s. Converse et al. proposed the name, craniofacial microsomia, in cases of coexisting cranial deformities where HFM is also associated with vertebral, cardiac, and renal defects, in a condition called as Goldenhar syndrome. It was termed "oculoauriculovertebral dysplasia" (OAVD) by Gorlin. It is also associated with epibulbar dermoids and ear deformities [2, 3].

78.1.1 Epidemiology and Etiopathogenesis

HFM is the second most common congenital anomaly of the face, with a male predilection and which is more common in the right than the left side. The incidence of HFM ranges between 1 in 3500 and 1 in 26,000 live births [4–7].

The cause of HFM remains largely unknown. Poswillo in 1973 reported that hematomas resulting from disruption of embryonic arteries (stapedial artery) in utero produce abnormalities in the development of the structures derived from the first and second pharyngeal arches. The extent of the hematoma and consequent tissue damage during the first 6 weeks of gestation determines the severities of deformities. He was able to produce the CFM phenotype in mice, thus proving his theory. He administered teratogens to produce a hematoma of the stapedial artery and the artery of the second arch which resulted in regional necrosis [4] (Fig. 78.1a, b).

The second widely accepted hypothesis is a change in the migration of neural crest cells (Fig. 78.2). Retinoic acid is believed to influence and alter the migration and distribution of neural crest cells, which may predispose to abnormalities in the pharyngeal arch derivatives. The intake of retinoic acid in humans during the early stages of pregnancy may cause multiple disorders collectively known as "retinoic acid embryopathies" (RAEs); these include variable defects of the jaws and the middle and external ear [3–5]. Apart from retinoic acid, thalidomide, primidone, ethanol and isotretinoin have also been studied as causative agents in HFM through their teratogenic effects [6, 7].

More recent studies have demonstrated an association between HFM and multiple gestations, along with other maternal risk factors such as assisted reproduction, smoking, maternal diabetes mellitus and vasoactive drugs. Moreover, HFM may demonstrate autosomal dominant and recessive Mendelian patterns in families. Positive family history accounts for 50% occurrence of features [8].

Genetic events like duplication of the OTX2 gene (chromosome 14q22.3) have also been researched upon. OTX2 encodes a transcription factor, essential for craniofacial development and anterior brain morphogenesis. Heterogeneity in aetiology along with variable penetrance

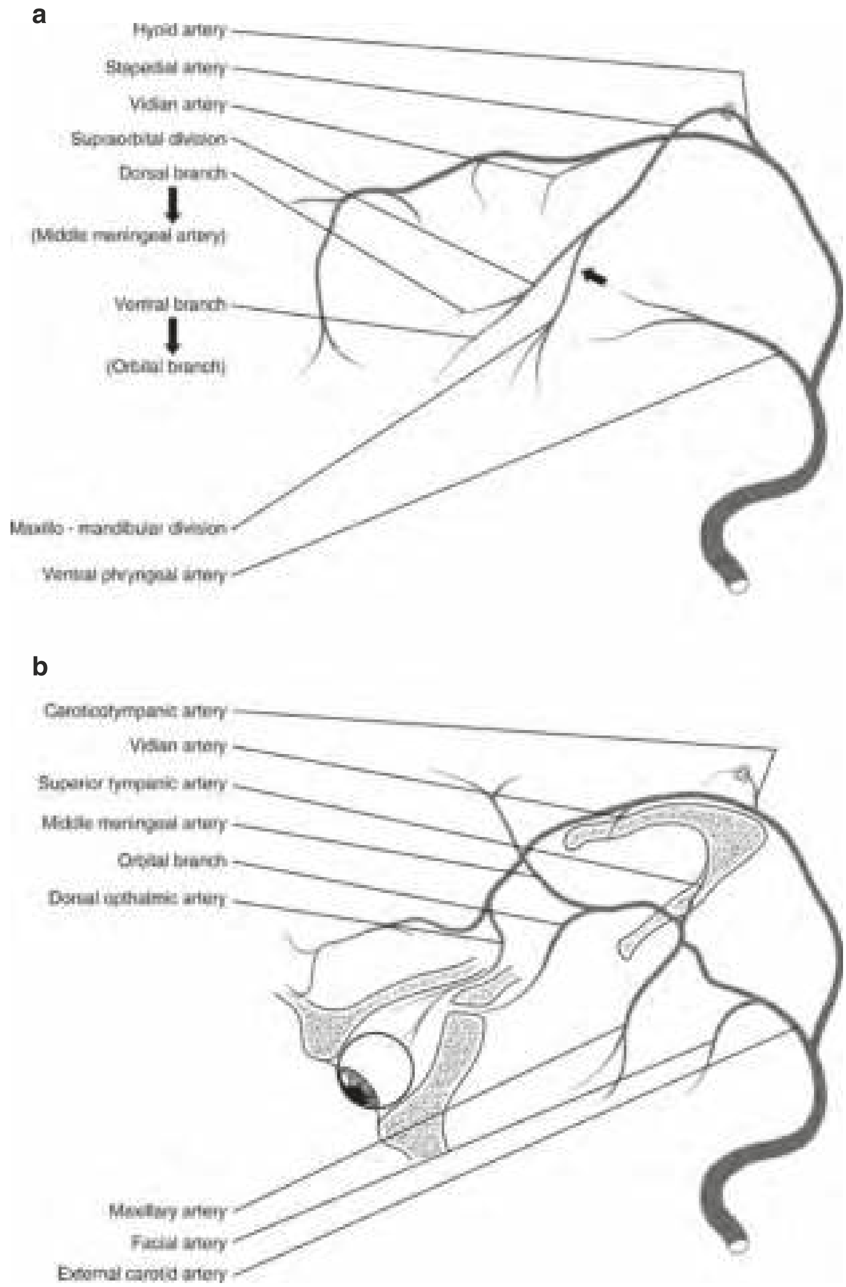

Fig. 78.1 (**a**, **b**) Anatomy of the stapedial artery during embryonic development

and expression is postulated to account for the widely variable phenotypic spectrum of HFM [9, 10].

78.1.2 Classification Systems

Various classifications have attempted to categorize various features of HFM as enumerated below [11–13]:

1. SAT classification.
2. OMENS classification.
3. Kaban-Pruzansky classification.

78.1.2.1 SAT Classification

The skeletal, auricle, and soft tissue (SAT) classification.

The SAT and the OMENS (Tables 78.1 and 78.2) classifications provide an elaborate system covering simple to complex skeletal, soft tissue and neurological involvement. On the other hand, the Kaban-Pruzansky classification explains malformations involving the mandible, masticatory muscles, and TMJ. Therefore, it is more useful for orthodontists and maxillofacial surgeons in reconstruction of the mandible and TMJ. Thus, this classification has become the gold standard. It involves four classes—

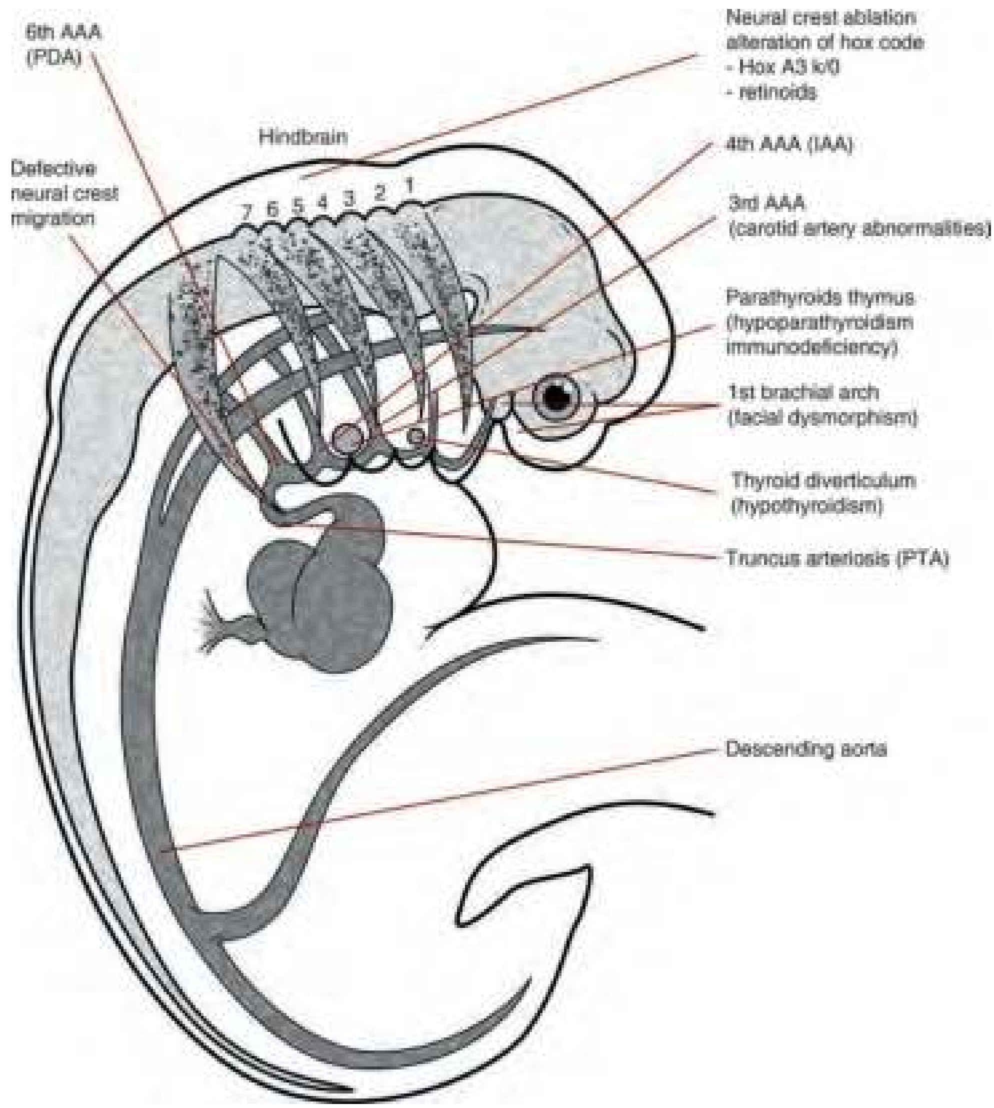

Fig. 78.2 Migration of neural crest cells during embryonic development

Table 78.1 SAT classification of HFM

Skeletal categories (S)	Auricle categories (A)	Soft tissue categories (T)
S1 = small mandible—Normal shape	A0 = Normal	T1 = contour defect minimal—No cranial nerve involvement
S2 = condyle, ramus, sigmoid notch discernible, distorted; mandible remarkably different in size and shape	A1 = small, malformed auricle—With characteristic features	T2 = moderate defect
S3 = severe mandibular deformity, poorly discernible, to agenesis of ramus	A2 = rudimentary auricle with hook at cranial end corresponding to the helix	
S4 = an S3 mandible with orbital involvement, lateral and inferior orbital rims displaced posteriorly	A3 = malformed lobule, pinna absent	
S5 = the S4 defects plus orbital dystopia, hypoplastic, asymmetric, neurocranium and a flat temporal fossa		

Table 78.2 OMENS classification

Orbit	Mandible	Ear	Nerve (cranial nerve VII)	Soft tissue
0 = Normal	Type I	Type I = small ear, the normal structure	0 = Normal	0 = Normal
1 = small size	Type IIA	Type II = severe external ear deformity with a rudimentary auricle	1 = upper branches impaired	1 = mild hypoplasia
2 = poor position	Type IIB	Type III = small rudiment of external ear with no pinna	2 = lower branches impaired	2 = moderate hypoplasia
3 = small size and poor position	Type III	Type IV = Anotia	3 = upper and lower branches impaired	3 = severe hypoplasia

the Type 1, Type 2A, Type 2B, and Type 3 (Fig. 78.3a–d).

Type 1
In this category, the TMJ morphology is normal with adequate bulk and function of masticatory muscles. The mandible is slightly hypoplastic and retruded which may project as a mild asymmetry with deviation of the chin to the affected side (Fig. 78.4a, b).

Type 2A
In this type, the affected side TMJ is shifted anteriorly and medially than its counterpart, but the overall morphology of the condyle and glenoid fossa remains unchanged. The joint is functional associated with moderate muscular hypoplasia. The patient demonstrates moderate hypoplasia of the mandible with occlusal canting or open bite, and the chin is deviated to the affected side.

Type 2B
There is moderate-to-severe involvement of the joint with condyle and the glenoid fossa grossly hypoplastic. The joint exhibits only rotation movement of the condyle and near-normal function. Involvement of other facial bones and deficiency of masticatory muscles are clinically evident. The patient demonstrates severe asymmetry and occlusal canting with or without an open bite (Fig. 78.5a, b).

Type 3
There is gross facial asymmetry with severely hypoplastic or absent muscles of mastication. There is associated severe deformity of the skull and orbito-zygomatic complex as well. The mandible is severely affected with a "floating mandible" appearance due to absence of the condyle and ramus (Fig. 78.6a, b). These patients from birth may often present with signs of a compromised airway due to severe degrees of mandibular retrusion.

78.1.3 Clinical Features

The diagnosis of HFM is challenging owing to its wide phenotypic spectrum. There are no definite diagnostic criteria and classifications. The condition is diagnosed based on its clinical features of phenotype ranging from involving the orbit or ear alone to full-blown hemifacial microsomia under development with jaw malformations. For this reason, certain classification systems have been established to standardize the assessment in an organized manner and formulate treatment plan accordingly. The areas of examination include various components of the face, i.e. external ear, mandible, temporal bone, zygoma, orbit middle ear, facial musculature, facial nerve supply, and other adjacent bony and soft tissues [2, 5, 7, 14] (Fig. 78.7a–d and Table 78.3).

78.1.3.1 Skeletal Defects

Cranio-orbital
The cranial involvement is mainly limited to the squamous part of the temporal bone. Most individuals affected with HFM demonstrate hypoplasia of the zygomatico-maxillary complex. These patients clinically show malar depression with orbital dystopia. The zygomatic bone hypoplasia can lead to alterations in the glenoid fossa.

Maxillomandibular
The maxillomandibular region is primarily affected due to abnormal development of the first and second branchial arches. It presents as unilateral facial deformities with reduced dimensions of facial bones in all three dimensions (3D). This produces varying degrees of gross morphological asymmetry of the face and compensatory changes of the contralateral side. The affected side in HFM may vary in severity and also alters the morphology of the so-called normal contralateral side, resulting in gross deviation in 3D, making it a difficult term as unaffected normal side (Figs. 78.5, 78.7, 78.8a–c and 78.9a–c).

Mandibular growth changes are the earliest manifestations of HFM and are accountable for its classical presentation of facial asymmetry. The ramus of the mandible is either absent or short, with a medial displacement. The contour of the entire mandibular corpus is altered with a shift of the Genium to the affected side. Dental compensations occur for the skeletal discrepancy, which may mask the actual severity of the clinical condition.

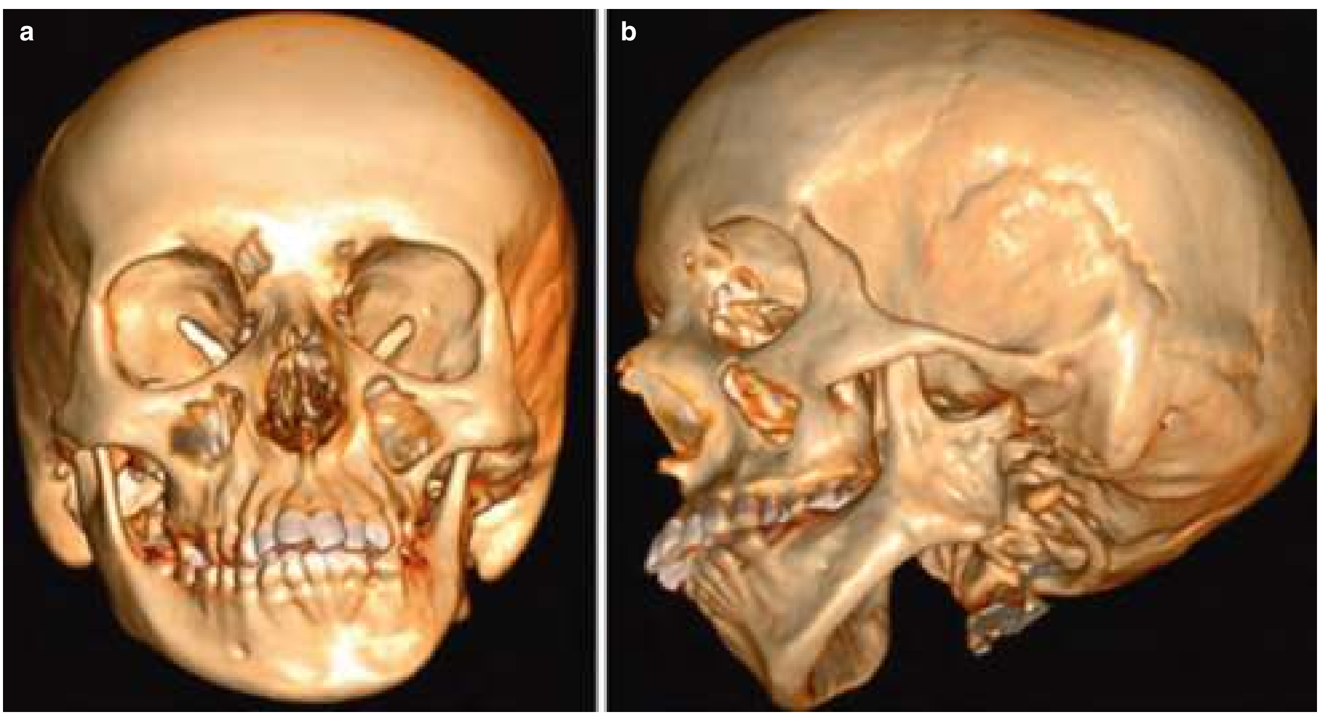

Fig. 78.5 (**a**, **b**) CT scan of patient with right-sided Type 2B Kaban-Pruzansky deformity

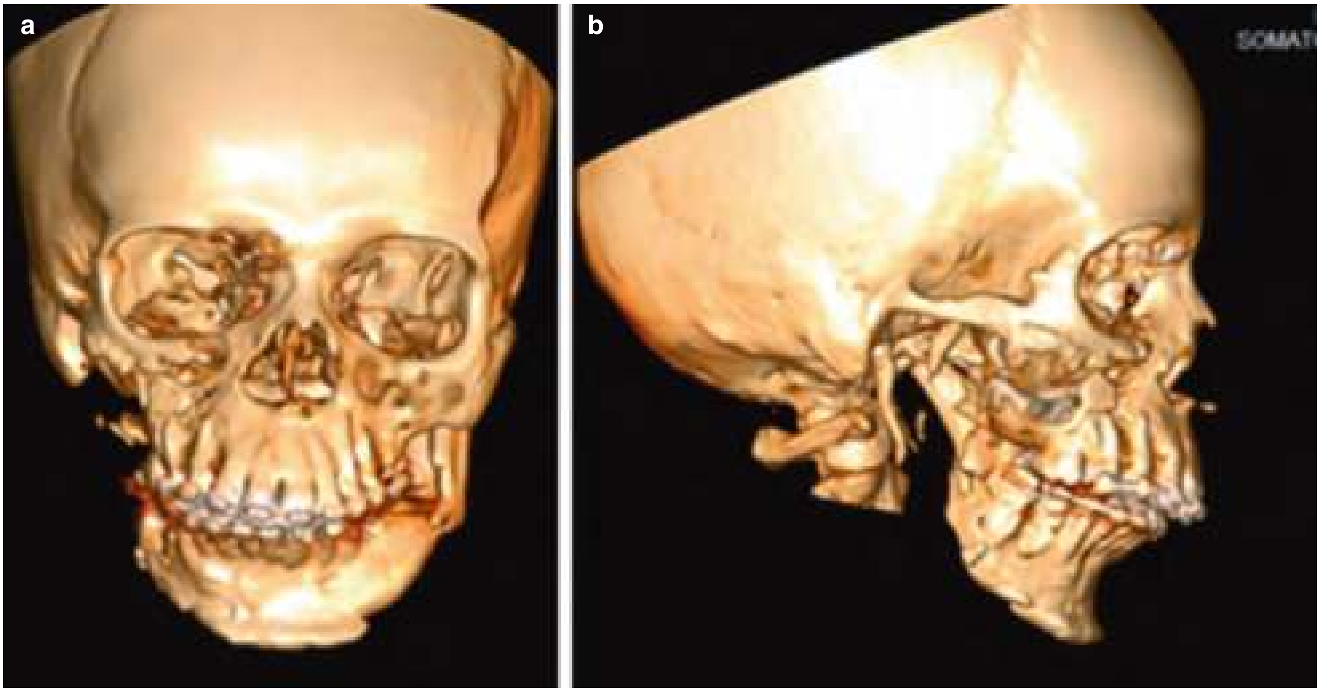

Fig. 78.6 (**a**, **b**) CT scan of patient with right-sided Type 3 Kaban-Pruzansky deformity

78.1.3.2 Soft Tissue Defect

Soft tissue deformities may involve the ear, the seventh nerve and the muscles of facial expression and mastication. Subcutaneous tissues of the face may also be affected to varying degrees. Macrostomia is a common feature along with the presence of skin tags between the tragus and the commissure of the mouth. Lateral facial clefts (Tessiers 6, 7 and 8) may be present involving the soft tissue or hard tissue or both. Function of the cranial nerves, essentially the seventh and rarely the fifth, may be compromised [15, 16]. General soft tissue bulk of the subcutaneous fat and muscles may exhibit deficiency (Fig. 78.7). There may also be compromise in the function of the soft palate.

Skin Tags

Vestigial skin rests also called as auxiliary hillocks or skin tags are usually present along an imaginary line connecting the tragus of the ear to the commissure of the mouth. This is the embryonic line of fusion between the first and second pharyngeal arches. The tags are frequently present in varying numbers and are associated with cartilaginous remnants, blind sinus tracts that may form inclusion cysts if obstructed [4–6] (Fig. 78.7).

Macrostomia

Macrostomia occurs as a result of failure of fusion of the maxillary and mandibular processes, leading to a cleft at the oral commissure including the skin and the underlying orbicularis oris (Fig. 78.10a, b). Sixty-one per cent of patients with HFM exhibit macrostomia as reported by Vento and colleagues [12].

External Ear Deformities

Meurman described a classification for deformities of the external ear which was modified by Marx [17, 18] (Fig. 78.11a–c):

- Grade I: Mild hypoplasia, with all structures present and obvious malformation.
- Grade II: Atresia of the external auditory canal, with a vertically orientated cartilaginous remnant.

Fig. 78.7 (**a**–**d**) 15-year-old male, frontal and profile view (**a**, **b**) showing features of hemifacial microsomia such as lateral cleft and preauricular skin tags. (**c**) demonstrates macrostomia and maloccusion while (**d**) shows exaggerated oral aperture with deviation of mandible to the right side on mouth opening (Also see Fig. 78.30b)

Table 78.3 Clinical features of hemifacial microsomia and the spectrum of associated anomalies

Head and neck	Associated congenital anomalies
Maxillary and mandibular asymmetry with hypoplasia on the affected side	Cardiac defects (tetralogy of Fallot, ventricular septal defect, aortic coarctation, patent ductus arteriosus)
Microphthalmia	Lung hypoplasia
Hypoplastic adnexal structures	Renal agenesis, ectopic kidney, multicystic
Coloboma	Dysplastic kidney, vesicoureteral reflux, or ureteropelvic junction obstruction
Zygomatic hypoplasia	Vertebral anomalies
External ear abnormalities or atresia	Mental retardation, Arnold-Chiari malformation, encephalocele
Internal ear abnormalities	
Temporomandibular joint hypoplasia or absence	
Hypoplastic dentition or oligodontia	
Parotid hypoplasia or agenesis	
Plagiocephaly	
Torticollis	

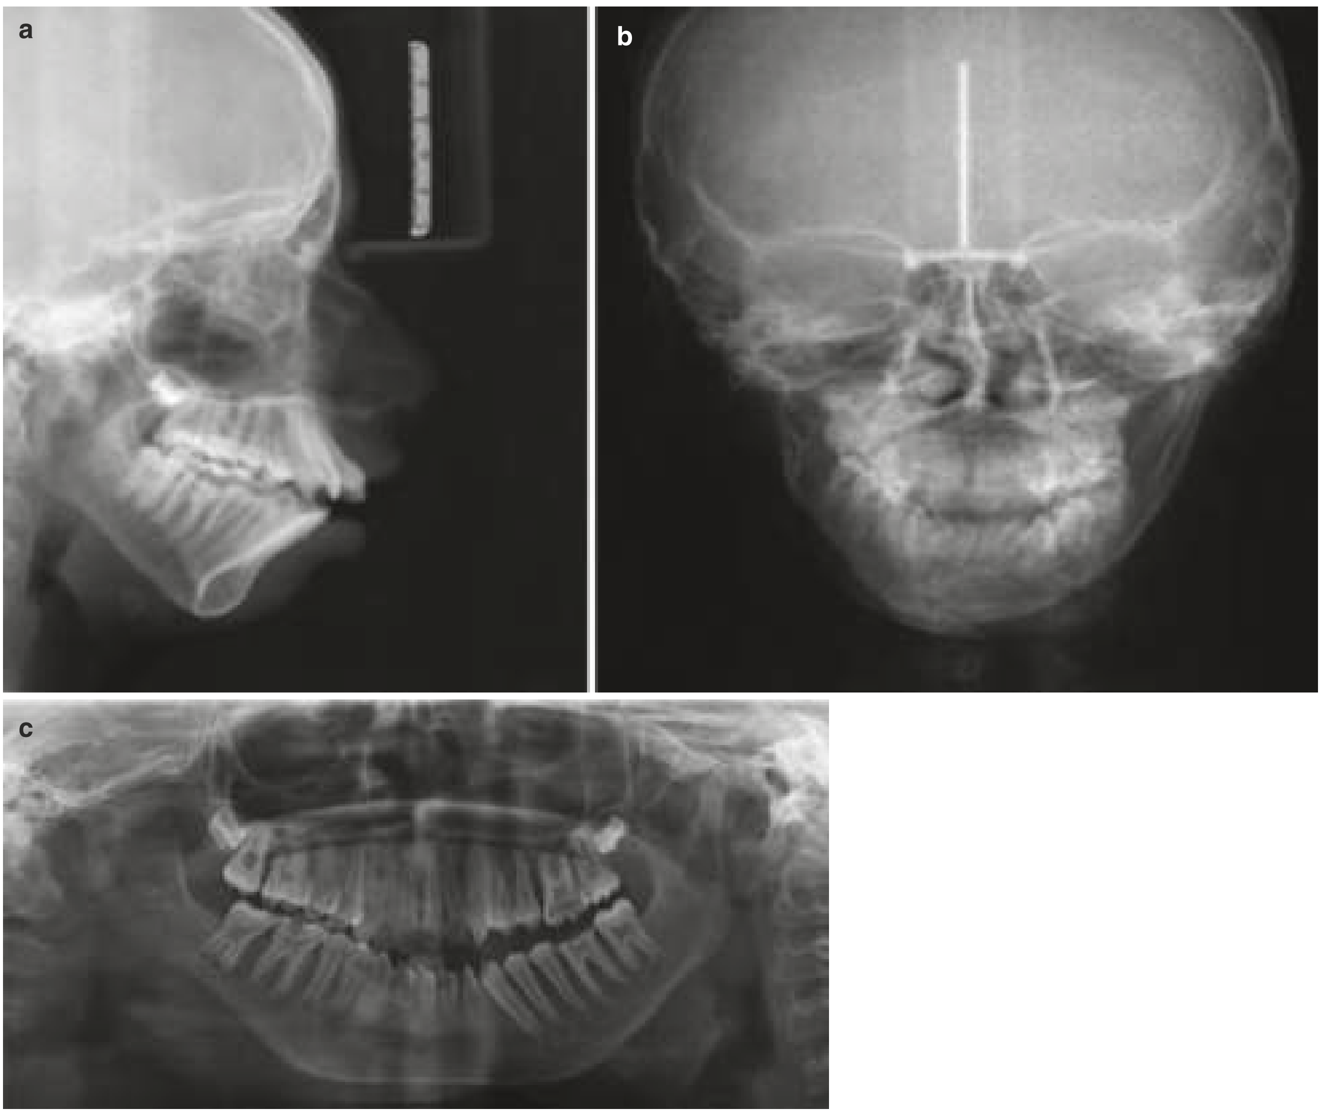

Fig. 78.8 (**a**–**c**) Radiographs lateral cephalogram (**a**), posteroanterior cephalogram (**b**) and OPG (**c**) showing features of asymmetry. OPG showing deficient body and ramus region

Fig. 78.9 (**a**–**c**) Intraoral views showing malocclusion, asymmetric anterior open bite, canting and crowding

Fig. 78.10 (**a**, **b**) (Left, profile view; right, frontal view): Adult with right-sided hemifacial macrostomia. Note the deviation on mouth opening to the deficient right side. Also note the preauricular skin tags and epibulbar lesions

- Grade III: Absent auricle, anteriorly and inferiorly displaced lobular remnant.
- Radiological assessment using temporal bone CT scans should be used to assess the middle ear structures.

Muscle Deficit

Deficits in the temporalis and the pterygo-masseteric group of muscles may be seen in HFM. This also contributes to the skeletal deficit seen. A hypoplastic temporalis may be associated with a hypoplastic or at times absent ramus-condyle unit (RCU) which includes the coronoid process also; a similar association is also evident with the presentation of the pterygo-masseteric muscles and the ramus of the mandible. With cases of increasing severity, the proximal aspect of the zygomatic arch may also be absent with the aponeurosis of the hypoplastic masticatory muscles filling that space. Lateral pterygoid muscle hypoplasia ranges from mild to complete absence and correlates with the extent of the skeletal defect. Hypoplasia of the muscles and deficiency of the RCU lead to abnormalities of the TMJ and also with absence or altered joint structures. This often leads to deviation of the mandible to the affected side at rest and on mouth opening (Fig. 78.12a).

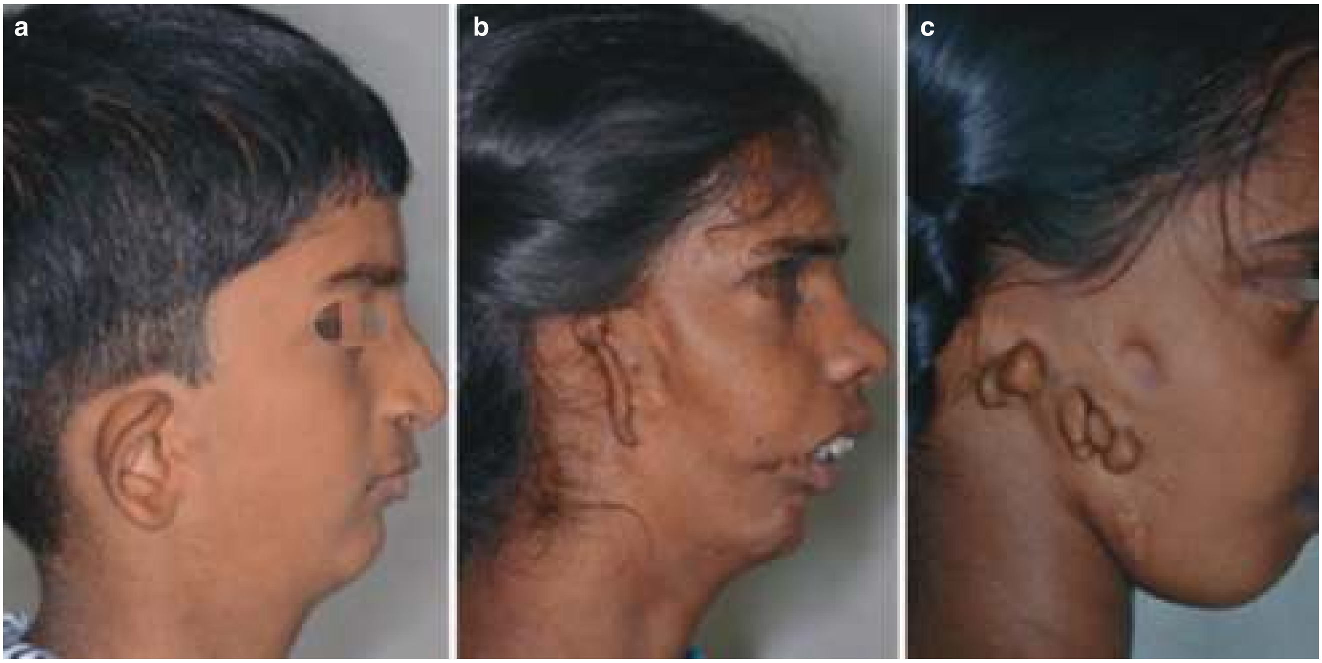

Fig. 78.11 (**a**) Grade 1 mild ear deformity, (**b**) Grade 2 moderate ear deformity, (**c**) Grade 3 severe ear deformity

Fig. 78.12 (**a**) Unilateral cleft lip and palate patient with right-sided hemifacial microsomia, Grade 1 ear deformity, right-sided muscle weakness of orbicularis oris, buccinator and orbicularis oculi. (**b**) Deviated smile due to facial nerve deformity

Cranial Nerve Abnormalities

Approximately 25% of the patients with HFM are affected with cranial nerve deficits, resulting in features ranging from nerve weakness to complete paralysis. The marginal mandibular branch is the most commonly affected followed by the frontalis muscle dysfunction. Rarely, there may be a sensory deficit due to trigeminal nerve involvement along with total involvement of the facial nerve [19] (Fig. 78.12b).

Soft Palate Function

The cause for the soft palate deviation (to the normal side) in HFM has long been debated. It is proposed that the deviation may be due to a combination of skeletal asymmetry, neurological deficits, and hypoplastic musculature. Literature shows that patients with HFM are predisposed to velopharyngeal dysfunction, even in the absence of a palatal cleft [20].

78.1.4 Radiological Assessment

Considering the three-dimensional skeletal nature of the deformity, radiological assessment is of paramount importance. Conventional methods of 2D imaging are very helpful and still relevant in assessing the condyle anatomy and extent of asymmetry. Orthopantomogram, posteroanterior cephalogram, and lateral cephalogram should be taken for initial assessment (Fig. 78.9). With the advent of reconstructed 3D imaging, the surgeons can now evaluate the full extent of asymmetry including the cranial base and glenoid fossa (Figs. 78.5, 78.6 and 78.7). Scintigraphy or technetium scan can be done in these cases to rule out apparent hypoplasia due to hyperplasia of one side condyle (Fig. 78.13a, b).

78.1.5 Differential Diagnosis of Hemifacial Microsomia

Patient with HFM must be distinguished from those with Goldenhar syndrome, Treacher Collins syndrome, hemimandibular elongation, Parry-Romberg syndrome, juvenile rheumatoid arthritis, Nager syndrome, traumatic postnatal deformity, postaxial acrofacial dysostosis, muscle dysfunction, branchio-oto-renal syndrome (BOR), and maxillofacial dysostosis. The following is a table of distinguishing features of hemifacial microsomia and other entities (Table 78.4).

Hemifacial Microsomia with Cleft Lip and Palate

The incidence of HFM with concomitant orofacial clefting is a range between 18 and 61%, including presentations of atypical clefts and macrostomia. Fan et al. reported cleft lip with/without cleft palate in 10% of HFM patients. Thus, cleft lip and palate may actually be considered as a part of the HFM spectrum [20, 21]. The laterality and severity of presentation of cleft lip/palate correlate with the severity and side of presentation of HFM. This shows common embryological aetiopathogenesis of HFM and orofacial clefting. However, patients with HFM often present with velar deficiencies, leading to hypernasality and velopharyngeal insufficiency. Patients with HFM have a higher incidence of cleft maxillary hypoplasia than non-syndromic cleft patients. The already present abnormality in maxillary growth in HFM may further influence the midface deficiency seen in HFM patients with CL only.

78.1.6 Principles of Management of Craniofacial/Hemifacial Microsomia

The principles involved in the management of HFM are described below. We have categorized them as per age and the required intervention. Growth considerations are important in formulating treatment plan. Various challenges and treatment methods have been described in literature with focus on the mandible and TMJ reconstruction (Fig. 78.14 and Table 78.5).

78.1.6.1 Neonates and Infants

Due to the morphological severity of the skeletal deformities, severe functional compromise of the infant's airway can happen after birth. Later on, the presence of a compromised airway can also affect the child's ability to swallow. Hence, the primary management in a neonate should be focused on stabilization of the airway and assisted feeding [22].

78.1.6.2 Airway

A grossly compromised airway may necessitate procedures to maintain the patency of the child's airway and facilitate the child to thrive. These procedures are neonatal distraction (early distraction osteogenesis), tongue lip adhesion, or tracheostomy [22, 23]. The neonatal distraction has fallen into disfavour due to future unpredictable

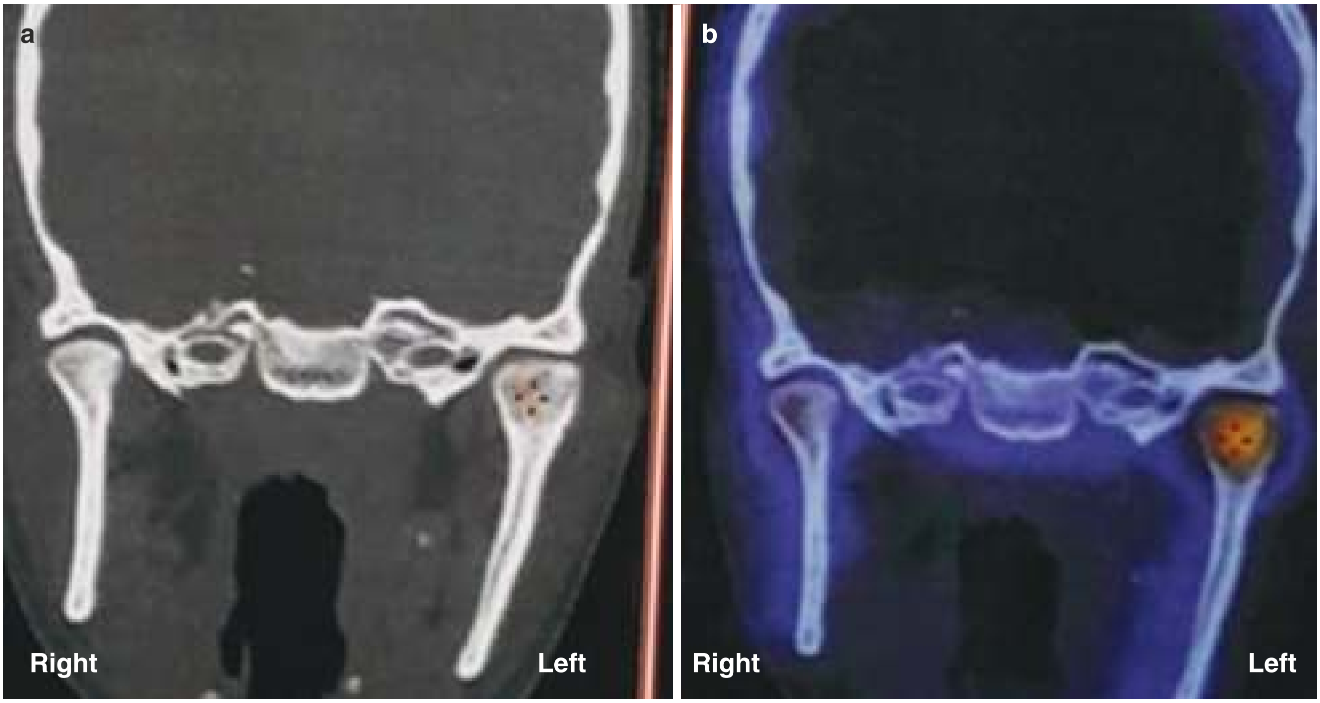

Fig. 78.13 (**a**) SPECT scan in the case of facial asymmetry. (**b**) Note the active uptake on the left side. Technetium scan can be done to rule out asymmetry due to contralateral condylar hyperplasia

Table 78.4 Differential diagnosis of Hemifacial Microsomia

Other entities	Distinguishing features
Treacher Collins	Always bilateral
Old undiagnosed condylar trauma	Condyle and ramus are short, absence of any other soft tissue features and normal ears. History of trauma at birth
Goldenhar syndrome	Vertebral anomalies and epibulbar dermoids and/or eyelid colobomas
Hemimandibular elongation	Mandible deviates to unaffected side. Normal form and size of condyle, slender neck and long ramus Not present since birth, unlike HFM
Juvenile rheumatoid arthritis	Pain and morning stiffness in the affected joint. Multi-articular nature of disease
Parry-Romberg syndrome	Facial atrophy of subcutaneous fat, associated skin, cartilage, and bone which is often unilateral and slow progressing Multisystem involvement in some cases. Presence of coup de sabre Acquired unlike HFM
Nager acrofacial dysostosis	Disorder of facial, limb, and skeletal morphogenesis

growth and possibility of tooth bud damages. Most children presenting with HFM may require assisted feeding using nasogastric tubes or gastrotomy for a few weeks to months.

78.1.6.3 Management of Associated Orofacial Clefting

The incidence of orofacial clefting occurring with HFM is approximately 10%. The most common form of clefting apart from cleft lip is Tessier 7 facial cleft or macrostomia (Fig. 78.15a, b). The cleft is repaired at 3–6 months of age as per the standard protocol [20]. Cleft lip and palate is more severe in HFM and is associated with worse outcomes. There is tissue hypoplasia and neuromuscular deficiency of pharyngeal muscles in patients with HFM. This may be responsible for the development of palatal fistulas and exacerbation of VPI, making management of cleft palate more challenging in such cases.

78.1.6.4 Intermediate Surgical and Orthodontic Management

Management during the growth phase in HFM differs from that of an adult. Intermediate surgical management includes reconstruction of the external ear which may be planned at 6–7 years as the contralateral ear achieves its full growth during this time. Reconstruction of the cranio-orbital region is usually accomplished between 7 and 9 years as calvarial growth is almost complete during this time. A split calvarial graft to reconstruct the lateral orbital rim and zygoma is the

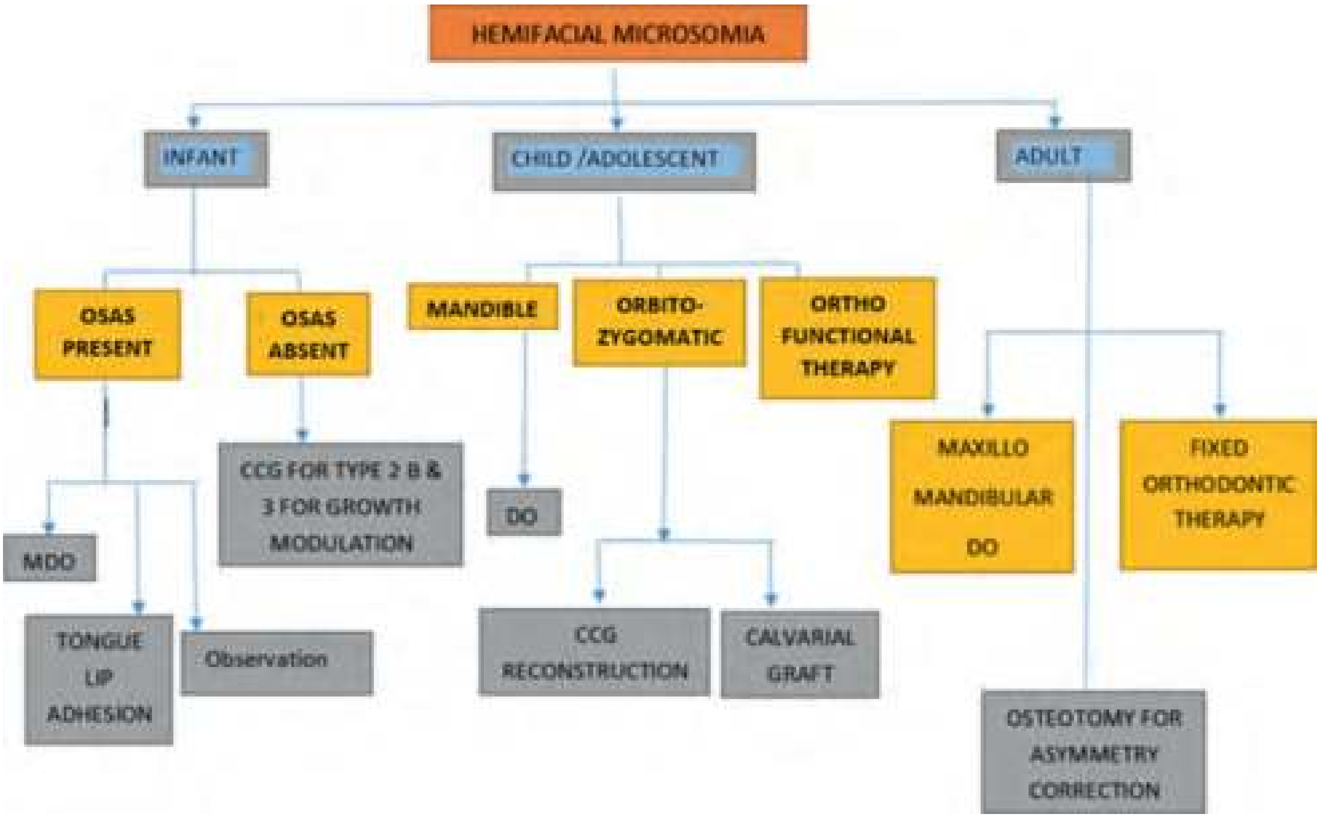

Fig. 78.14 Flowchart depicting algorithm of treatment at various levels according to growth

Table 78.5 Challenges and corrections needed necessary at different ages

Early	Intermediate (during growth)	Delayed (after completion of growth)
• Airway • Swallowing • Vision • Hearing • Cleft lip and palate	• Skeletal correction (DO) • Soft tissue correction (free fat transfer) • Nerve deficit	• Definitive skeletal correction (DO + OGS) • Soft tissue correction (fat/microvascular free flaps)

graft of choice for reconstruction of deficient zygomatico-orbital region. Surgeons have also used temporo-parietal myo-osseous flaps for better bulk, contour and retention of graft in place.

Orthopaedic growth modification can help these patients to correct occlusion in early stage [23–25]. If the patient has growth potential, with the stimulus provided by a hybrid functional appliance and stretching the soft tissue, growth can be increased on the affected side. The child must have at least 20 mm mouth opening to ensure that proper translation of condyles allows mandible growth. An asymmetric functional appliance (hybrid) that guides the mandible to a new postural position, controls the eruption of teeth and inhibits the soft tissue pressure is used [26]. It directs the developmental growth of mandible three dimensionally.

An orthodontist should constantly monitor the eruption of primary and permanent teeth to improve mandibular deficiency and maxillary canting. After the adolescent growth spurt, occlusion can be achieved by means of fixed orthodontic appliances.

78.1.6.5 Correction of Maxillomandibular Complex

Variations in the maxillomandibular complex management range from early intervention (Figs. 78.16a, b, 78.17a, b and 78.18a, b) to late reconstruction after growth completion. Wait-and-watch policy with only dental and orthodontic interventions may be adopted to reduce the impact of the deformity on the dental occlusion and masticatory function. Definitive surgical reconstruction of the maxilla, mandible and TMJ can be taken up after cessation of growth [27–31].

Functional Appliance Therapy

In cases where the ramus-condyle unit (RCU) shows reasonable function to translate into skeletal growth, growth modification with the use of functional appliances does play a role by achieving the following outcomes:

1. To facilitate eruption of the dentition in a favourable pattern.
2. To prevent dentoalveolar compensatory mechanisms from worsening the deformity.
3. To passively guide the growth of the ramus-condyle unit.

The focus of functional therapy is repositioning the affected condyle to a more inferior and anterior position to enable the mandible to grow and catch up for the intrinsic skeletal deficit [29–31].

Ear Reconstruction

Construction of the external ear is a priority in the aesthetic management of HFM patients. Two important factors that affect the ability to construct the ear are the decreased anteroposterior dimension of the upper face and the absence of an adequate platform (i.e. temporal bone cavity). The position and quality of the soft tissue remnants should also be kept in mind while planning surgery. An ear reconstructive surgeon and the maxillofacial surgeon should work collaboratively to determine the most ideal location of the ear relative to the future constructed ramus-condyle unit. Reconstruction options include (1) autogenous rib cartilage, (2) alloplastic options such as Medpore, and (3) tissue-engineered auricular framework. The technique of ear reconstruction is dealt with in detail in Chap. 35 on “Ear Reconstruction”.

Though autologous chondral cartilage for reconstruction still remains the best option, it requires a multistage approach to (1) harvest the costal cartilage grafts and create a framework by carving (time-consuming and fixation and retaining of shape challenges), (2) place the graft (positioning as per existing altered morphology), (3) transpose the lobule (soft tissue deficiency—tissue expander may have to be used) and (4) create a post-auricular sulcus (with skin graft and split temporalis graft) (Fig. 78.19a, b).

Various materials have been used for alloplastic ear reconstruction with varied results. Porous polyethylene’s inert nature and pore size provide and allow for some tissue ingrowth and are safe to use. The alloplastic materials always carry a risk of rejection and infection and may not have accurate sizes and shapes as they are stock implants with limited sizes.

Fig. 78.19 (**a**) Pre- and (**b**) post operative photograph of ear reconstruction using rib graft (Also refer Chap. 35 on Ear reconstruction)

Tissue-engineered 3D cartilage reconstruction and its use in regular clinical practice are under trial in many parts of the world though long-term clinical studies still lack regarding its application and optimal results.

Delayed Management in Adults

Management in adults includes definitive reconstruction for skeletal and residual soft tissue deficits. With the advent of 3D imaging and computer-assisted surgical planning and printing, precise spatial relationship of the cranial structures with maxillomandibular complex can be studied. This printed models give the surgeon extra weapon outside theatre to simulate surgery and make appropriate decisions before going to theatre. Appropriate treatment plan can be virtually executed, and a CAD-CAM splint can be fabricated to facilitate the accurate surgical outcome [32, 33] (Table 78.6).

Table 78.6 Principles of management of the deformed temporomandibular joint

Type of TMJ involvement	Management
Type I	Correction of vertical dimension Adjusting maxillomandibular relationship and facial asymmetry
Type IIa	Augmentation of RCU, preservation of condyle/glenoid fossa
Type IIb	Neocondyle reconstruction/preservation of glenoid fossa, augmentation of RCU + type I management
Type III	Neocondyle and glenoid reconstruction, augmentation of RCU + type I management Autogenous or alloplastic reconstruction (refer Chap. 89)

Orthodontics for Definitive Skeletal Surgery

Orthodontic preparation before definitive surgical correction of the face is similar to the conventional pre-surgical orthodontic protocols. These include arch levelling and alignments, de-crowding and transverse widening if necessary. Compromise may be necessary in many cases due to the extreme lingual tilt on the affected premolar-molar areas, leaving few options for the orthodontist due to limited bone availability for straightening the teeth [29, 30].

Conventional orthodontic treatment may take longer period and may necessitate the use of anchorage screws for aligning some teeth.

Type 1 and 2A

In types 1 and 2A, the glenoid and condylar components of TMJ are morphologically intact with minimal hypoplasia. There is no specific indication for the reconstruction of the TMJ since the joint exhibits normal movement characteristics, and the patient is able to demonstrate adequate mouth opening and masticatory function. Deviation while mouth opening can be seen towards the affected side.

Teeth eruption and angle of its placement will be hampered even in these two types of situations which will require further definitive treatment. Simultaneous maxillomandibular distraction introduced by Monasterio and Molina is an alternate method for achieving maxillary and mandibular corrections without disturbing the dental intercuspation and occlusal cant [34] (Figs. 78.20a, b and 78.21a, b).

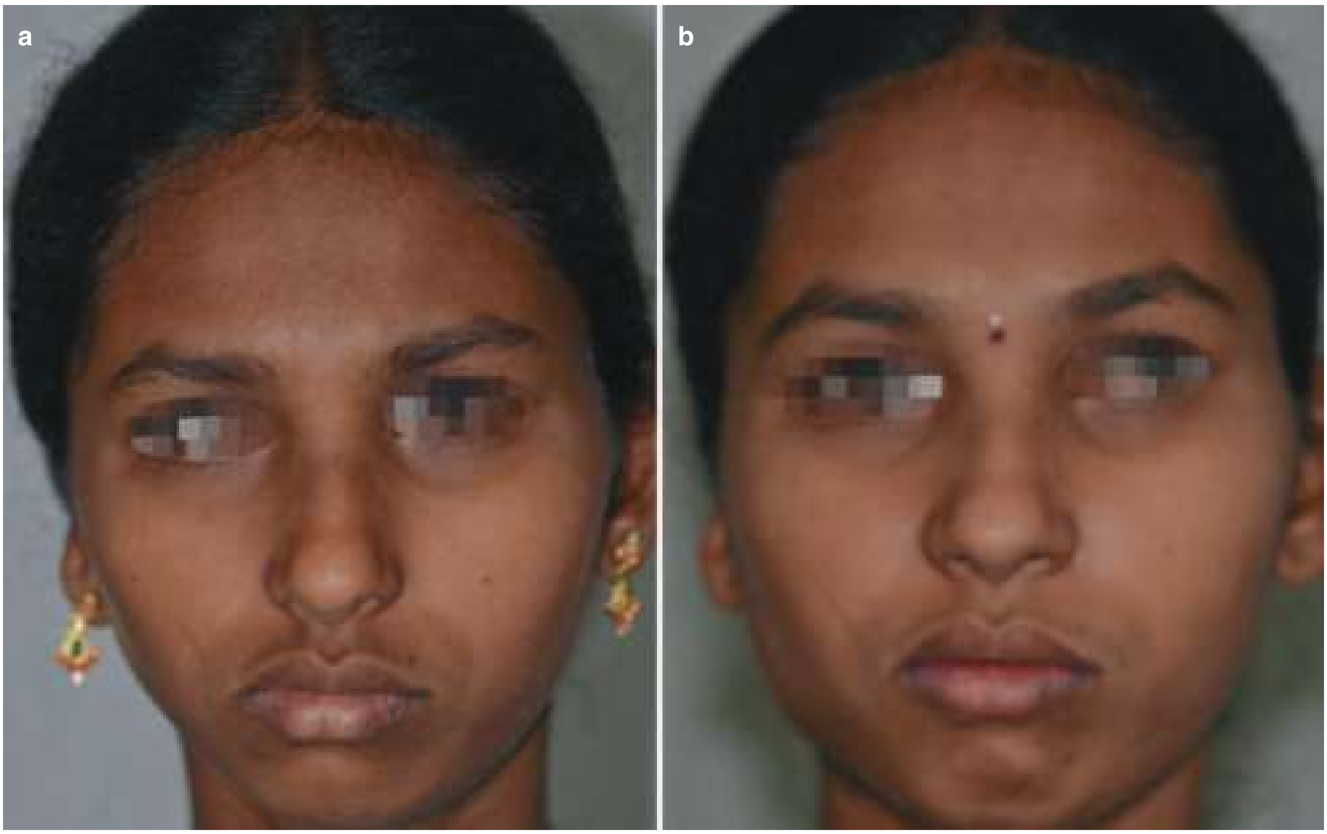

Fig. 78.20 (**a**) Preoperative view showing right-sided maxillomandibular deficiency. (**b**) Postoperative view showing correction of asymmetry following simultaneous maxillomandibular distraction

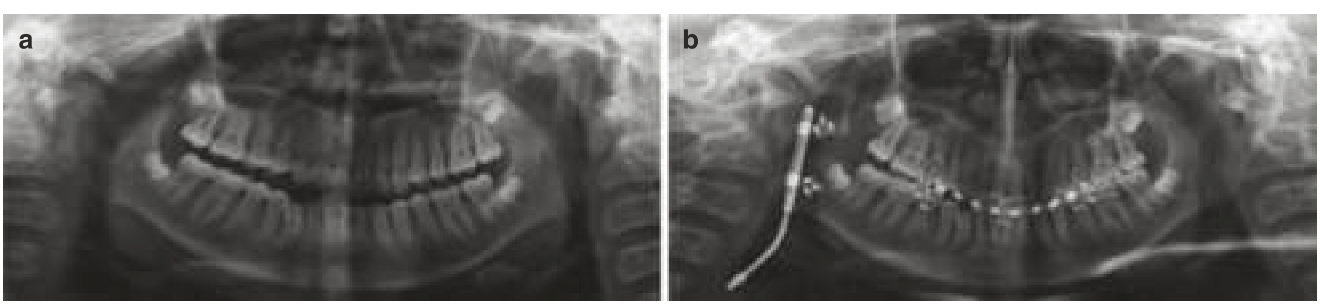

Fig. 78.21 (**a**, **b**) Radiographs of the same patient as in Fig. 78.20 treated with maxillomandibular distraction (Molina's technique). (**a**) Pre-distraction orthopantomogram demonstrating vertically deficient ramus-condyle unit on the right side. (**b**) Post-distraction xray showing lengthening of the right ramus-condyle unit with the distractor in-situ

Type 2B

Type 2B patients exhibit severe hypoplasia of both the condylar and the glenoid elements of the joint, thus causing altered functioning of the joint. This greatly reduces or there is a complete absence of the translatory movement of the joint sparing the rotatory movement. The mandible may completely deviates towards the affected side. The arc of rotation completely shifted, leading to malocclusion and scissor bites sometimes.

Distraction osteogenesis can be used to correct the deficiency of the mandibular body along with reshaping the glenoid and condylar process. The use of osteotomies to correct the dentofacial deformity is also performed either in the same setting or in a staged manner.

Options for reconstruction of the ramal-condylar unit are another concern which can be approached with costochondral grafting and alloplastic joint reconstruction [35]. The costochondral graft for stimulated growth should be used by the age of 7 years, which can be used as an onlay graft on top of the existing ramal segment in the correct position of glenoid fossa. However, large series of cases with success in this technique lacks the scientific evidence of growth similar to the unaffected joint, and reports of under- and overcorrection are plenty in literature.

Type 3

Patients with Type 3 deformities require total reconstruction of the TMJ, i.e. the glenoid-zygomatic complex region and the ramal-condylar unit. For the growing adolescent due to growth completion, glenoid reshaping and costochondral graft reconstruction of the RCU may be undertaken. Total alloplastic joint reconstruction with concomitant orthognathic surgery should be done in adults.

Posterior distraction of existing mandibular segment to create ramal-condylar unit has ended up with limited success due to lack of posterior support of distraction advancing segment and unpredicted movement in 3D dimensions. It was found in authors' experience that the correct direction control of upwardly directing condylar segment is difficult to achieve towards a missing or defective glenoid fossa, and many times the position can alter more medial and anterior than expected rather than posterior towards external auditory meatus.

Management of the Maxillomandibular Complex

Type 1

The minimal asymmetry and deformity associated with a Type 1 HFM may be amenable to minor surgical corrections such as genioplasty (Fig. 78.22a, b). Since the occlusion may

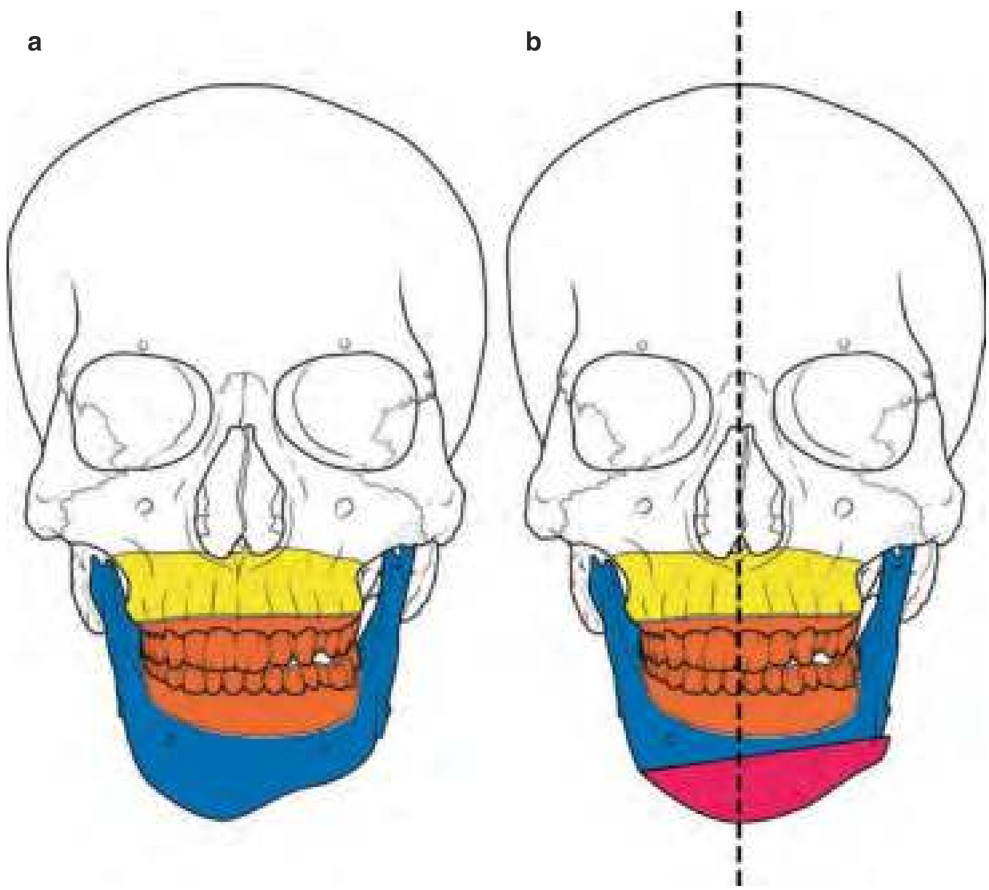

Fig. 78.22 (**a**, **b**) Diagrammatic representation of surgical management of Type 1 Kaban-Pruzansky (**a**) deformity with isolated genioplasty for asymmetry correction (**b**)

be normal or demonstrate minimal occlusal canting, orthognathic surgical correction may not be warranted.

In cases with minimal asymmetry where the patient is not willing to undergo a surgery of the entire maxilla-mandibular complex, it is possible to achieve facial midline symmetry by means of altering the midline chin and mandibular body orientation through an extended operation involving the basal bone of the chin and body of the mandible. It was published by Paul C Salins in 2008 [36]. The author of this chapter was happy to have learned this technique from Salins himself and greatly understood the concept of this 3D movement of genial bone along with body and ramus of the mandible to the unaffected side without altering the occlusal relationship of the maxilla or mandible.

But this technique had obvious disadvantage in the form of significant relapse due to large movements and requirement for multiple points of fixation.

At this juncture, the author of this chapter has designed a distractor which can be placed below the lower border of the mandible to move the genial-body-ramus unit in desired direction by incremental distraction similar to other distraction protocols. This completely eliminated the need for any plate usage, better stability without relapse and more or less excellent unlimited movement in all three directions. This is completely a basal bone distraction which can be either performed in isolation or in combination with other distractions and osteotomies of the maxilla-mandibular skeleton (Figs. 78.23a, b, 78.24a, b, and 78.25a, b).

One of the key advantages of MDO is that the bone movement produces good contour of the chin area along with flat unaffected part of the mandible, and it obviously stretches and accommodates the redundant excess submental-submandibular skin available to a more symmetrical position as shown in Fig. 78.26a, b.

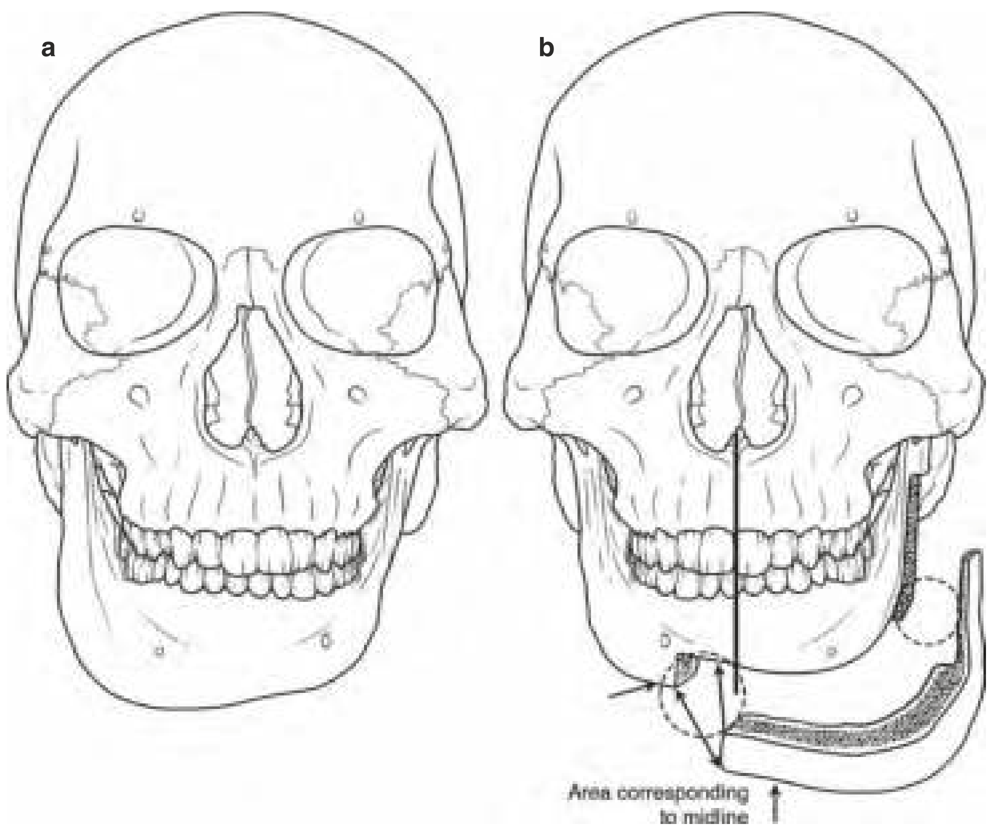

Fig. 78.23 (**a**, **b**) Orthomorphic correction of deficient mandible. (**a**) Diagrammatic representation of a left sided HFM, (**b**) osteotomy design for correction of the left sided deficiency

Type 2A
Patients with Type 2A deformities require planned pre-surgical orthodontic interventions for definitive orthognathic correction (Fig. 78.27a–d).

Bimaxillary surgery is planned to achieve the following goals:

Maxilla and midface

1. Segmental maxillary procedures for correction of cross-bites.
2. Derotation of the maxilla to achieve midline corrections.
3. Augmentation of the zygomatic complex where necessary.
4. Cant correction.

Mandible

1. Bilateral sagittal split osteotomy procedure to correct the occlusal canting and yaw correction.
2. An inverted "L" or a subsigmoid osteotomy is indicated to achieve elongation of the RCU.

Types 2B and 3
As explained earlier, types 2B and 3 patients require reconstruction of the TMJ as the primary goal. This may be executed either as a Stage 1 correction with only maxillomandibular correction or as Stage 2 with joint reconstruction (Fig. 78.27).

Thus, although skeletal correction improves the dental occlusion and skeletal symmetry, it may accentuate the existing soft tissue discrepancy. Soft tissue augmentation should be taken up after hard tissue correction. Various methods are available such as fat transfer, microvascular free flap for adipose tissue transfer and alloplasts such as Medpore and nanogels to give shape to deficient soft tissue (Fig. 78.28a, b).

78.1.7 Controversies in Surgical Management of HFM

Growth Considerations and Role of Early Mandibular Reconstruction in HFM.

HFM has been reported as a nonprogressive disorder, i.e. proportional deficiency of the face is maintained throughout the growth of the child. Indications for early reconstruction of the RCU during early childhood, especially in types 2B and 3

classes, has mixed reports of success. Longitudinal studies provide evidence for stable results with early osteodistraction in mild-to-moderate skeletal deformities [20, 33, 34] (Type 1 and Type 2A). However, the role of mandibular distraction may be more relevant in severe deformities. It is also suggested that early intervention makes definitive final correction easier to achieve, since the extent of deformity is reduced.

78.1.8 Long-Term Results

Long-term evaluation of growing HFM patients treated by surgical correction and distraction osteogenesis depends on two main factors: the time of intervention and the severity of the skeletal deformity. According to Hollier et al., by achieving normal mandibular dimensions at a young age, it is

Fig. 78.28 (**a**, **b**) Soft tissue augmentation using abdominal autologous fat transplant. (**a**) pre-surgical frontal view demonstrating severe right sided deficiency in a patient with HFM, (**b**) frontal view showing soft tissue augmentation

hypothesized that the maxilla, overlying muscle and soft tissue envelope may develop along with a balanced functional matrix [19]. Proponents of mandibular distraction believe that an early intervention would prevent the secondary compensations from taking place or would unravel the compensations at the onset. This means the contralateral and ipsilateral distortions can be reduced in comparison with patients not undergoing distraction in the younger age (Figs. 78.29a, b and 78.30). Clinicians have found that early distraction can also prevent the long orthodontic decompensation phase followed by orthognathic surgery. Considering severity of deformity, the more severe deformities demonstrate less stable and favourable results when attempted early.

The indications for early skeletal correction maybe (1) compromise of airway necessitating immediate mandibular lengthening irrespective of age and (2) negative psychological impact on the child in school-going age.

In authors' experience irrespective of area and direction of distraction in the mandible or in maxilla in younger age, the following findings were concluded in 20 years of clinical follow-up:

1. It is difficult to predict the future growth of already distracted area of bone though claims of growth potential on distracted bone have been debated by many.
2. In majority of the cases, the intensity of the severity of the disease has reduced due to distraction than simply curing the disease as the age advances.
3. The 3D volume achievement in the ipsilateral side is difficult to achieve irrespective of technique of distraction and conventional osteotomies in later ages.
4. Orthodontic compensations, alignment and other associated corrections of teeth on a weak hypoplastic bone are difficult at least in some cases.
5. Many cases after pubertal age needed conventional orthognathic surgeries to achieve symmetry.
6. Soft tissue augmentation was necessary in many patients to balance the soft tissue profile equal on both sides.
7. Compromised occlusions and dental rehabilitation were necessary in some cases especially Type 2B and Type 3 cases and accepted as standard norms to finish orthodontic alignments.
8. The airway disease is not cured to 100% in all cases due to extreme variability treatment outcomes and procedures followed by different surgeons.
9. Expectations of the patient may not be achieved completely, so caution should be given to patient the compromised results outcomes in extreme cases of asymmetry.

Fig. 78.29 (**a**, **b**) Long-term results of patient treated with mandibular distraction in childhood. (**a**) frontal photo of patient with right sided HFM at, (**b**) frontal photo of patient after 8 years follow up

10. Alloplastic prosthetic condyles should be reserved as a last resort if all other techniques fail to achieve a functionally stable total agenesis of condyles [21].

78.1.9 Recent Advances

The assessment of facial topography using non-invasive methods, such as laser surface scanners, stereophotogrammetry or ultrasonographic measurements, has been recently reported in several studies. Particularly, 3D stereophotogrammetry for the evaluation of soft tissue surface facial asymmetry has been extensively studied [36]. In distraction osteogenesis, recent advancements like automated distraction using battery-operated and hydraulic distractors have been tried. Since hemifacial microsomia involves bone augmentation in a multiplanar fashion, the advent of curvilinear and multiplanar distractors has greatly helped overcome this challenge [37, 38].

Tissue-engineered osteogenic material comprising of culture-expanded mesenchymal stem cells (MSCs) and platelet-rich plasma (PRP) can now be injected at the distraction site to ensure more predictable bone formation. Not only animal studies but also clinical trials have demonstrated that this material can effectively regenerate osseous tissue [39, 40].

78.2 Treacher Collins Syndrome

78.2.1 Introduction

Treacher Collins syndrome (TCS), also called mandibulofacial dysostosis (MFD), is an autosomal dominant disorder of craniofacial development with variable penetrance. It has a worldwide incidence of 1 in 50,000 live births (Gorlin et al. 1990) [41]. Early descriptions were given by Berry (1889), Treacher Collins (1900) and Franceschetti and Klein in 1949. Therefore, this entity is also named as Berry's syndrome and Franceschetti-Zwahlen-Klein syndrome [42, 43]. While 40% of TCS cases have a previous family history, 60% of cases could possibly arise as a result of de novo mutations (Jones et al. 1975) [44].

The TCOF1 gene plays an important role during early embryonic development for tissues derived from the first and second branchial arches, ectodermal clefts and endodermal pouches. TCOF1 gene encodes a nuclear phosphoprotein "Treacle" that may serve as a link between rRNA gene transcription and pre-rRNA processing. TCOF1 mutation leads to abnormal neural crest cell migration or anomalies in the extracellular matrix [45]. Sulik et al. also documented excessive cell death in the maxillary and mandibular processes of the first branchial arch and the apical ectodermal ridge of the limb bud [46]. These deductions have been made on the basis of experimental studies wherein animals were exposed to

Fig. 78.30 (**a, b**) Definitive skeletal management of patient with HFM. (**a**) Preoperative Frontal photo of patient with right sided HFM at 15 years of age. He underwent mandibular distraction for correction of asymmetry followed by second stage Bi maxillary orthognathic surgery at 18 years of age (Fig. 78.7a). (**b**) Stable skeletal results after a 7 year followup when patient is 25 years of age

teratogenic cis- or trans-retinoic acid during embryonic development. Recently, Dauwerse et al. [47] detected mutations in genes encoding subunits of RNA polymerases I and III in Treacher Collins patients.

Normally, prenatal diagnosis is recommended for families with a history of TCS using fetoscopy or ultrasound imaging [USG]. Prenatal diagnosis using either of these methods can only be performed in the second trimester of pregnancy (approximately 18 weeks). Due to the late nature of the diagnosis, termination of pregnancy can be a particularly traumatic procedure. Imaging with USG has improved immensely in recent years [e.g. 3D sonography], allowing non-invasive prenatal diagnosis to be made. However, mild cases of TCS are still difficult to diagnose. Genetic counselling is highly recommended for affected individuals and their families for prevention of further affected child birth.

78.2.2 Clinical Features and Presentation

The complete spectrum of features which can be present are explained in the table below [48] (Table 78.7).

A case of Treacher Collins syndrome in a 13-year-old female with the following features (Fig. 78.31a, b):

- Eyes: Antimongoloid palpebral fissures are short and slope laterally downwards with either a notch or coloboma of the outer third of the lower eyelid. Lashes are absent medial to coloboma.
- Face: Bilateral and usually symmetric hypoplasia of facial bones is present, e.g. malar and mandibular bones. Depressed cheekbones, receding chin, tongue-shaped process of the hair that extends towards the cheek and large down-turned mouth can be identified.

- Ears: Malformation of the external, middle and inner ear, with low implantation of the auricle which is common. The pinnae are often crumpled and misplaced towards the angle of the mandible. Bat-fan ears, deafness, microtia, extra ear tags and blind fistulas [which may occur anywhere between the tragus and the angle of the mouth] are the other common findings.
- Oral findings: Cleft palate, congenital palatopharyngeal incompetence, high-arched palate and a narrow maxillary and mandibular arch with dental crowding are common (Fig. 78.32a–e).
- Nose: The nose appears larger due to the hypoplastic midface skeletal structures. Hypoplastic alar cartilages, narrow nares and obliteration of the nasofrontal angle are also common.

Table 78.7 Clinical features of TCS

Region	Characteristic feature
Eyes	Antimongoloid slant of palpebral fissures
	Colobomata and hypoplasia of the lower lids and lateral canthi
	Hypertelorism
	Partial absence of eyelid cilia
Ears	Microtia
	Conductive hearing loss
	Hypoplasia of middle ear ossicles
Nose/mouth	Nasal deformity
	Cleft palate with or without cleft lip
	High-arched palate
	Class II or III malocclusion open bite
Facial bone formation	Hypoplasia of the malar bones
	Hypoplastic lateral aspects of orbits
	Hypoplastic maxilla and mandible
	Variable effects on the temporomandibular joints
	Anterior open bite
	A steep occlusal plane

78.2.3 Imaging for TCS

The conventional OPG and the lateral and frontal cephalometric image are pivotal in diagnosing TCS along with clinical correlation. The OPG helps identify the following: hypoplastic condyle with a short condylar neck, absent articular eminence, shortened ramus-condyle unit and severely hypoplastic coronoid process (Figs. 78.33 and 78.34). The lateral cephalogram shows a severely retrognathic mandible with microgenia, clockwise-rotated maxillomandibular complex and a reduced posterior airway space. However, three-dimensional computed tomography [3DCT] is the gold standard in diagnosis as well as treatment planning (Fig. 78.35a–c). The features that are remarkably seen on the 3DCT are hypoplasia of the orbito-zygomatic complex, poorly developed lateral orbital and supraorbital ridges, mandibular hypoplasia and reduced overall facial width. The orbits are hyper-teloric and the infraorbital foramen is usu-

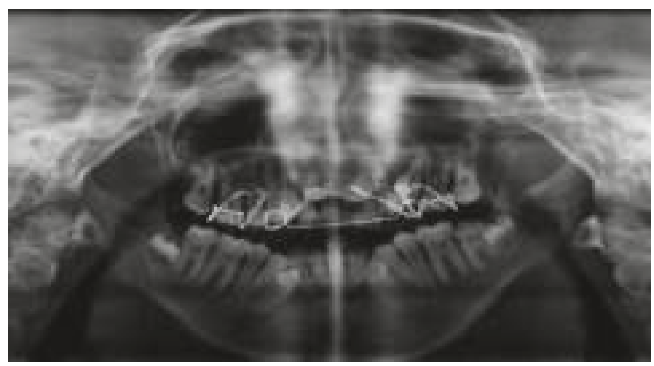

Fig. 78.34 Orthopantomogram of the same patient in Fig. 78.31 showing hypoplastic ramus-condyle unit

ally absent. The paranasal sinuses are often small and may be completely absent. Furthermore, the mastoids are not pneumatized and are frequently sclerotic. The cranial base is also progressively kyphotic [48]. Lastly, these patients require long-term follow-up in order to evaluate the effects of mandibular growth, airway dimensions, degree of surgical relapse and the need for additional surgical intervention.

78.2.4 Proposed Classification

A classification system of the orbito-zygomatic skeletal deformities seen in TCS has been proposed by Nikkah D et al. The classification is designed to characterize the degree of deformity and as a guide to the reconstructive planning [49]. Treatment planning becomes complex as TCS can have a variable presentation with respect to the severity of the hypoplasia/dysplasia of the skeletal and soft

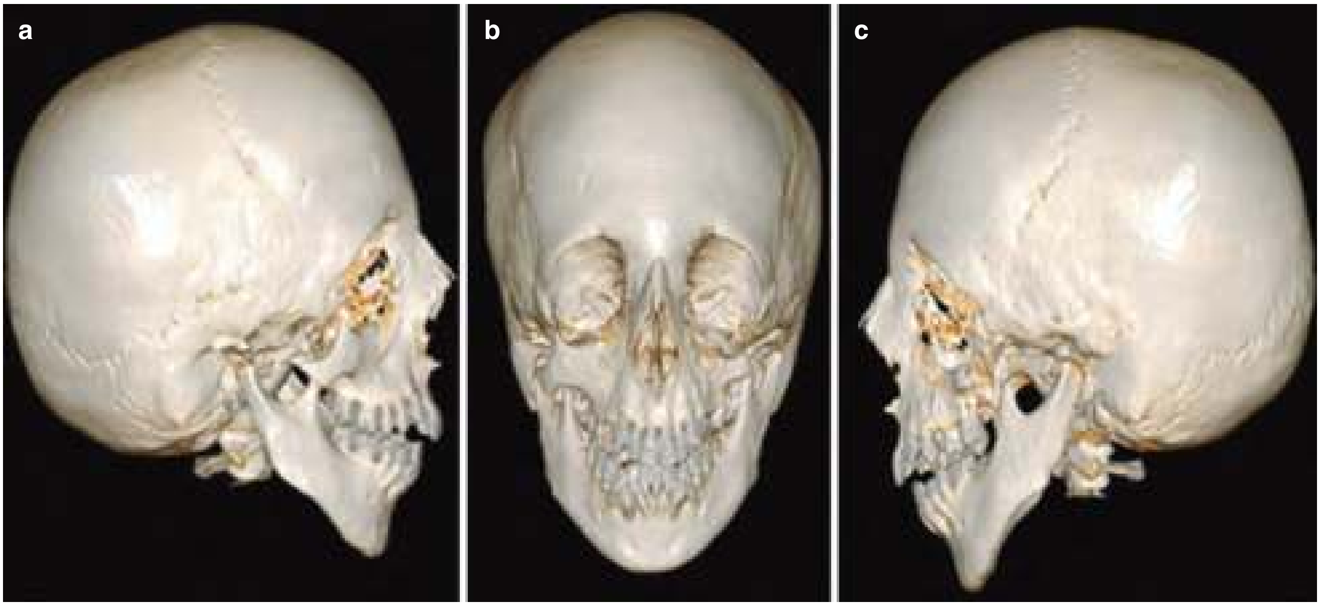

Fig. 78.35 (**a**–**c**) 3DCT view of TCS patient showing hypoplasia of orbito-zygomatic complex. (**a**) Right lateral view demosntrating type 2b deformity, (**b**) frontal view showing type 2b deformity on the right and type 3 deformity on the left, (**c**) left lateral view showing type 3 deformity

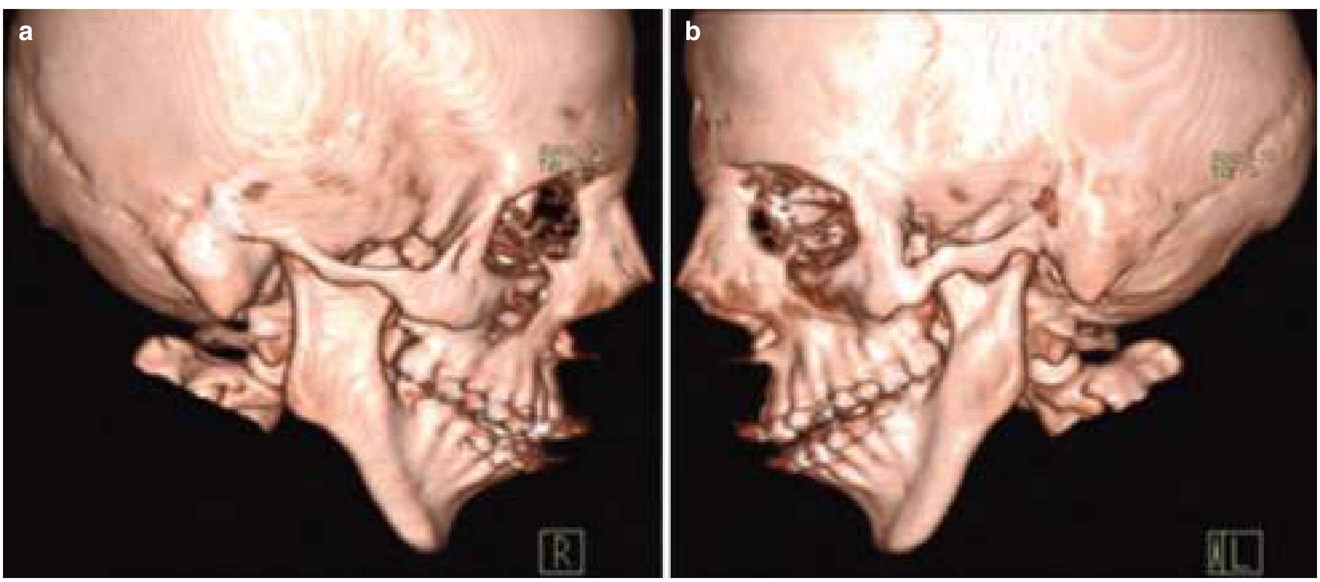

Fig. 78.36 (**a**, **b**) Type 1: Patients have the entire orbito-zygomatic complex present but the region is dysplastic and hypoplastic

tissue elements, shape and position of the affected structures and resulting functional deformity. Thus, the challenges faced in treating TCS are similar to those faced in treating HFM.

78.2.4.1 Methods

- *Type 1*: orbito-zygomatic complex present but, dysplastic and hypoplastic (Fig. 78.36a, b).
- *Type 2*: a hypoplastic zygomatic body with a vestigial zygomatic temporal process and a lateral orbital wall that is either dysplastic (2a) or absent (2b) (Fig. 78.35a, b).
- *Type 3:* a hypoplastic zygomatic body and dysplastic orbital wall but with complete absence of the zygomatic temporal process (Fig. 78.35b, c).
- *Type 4*: complete absence of the entire orbito-zygomatic complex (Fig. 78.37a, b).

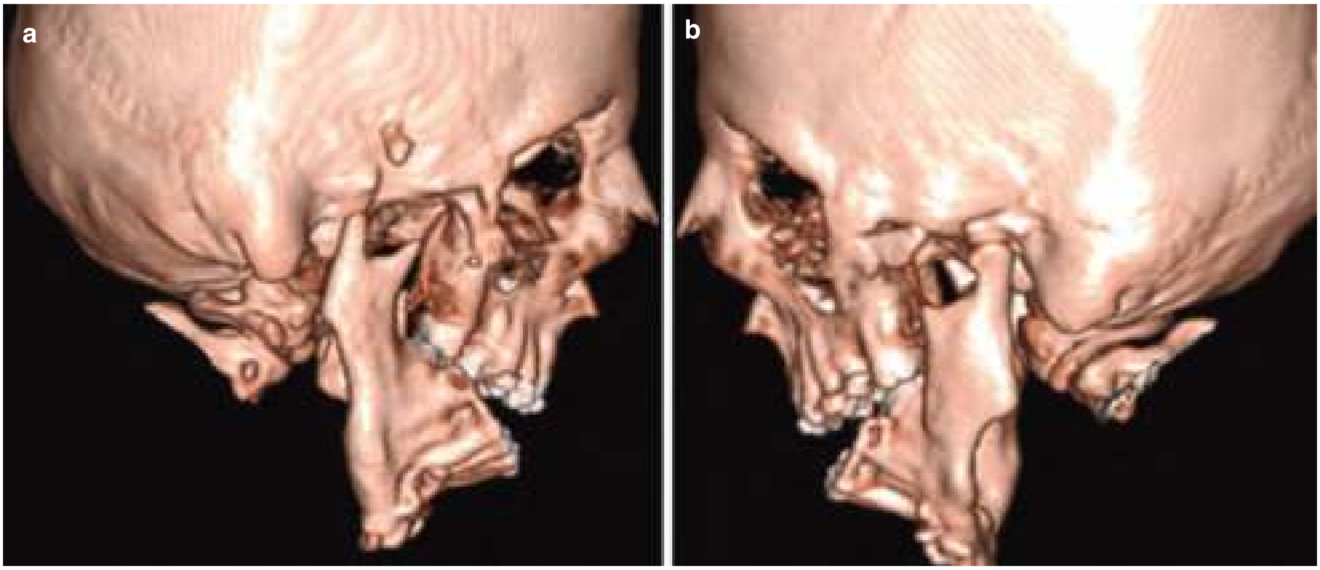

Fig. 78.37 (**a**, **b**) Type 4: Is the most severe with complete absence of the entire orbito-zygomatic complex

There is not always a symmetrical classification as 25% of the TCS demonstrated asymmetry.

78.2.4.2 Classification of Temporomandibular Joint and Mandibular Malformation

The Kaban and Pruzansky classification system for the degree of TMJ-mandibular malformation in HFM is applicable to TCS patients as well [13, 26]. This classification is useful in defining the anomalies and directing reconstruction similar to HFM patients.

78.2.5 Differential Diagnosis

Differential diagnosis of TCS includes acrofacial dysostosis (Nager and Miller syndromes) and oculo-auriculo-vertebral spectrum (hemifacial microsomia and Goldenhar syndrome).

Nager syndrome has facial features similar to that of TCS. In addition, the thumb[s] may be hypoplastic, aplastic or duplicated, and there may be fusion of the radius and ulna. Miller syndrome also has features similar to TCS. Ectropion or out-turning of the lower lids is an additional diagnostic feature. Clefting of the lip and palate is more common in this syndrome than in TCS [50]. HFM primarily affects development of the ear, mouth and mandible. Goldenhar syndrome has a spectrum of deformities that include those of HFM in addition to vertebral abnormalities and epibulbar dermoids [51].

78.2.6 Treatment

Though there have been immense medical advances in terms of in utero surgery, stem cell therapy and genetic manipulation, there is currently no treatment for TCS in utero. Treatment is performed postnatally according to the nature of the deformity and severity of functional disturbance [52].

The following issues are present in case of TCS:

1. Airway, i.e. obstructive sleep apnoea.
2. Feeding problems.
3. Brain development.
4. Orbito-zygomatic growth.
5. Mandibular retrognathism with open bite.
6. Dentoalveolar issues including orthodontic alignment.
7. Cleft palate.
8. Hearing issues.
9. Psychosocial development.
10. Deficient soft tissue.

These issues can challenge clinicians from birth to adulthood as concerns vary from aesthetic to functional in nature. Thus, a multidisciplinary approach is indispensable for achieving optimal outcomes.

78.2.6.1 Multidisciplinary Management: Team Members Necessary from Birth to Adult Stage

1. Geneticist.
2. Paediatrician.
3. Anaesthetists.
4. Oral and maxillofacial surgeon.
5. Orthodontist.
6. Paedodontist.
7. General dentist.
8. Paediatric neurosurgeon.
9. Psychiatrist.
10. ENT surgeon.
11. Audiologist.
12. Pulmonologist.
13. Paediatric neuro-physician.
14. Speech therapist.
15. Oculoplastic surgeon.

78.2.6.2 Airway Management

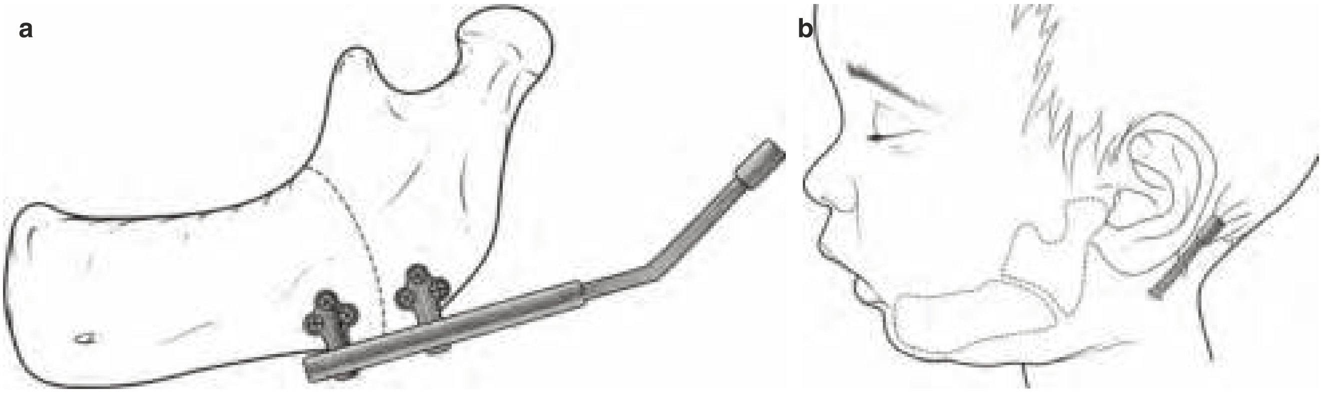
Syndromic patients [e.g. TCS] with micrognathia suffer from OSA frequently due to narrowing of the upper airway [53]. Despite respiratory effort, partial or complete obstruction of the upper takes place, leading to frequent episodes of oxygen desaturation and sleep disruption. In the long term, OSA can harm an individual's physical and mental health, as has been documented recently in the literature [54].

Respiratory compromise is due to two reasons:

(i) Maxillary hypoplasia, constricting the nasal passages and resulting in a degree of choanal stenosis or atresia.
(ii) Mandibular micrognathia and a retro-positioned tongue obstructing the oropharyngeal and hypopharyngeal airway.

Earlier, long-term tracheostomy was the only solution available for severe cases of infantile OSA. However, long-term tracheostomies are commonly associated with morbidities like tracheomalacia, chronic bronchitis, throat tightness and dislocation of the tracheostomy tube [55] (Fig. 78.38a, b). Today, distraction osteogenesis [DO] has become the favoured treatment method for TCS patients with OSA. Mandibular advancement by means of DO helps in increasing the posterior airway space, thus relieving the symptoms of OSA and preventing severe respiratory distress [56]. Due to the unique mandibular and oropharyngeal anat-

Fig. 78.38 (**a**, **b**) Photograph of a 4-year-old male with TCS. Patient had history of hospitalization due to respiratory distress. Tracheostomy tube in situ since 7 months of age



©Association of Oral and Maxillofacial Surgeons of India

Fig. 78.39 (**a**, **b**) Mandibular advancement using distraction in neonates to increase posterior airway space as a treatment of obstructive sleep apnoea. (**a**) Position of the distractor on the mandible, (**b**) Emergence of activation port in the retromandibular region

omy of TCS patients, a fibre-optic-assisted intubation method similar to that described by Ellis et al. can be successfully used [57].

Paediatric mandibular advancement was initially performed using bilateral external distractors which are advantageous because of their ease of use, manipulation and versatility [58]. However, external devices also create aesthetic [e.g. scarring] and social problems. Another important point to be noted is that retention period of such devices is reduced and an increased relapse rate is seen compared to internal distractor devices [59]. If the child is extremely uncooperative and parents are unable to maintain and monitor the external distractors, an internal distractor should be used (Fig. 78.39a, b).

Recently, paediatric mandibular distraction for OSA has been discouraged in many centres around the world due to concern of permanently damaging the teeth buds. Instead, tongue lip adhesion (TLA) has been popularized by many centres instead of DO as it has significantly lower morbidity. After the airway improves, better feeding and weight gain are expected and cleft palate closure is done. Subsequently, TLA release can be attempted [60]. In comparison to DO, the TLA needs stricter postoperative care in intensive setup as feeding and breathing need to be assessed regularly for a week at the minimum.

78.2.6.3 Feeding Problem

The abnormal or hypoplastic craniofacial issues in TCS can sometimes produce severe feeding problem for infants, leading to weight loss and failure to thrive. Most feeding problems relate to cleft lip and palate, retrognathic jaws and airway problems. Ideally, a craniofacial feeding management team should guide the parents regarding position of feeding, type of nutrition and dietary plan for such children.

Position (holding the baby upright or supporting the cheek and jaw while feeding) is important to avoid aspiration. It is also preferable to do a video-fluoroscopic swallow study (VFSS) to understand the swallowing pattern of the patient and its coordination with breathing [61].

Primary palatoplasty for closure of the cleft palate should be done once the patient gains weight, to assist in normalizing the swallowing pattern without nasal regurgitation.

78.2.6.4 Brain and Psychological Development in TCS

Individuals with TCS have a tendency towards a shorter stature, at least early in life. Intelligence is usually unaffected, but brain and behavioural anomalies such as microcephaly and psychomotor delay have been occasionally reported as part of the condition. Additionally, the facial deformity of this syndrome may affect psychosocial development, school adjustment and other milestones. A psychologist or social worker should be made available for evaluation and counselling if needed.

In the Indian scenario, poor parental awareness, lack of medical advice, social taboos and feeding difficulties lead to failure to thrive among TCS infants and children belonging to lower socio-economic classes. Psychological stress during schooling [e.g. marked out as different by peers] is one of the more challenging issues to be addressed throughout the life of the patient.

78.2.6.5 Management of Cleft Palate

Isolated cleft of the soft palate is the most common form of cleft in TCS. Complete cleft palate up to the alveolus may also be seen. Closure of the soft palate is routinely done at the end of 1 year. Meticulous dissection and suturing of soft palate muscles can produce excellent results, nearing to that of a normal palate. Postoperative maintenance of oral hygiene is necessary and can become challenging in these children for fear of aspiration. Velopharyngeal insufficiency [VPI] is a common issue in these children. VPI can be corrected secondarily with intra-velar palatoplasties or buccal advancement flaps for velar lengthening.

78.2.6.6 Ophthalmological, Auricular and Hearing Issues

Ophthalmological Issues

Eye anomalies include aberrations in the extraocular muscle function, corneal exposure difficulties and visual acuity. Ophthalmologic issues may include vision loss (37%), amblyopia (33%), refractive errors (58%), anisometropia (17%) and strabismus (37%). A thorough paediatric ophthalmological assessment should be done to establish proper management.

Hearing Issues

A 3D CT of the petrous temporal bones should be done to accurately assess the external auditory canal and middle and inner ear anatomy. TCS patients with microtia can have congenital aural atresia and extremely narrow canals, leading to significant conductive hearing loss as the bone blocks passage of sounds to tympanic area and middle ear. Furthermore, exfoliated skin cells and ear wax cannot drain out, leading to otitis media and occasionally form cholesteatoma. Despite hearing loss, these children tend to grow normally. However, the chances of developmental cognitive deficits are not uncommon.

Microtia Correction

Microtia ear correction can be done when the patient is around 6 to 7 years old, an age at which external ear development is complete. The most preferred way of auricle reconstruction is the use of autogenous rib cartilage, in a staged manner. The rib cartilage is harvested from the sixth to the ninth rib. The sixth and seventh rib cartilage are utilized to form the base of the framework. The triangular fossa and scapha are carved in the superior portion of the previously created cartilaginous base. The eighth rib cartilage is then carved to replicate the helical rim. The carved cartilage is then inserted under the skin in the region of the missing ear, with or without skin expansion (Fig. 78.19).

Bone-conduction hearing aids such as the bone-anchored hearing appliance (BAHA) or a middle ear implantable prosthetic device can significantly improve hearing in these patients.

78.2.6.7 Nasal Issues

Nasal deformities can be classified as external or internal in nature. Commonly seen external nasal deformities are the dorsal hump (73%), external deviation (≤55%), bifid or bulbous nasal tip (55%) and columellar septal luxation (55%). Commonly seen internal nasal deformities are nasal obstructions due to septal deviation and presence of spurs. Due to presence of the above structural deformities, functional problems, e.g. snoring and impaired phonation, are commonly present in these patients.

A detailed physical examination along with nasal endoscopy and 3D CT of the nasal and paranasal regions can help identify all the deformities present. The commonly performed procedures that should be paid attention to are dorsal hump reduction, correction of the deviated external osseous deformity, septoplasty and tip plasty.

78.2.6.8 Dentoalveolar Issues and Orthodontic Alignment

- Due to the presence of an anterior open bite and compulsive mouth breathing, there is an increased risk for poor oral hygiene. This is evidenced by the face that up to 60% of TCS patients need dental care [e.g. restorative treatment]. However, the difficulty of performing even simple dental procedures is far higher due to reduced mouth opening, presence of concurrent medical co-morbidities [e.g. congenital heart defects], decreased posterior airway space and hearing loss [61, 62].
- During the late mixed dentition phase, orthodontic treatment aims to increase the transverse dimensions of the constricted maxilla [e.g. quad helix]. In the permanent dentition phase, the fixed therapy is used in order to achieve intercuspation and arch levelling.
- For moderately severe cases, the final goal is to prepare the patient for orthognathic surgical correction of the anterior open bite and skeletal class 2 relationship [63]. Studies have established that bimaxillary orthognathic surgery gives stable long-term results in TCS patients [64]. Sometimes, additional procedures to improve the shape of the chin are required. Figures 78.40a, b, 78.41 and 78.42a, b show double sliding genioplasty done in a patient in early age due to psychological impact owing to the facial appearance.
- For severe cases, DO with external distractors is the ideal surgical intervention wherein gonial angle control is necessary for increase in height of the ramus and lengthening the body of the mandible. In this aspect, multi-vector devices have an advantage with respect to the ability to control the transverse width during distraction (Fig. 78.43a–f).

78.2.6.9 Management of the Adult TCS Patient

Clinical and Cephalometric Features

The adult patient with TCS has a convex facial profile due to severe mandibular retrognathia. However, the horizontal projection of the maxilla to the cranial base remains normal. Over the growth period, the facial convexity angle remains relatively constant, thus confirming that the facial profile morphology of the infant with TCS remains similar to that of the adult.

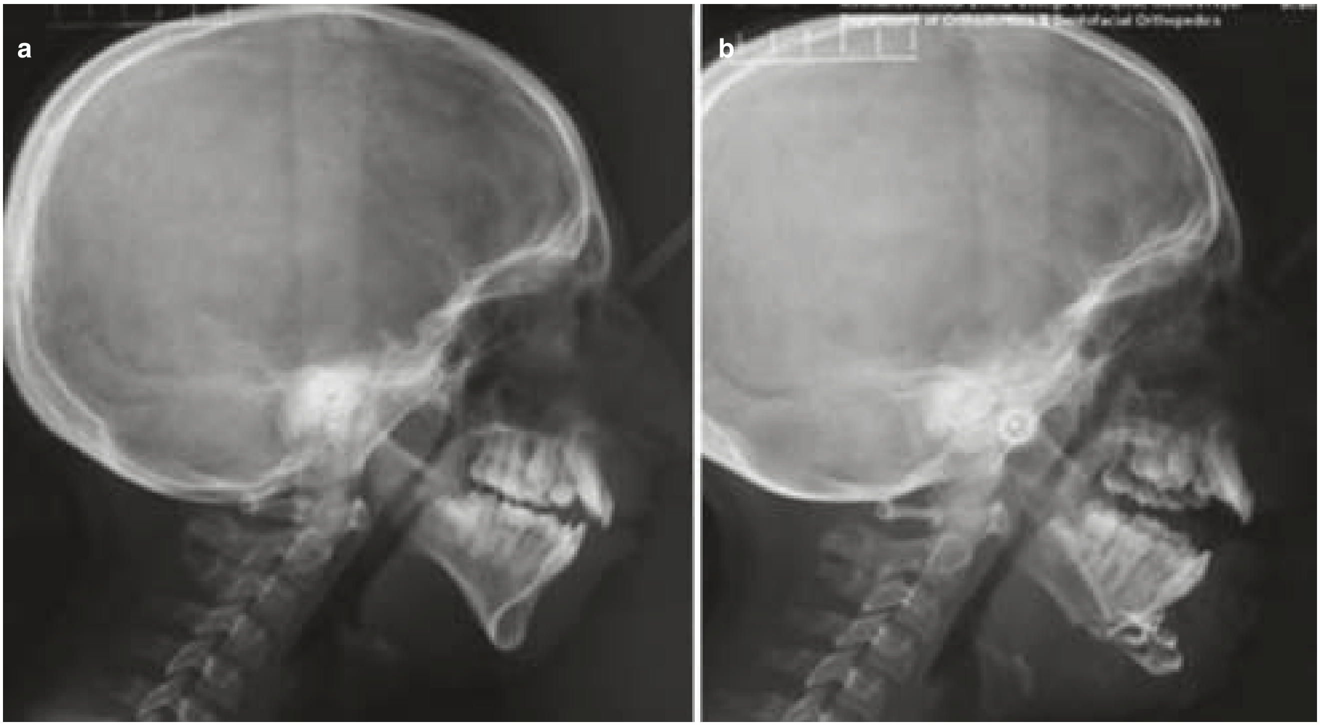


Fig. 78.40 (**a**) Preoperative and (**b**) postoperative lateral cephalogram radiographic view of a patient with Treacher Collins syndrome who underwent double sliding genioplasty

The total facial height is often excessive, with a normal upper facial height. This is due to combination of anterior open-bite malocclusion, mandibular retrognathism and chin dysplasia. Hypoplasia of the orbito-zygomatic complex is a characteristic feature. These hypoplastic facial skeletal features have variable effects on the TMJ, masticatory function and facial soft tissues and expressions.

Both the maxilla and mandible are rotated in a counterclockwise rotation. Thus, the maxillary and mandibular plane angles are excessively steep. Clinically, this translates to a shorter posterior facial height in TCS patients.

The mandible size is evidently decreased in both the ramus height and the body length. The gonial angle is obtuse with anti-gonial notching. The steepness due to clockwise rotation of the maxillomandibular complex along with the anterior and posterior vertical height disproportions and severe horizontal deficiency is reflected in the A-point-to-B-point discrepancy. All of these cephalometric findings explain the clinical facial dysmorphology.

Incidence of cleft palate with or without cleft lip (and choanal atresia of the nasal cavity) is variable. Dental anomalies are present in 60% of individuals such as tooth agenesis enamel, opacities and ectopic eruption of the maxillary first molars.

78.2.6.10 Surgical Management of the Orbito-zygomatic Region

Treatment of the skeletal defect in the orbito-zygomatic region varies according to the severity of the defect. The following classification categorizes the deformities according to severity and their treatment. Since this region attains growth by age of 9, most surgeons postpone definitive reconstruction up to this age.

Type 1 defects: The orbito-zygomatic complex is dysplastic and hypoplastic. Type 1 represents the mildest form of the defect and can be easily treated by autologous fat, either by liposuction and injection or dermis fat graft [65]. The merit of autologous fat grafting is that it is repeatable with minimal donor site morbidity and can be done before growth completion. It is ideal for growing children who are psychologically affected due to a poor facial appearance. The disadvantage of this technique is that it may have to be performed repeatedly to maintain the volume of correction.

Fat transfer can be used alone for correction of minor defects. It has more of an adjunctive role in severe defects after wherein hard tissue augmentation is the preferred intervention.

Fig. 78.41 (**a**, **b**) Extraoral profile view showing marked improvement in the lower third of the face. (**a**) Pre-surgical profile photo showing retrogenia (Fig. 78.31a1), (**b**) post-surgical profile photo after a double sliding genioplasty, showing good chin prominence

(**a**) Surgical exposure of the genium, (**b**) osteotomy design marked on the chin and (**c**) completion of genioplasty with fixation (also see Figs. 68.32 and 68.33 for use of double sliding genioplasty in other clinical situations)

Fig. 78.43 (**a**–**f**) Case of TCS who underwent early osteodistraction. (**a**, **b**) Pre-operative frontal and profile photos, (**c**, **d**) Frontal and profile photos post distraction with bilateral uni-directional distractors, (**e**, **f**) Frontal and profile views after five years follow-up

Type 2 defects: Defect consists of hypoplastic zygomatic body with a reduced zygomatic temporal process and a dysplastic or absent lateral orbital wall. This class of defect usually requires surgery to address the bony deficiency. Studies have established that a malar osteotomy offers better contour as compared to onlay bone autografting [66]. Though the malar osteotomy is aimed at correcting the width of the midface, it is difficult to augment anteroposterior projection by osteotomy only. It should be noted that this defect is characterized by a deficient vertical dimension as well. Thus, a zygomatic osteotomy is preferably combined with an onlay graft. The Mommaerts zygomatic osteotomy is favoured in some units because it does not alter orbital dimensions. Alloplastic materials [e.g. Medpore] can be very effective alternatives to the traditional onlays [67].

Types 3 and 4

The defects range from severe hypoplasia/dysplasia to complete absence of orbito-zygomatic bony complex. Patients belonging to these groups require bony augmentation. In adults, alloplastic augmentation with patient-specific implants can be considered as they provide optimal results.

In general, the zygomatico-maxillary-orbital bone complex can be reconstructed using an autologous free bone or regional pedicle graft. Non-vascularized autologous bone grafting for larger defects is increasingly prone to loss of graft due to infection and resorption if not fully covered by surrounding soft tissue. Studies have established that resorption occurs due to reduced vascularity and increased functional loads on the graft. Therefore, it is prudent to line the bone grafts by soft tissue on its inner side in the proximity of maxillary sinus and nasal cavity [68].

Calvarial bone grafts have been used for reconstruction of midface in various craniofacial deformities. Full-thickness calvarial grafting outcomes are more stable in the long term due to the dense cortical nature of the graft (Fig. 78.44a, b). Studies [69] have also established that dense membranous bone grafts [e.g. calvarial] are more effective than endochondral grafts [e.g. iliac crest] in the craniofacial skeleton. Calvarial bone grafts have become popular because of their low resorption rates and minimal donor site morbidity for orbito-zygomatic complex reconstruction [70].

78.3 Conclusion

Hemifacial microsomia and Treacher Collins syndrome are both congenital craniofacial anomalies that negatively impact the physiological and psychological wellbeing of an individual [71]. Due to multidimensional nature of the deformity, a multidisciplinary holistic approach is required with proper guidance and counselling of the patients at every level of treatment. However, with the advances in regenerative sciences and genetic engineering, diagnosis and management of such congenital deformities is becoming less challenging. Disclosure Authors have no financial conflicts to disclose.

79 Modern Management of Craniosynostosis

David Koppel and Jaime Grant

79.1 Introduction

The different presentations of craniosynostosis form the majority of the workload of craniofacial services, and it is important to note that the surgical interventions only form a small part of the overall management of this vulnerable group of patients and their families.

79.1.1 Definition

Craniosynostosis is defined as the premature fusion of one or more of the cranial sutures. This premature fusion can either be an isolated disorder (e.g. sagittal synostosis) or form part of a syndrome (e.g. Apert syndrome). In many cases the resultant head shape is typical of the involved suture such that the Greek/Latin descriptive terms are used synonymously with the description of the affected suture. For example scaphocephaly (boat-shaped head) is used to describe sagittal synostosis; however this approach can lead to confusion as can be seen in the use of the term plagiocephaly (flat head) which may refer to a unicoronal synostosis but also can be used in unilateral lambdoid synostosis, skull base torsion, the deformity resulting from torticollis and positional skull deformities. For this reason it is probably best to avoid the Latin/Greek descriptive terms and identify the affected suture(s) by name.

The majority of craniosynostoses are primary in nature and congenital; however a small proportion are termed secondary—caused by another pathology, usually resulting in reduced brain growth as seen in microcephaly or post-shunting.

D. Koppel (✉)

79.1.2 Aetiology

79.1.2.1 Primary Craniosynostosis

In the majority of cases, no cause for the synostosis is identified, but in an increasing proportion (currently about 25%), a mutation is identified. A significant proportion of these mutations are related to six genes FGFR2, FGFR3, TWIST1, EFNB1, TCF12 and ERF, however there is an increasing frequency of additional mutations being identified by more complex genetic analysis.

The incidence of identifying a mutation is much higher in syndromic craniosynostosis cases (69%), but the rate of mutation identification in the non-syndromic cases is increasing (currently 5%) particularly in the bicoronal, multisuture and unicoronal (in decreasing frequency) [1].

These genetic advances have assisted in the diagnosis of these conditions and influence the genetic counselling but have yet to impact on the management of the resultant problems related to the premature suture closure. As the mechanisms of sutural control and homeostasis are elucidated, novel therapies may be introduced.

79.1.2.2 Secondary Craniosynostosis

Microcephaly and babies who have been shunted as well as other systemic conditions such as sickle cell disease, thalassaemia and rickets can lead to synostosis usually affecting all the sutures. In cases of microcephaly, it is important to differentiate between a primary pansynostosis resulting in a small head often with raised intracranial pressure from a secondary synostosis with normal intracranial pressure [2].

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_79

79.1.3 Epidemiology

The incidence of craniosynostosis ranges from 1 in 1400 to 1 in 2100 live births worldwide with a slight male preponderance.

The different types of craniosynostosis occur in the following proportions:
- Sagittal 45%.
- Metopic 20%.
- Bicoronal and unicoronal 15%.
- Multiple suture 5%.
- Lambdoid <2% [3].

79.1.4 Classification

The classification of craniosynostosis has, in recent years, changed; the previously utilised terminology of simple and complex, referring to single-suture and multiple suture abnormalities, respectively, has been abandoned. It has little utility and is in fact misleading—the deformity as a result of a unicoronal synostosis is extremely complex and as more is understood about the genetic basis the more complex the condition becomes.

In terms of utility, the craniosynostosis is best classified by the suture(s) involved and whether this is associated with a syndrome (i.e. other abnormalities). See Table 79.1 and Illustrations 79.1, 79.2, 79.3, 79.4, 79.5, 79.6 and 79.7. The condition can be further defined by the genetic abnormalities. In general the syndromic craniosynostosis cases tend to be more severe and have a greater incidence of complicating features.

79.2 Management

The care of babies and children with craniosynostosis is best delivered in a centre with access to a full multidisciplinary team. This team involves the core specialities of paediatric neurosurgery and craniofacial surgery (either OMFS or plastics based) as well as support from paediatricians, neonatologists, geneticists, respiratory specialists, ophthalmologists and ENT surgeons. The input from specialist nurses and psychologists is vital [4].

Table 79.1 Overview of craniosynostoses

Suture affected	Description of shape	Diagram of shape	Description
Metopic	Trigonocephaly	Illustration 79.1a, b	Pointed, protuberant, prow-shaped forehead Reduced intercanthal distance Bitemporal narrowing
Unicoronal	Anterior plagiocephaly	Illustration 79.2a, b	Flattened forehead on affected side with raised eyebrow and shallower orbit Failure of forward growth of the hemiforehead with the ipsilateral ear also posterior
Bicoronal	Brachycephaly	Illustration 79.3a, b	Shortened AP—Coronal dimension Flattening of whole forehead Flattened supraorbital rims
Sagittal	Scaphocephaly	Illustration 79.4a, b	Forehead bossing Occipital bulleting Bitemporal narrowing Increased AP—Coronal dimension
Lambdoid	Posterior plagiocephaly	Illustration 79.5a, b	Bossing of mastoid on affected side Contralateral parietal bossing Ipsilateral ear posteriorised
Pansynostosis	Turricephaly or Oxycephaly	Illustration 79.6a, b	Restricted growth at all or multiple sutures—Upward growth in the region of the Fontanelle Small circumference 'Cone'- or 'turret'-shaped head

Table 79.2 Treatment options in infancy for complex synostosis problems

Clinical problem	Emergency/urgent treatment options	Definitive treatment options
Upper airway obstruction 2° to midface retrusion	Nasopharyngeal airway Intubation, O_2 support, CPAP, tracheostomy	Transcranial monobloc advancement (± distraction), CPAP, tracheostomy, Subcranial Le fort III advancement
Corneal exposure	Intensive eye care, tarsorrhaphy	Fronto-orbital advancement, Monobloc advancement
Hydrocephalus	External ventricular drain, ventriculo-peritoneal shunt, third ventriculostomy (in selected cases)	Ventriculo-peritoneal shunt
Elevated ICP	Medical treatment with acetazolamide, steroids	Skull vault expansion, fronto-orbital advancement and remodelling (FOAR), monobloc advancement ± implanted telemetric device

79.2.1 Prenatal Diagnosis

The use of high-definition prenatal ultrasound has increased the early diagnosis of both hydrocephalus and craniosynostosis [5]. This facilitates the preparation of parents for the birth of a child who is likely to have additional medical, surgical and emotional needs. In these circumstances parents getting to know the craniofacial team and being better informed of the potential problems often makes supporting them much easier.

79.2.2 Perinatal Care (Table 7.2)

In the perinatal period, care is directed at optimising the airway, ensuring the child is well oxygenated, preventing corneal damage (ocular protection) and confirming the diagnosis. In the majority of single-suture abnormalities, there are often no issues that prompt early intervention; however in the complex syndromic cases, this is not the case. Airway problems due to severe midface retrusion; breathing disturbance due to central problems, often due to posterior fossa crowding and Chiari malformation; corneal exposure secondary to midface and brow retrusion; and associated non-craniofacial anomalies prompt more urgent interventions. The necessity for such interventions is greatest in the syndromic conditions such as Apert, Pfeiffer, Crouzon and Carpenter syndromes. In cases where there is significant midface retrusion, there may also be feeding difficulties [6].

In the severe cases, initial care is supportive. The airway should be assessed and intervention initiated if necessary. It is important to assess the oxygen saturation and the work of breathing and correlate these findings with formal blood gas measurements. This assessment can be augmented with a formal sleep study, and on occasion simultaneous measurement of intracranial pressure may be helpful. Airway support can range from positional nursing, the use of a nasopharyngeal airway, intubation and in some cases tracheostomy. As part of this assessment, when the airway is an issue of concern, consideration should be given to performing a CT scan, and this will be useful to look at cranial anatomy but also the nasal anatomy, particularly to exclude choanal atresia. In assessing the airway, babies often manage satisfactorily but may suddenly decompensate with a minor upper respiratory tract infection or whilst feeding [6].

Surgical intervention in this period is only undertaken when the airway is such that no simple measures are able to overcome the symptoms; often a period of intubation is helpful to allow for a more thorough assessment rather than rushing to either tracheostomy or a monobloc fronto-facial advance.
During this period parents and family members have to come to terms with the often unexpected consequences of having a child with additional needs and medical interventions. Early and ongoing support needs to be delivered; this can and should be through multiple avenues. Many such children are born in institutions with little or no experience of the condition(s), and this professional unfamiliarity often adds to parental anxiety. For these reasons early contact with a dedicated craniofacial team is invaluable. Specialist nurses, psychologists and support groups can often ease the stress of this difficult time [7].

79.2.3 Care in Infancy

The management of craniosynostosis in infancy is primarily aimed at addressing the primary consequences of the premature suture closure as well as dealing with the associated problems.

The management of the synostosis has, over the years, evolved considerably and in some respect completed a complete circle. The treatment is aimed at ensuring cranial volume is satisfactory to ensure that there is no elevation of ICP (in the absence of hydrocephalus) as well as attempting to normalise the head shape. The normalisation of head shape is done to maximise the chances of a normal head shape at the completion of growth. Initial treatment introduced in the second half of the last century involved a procedure known as suturectomy [8]. The principle of this was to excise the pathological, prematurely fused suture with the idea that removal of the pathology would allow the skull to continue to grow into a normal shape possibly aided by the continued growth of the brain. This was found to be partially effective especially when done before the age of 18 months [9]. It was however noted that in many cases re-fusion of the suture occurred and a number of surgeons began wrapping the bone edges on either side of the resected suture with silicone edging in an attempt to minimise the chances of re-fusion. Unfortunately this approach did not prevent re-fusion, and this often occurred on the dural side of the silicone edging. In pansynostosis cases the sutures were excised and the remainder of the skull was morselised [9]. These simple techniques have been superseded with more complex reconstructive procedures involving suturectomy and remodelling. (See case series examples (Figs. 79.2, 79.3, 79.4 and 79.5). When the coronal sutures are involved, either unilaterally or bilaterally, and/or the metopic sutures, the mainstay of treatment is a fronto-orbital advancement, with remodelling of the affected bones. When the sagittal suture is involved, the affected suture is excised and the remaining skull remodelled. The extent of remodelling varies from case to case but can involve addressing the frontal bossing, bitemporal narrowing and the occipital bullet [4]. These procedures involve extensive exposure and blood loss with their attendant risks, and for these reasons there has been a move to attempt to correct these abnormalities with less invasive procedures. These less invasive approaches utilise endoscopic suturectomy coupled with active postoperative helmet therapy to mould and harness the ongoing brain and hence skull growth [10]; another approach has used a minimal access suturectomy and specially designed springs to actively separate the affected suture edges [11]. A further technique, particularly in bicoronal or pansynostosis cases, is to utilise distraction osteogenesis; a craniotomy of the occipital bone is performed, and two or three distraction devices are applied; these are then activated over a period of 2–3 weeks, expanding the skull volume and in many cases improving the posterior fossa crowding seen in such cases. For reasons not fully understood, this technique often leads to a significant improvement in the contour of the frontal bones [12].

In terms of timing of surgery, there is considerable variation between different centres. In general elective (not motivated by functional concerns), suturectomy and skull remodelling procedures are performed between the ages of 5 months and 2½ years. The younger the patient, the greater the contribution of normal brain growth in normalising head shape; however the drawback of earlier surgery is the fragility of the skull bones and most importantly the risks of complications—particularly excessive blood loss [13].

During this period patients are generally followed up to monitor for signs of raised intracranial pressure, obstructive sleep apnoea (OSA) and evidence of a significant change in the rate of head growth as indicated by head circumference. Discrepancies between the plots on the growth charts (Fig. 79.1a, b) for length, weight and head circumference as well as plots crossing the centile lines should prompt further investigation.

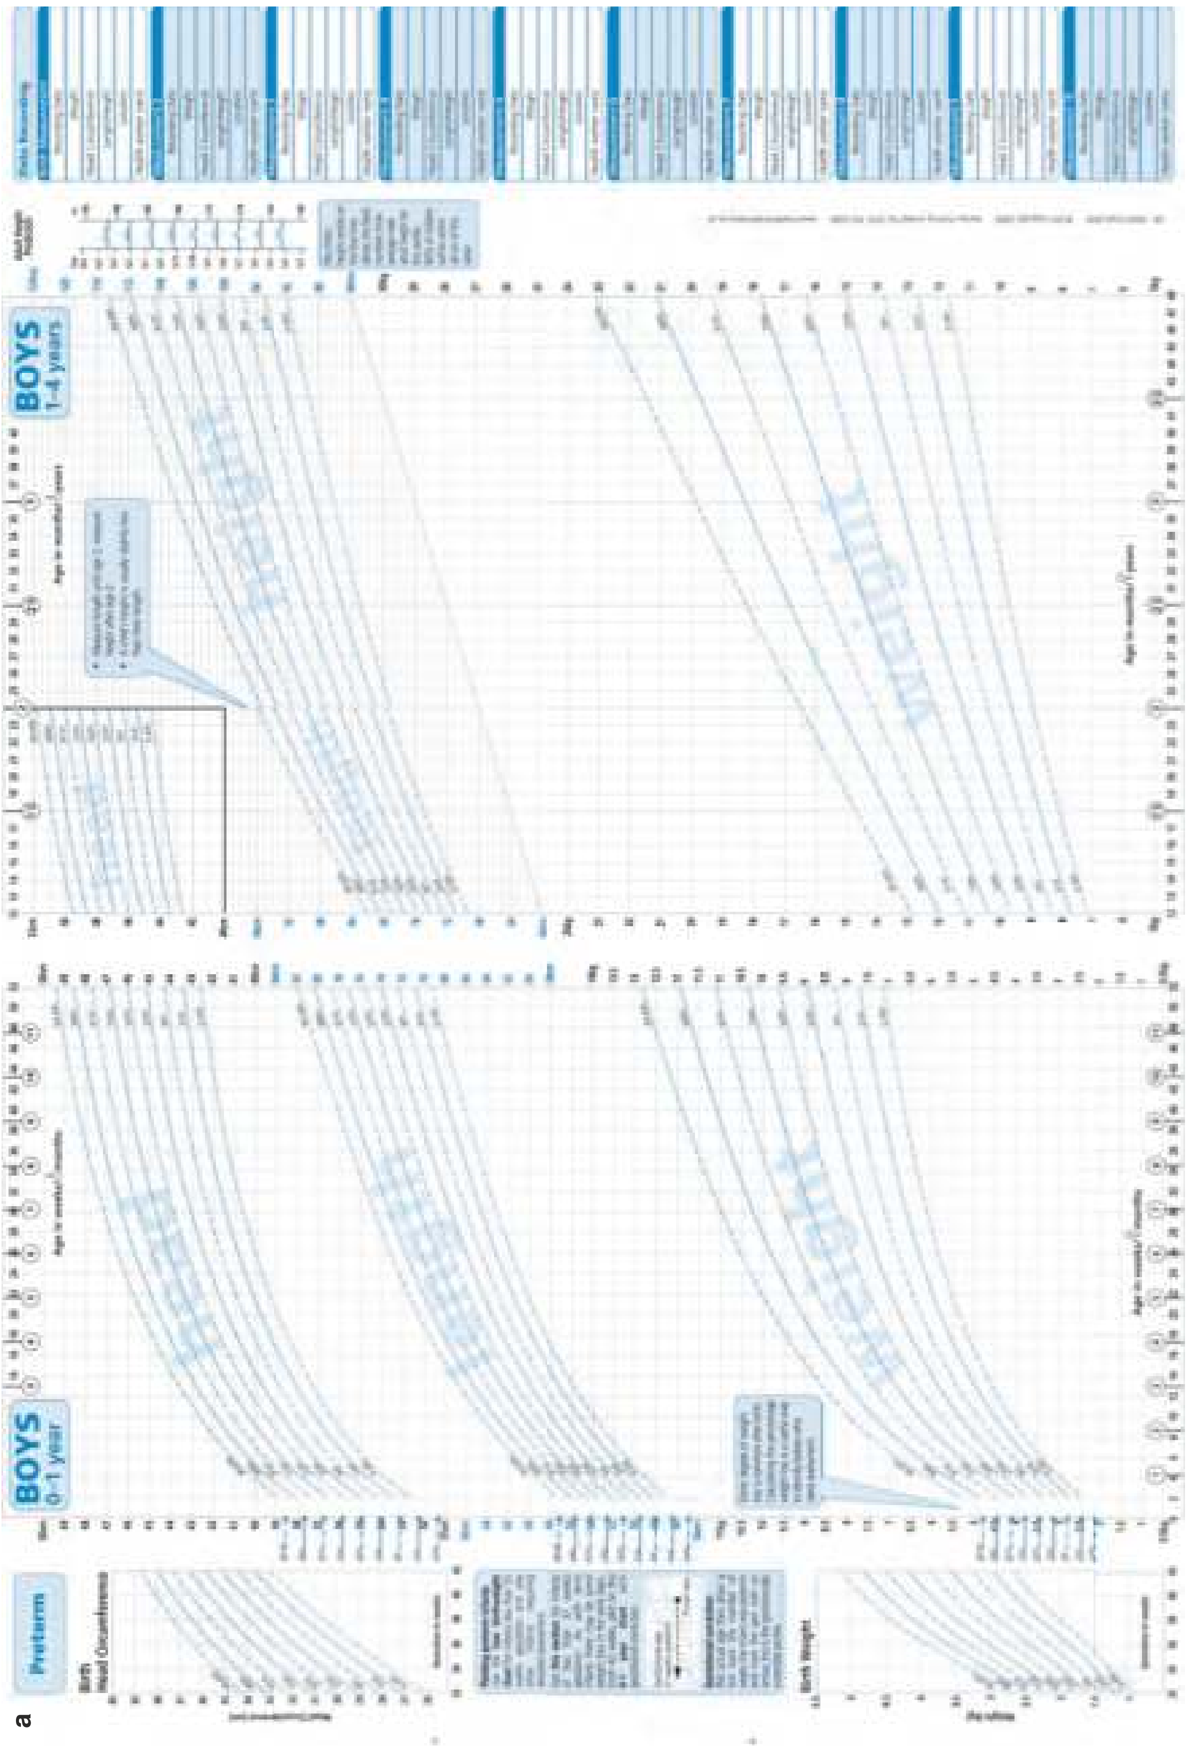

Fig. 79.1 (**a**) (boys), (**b**) (girls) WHO UK growth the chart (**a**) and (**b**) is available Online at https://www.rcpch.ac.uk/resources/uk-who-growth-charts-0-4-years

Fig. 79.2 (2.1–2.9) Case series of sagittal synostosis. (2.1–2.4) Preoperative facial views of patient with sagittal synostosis aged 13 weeks. Note elongated A-P dimension and bitemporal narrowing with prominent forehead and occiput. (2.5–2.7) Postoperative facial views of patient with sagittal synostosis after full calvarial remodelling. (2.8 and 2.9) Preoperative CT scan of the same patient with sagittal synostosis

Fig. 79.2 (continued)

Fig. 79.2 (continued)

Elevated ICP manifests as distressed behaviour, inconsolable crying and headbanging with symptoms being worse at night. When symptoms are combined with papilloedema, urgent intervention is indicated. The absence of papilloedema does not exclude raised ICP, but its presence is of significance. In cases of doubt, formal ICP monitoring can be undertaken. In established cases the use of an indwelling telemetric ICP measurement device may be helpful [14].

Formal ophthalmological assessment should be undertaken and appropriate intervention initiated. Regular assessments are necessary to identify deterioration, particularly to identify corneal exposure and avoid the development of amblyopia.

Routine computerised tomography (CT) cross-sectional imaging is not indicated, and the diagnosis can, in the vast majority of cases, be made on clinical findings alone. In cases where the diagnosis is in doubt or there is the suspicion that there may be posterior fossa crowding, Chiari malformation or craniocervical abnormalities, a CT is indicated. Magnetic resonance imaging (MRI) is indicated to investigate the brain for structural abnormalities. The objective with this very conservative approach to imaging is to minimise the ionising radiation exposure, which has been demonstrated to adversely affect brain development and damage the developing eye [15].

Obstructive sleep apnoea can manifest as noisy snoring, characteristically crescendoing to a maximum followed by a period of silence, representing the apnoeic period with a cyclical restart, or a failure to thrive coupled with daytime tiredness. If OSA is suspected, an initial overnight pulse oximetry study can be undertaken, and if this proves to be suggestive of OSA, a full polysomnogram sleep study should be performed. This can be combined with formal ICP monitoring should there be any concerns about raised ICP. The active management of established OSA requires intervention from the multidisciplinary team, and the respiratory/ENT specialist input is paramount. It is important to establish the causes of sleep disorder and the level(s) of airway obstruction so that the most appropriate intervention(s) can be employed. Further investigations might involve microlaryngoscopy to exclude tracheal abnormalities. Imaging with CT is useful, and interventions should be stepwise with consideration being given to tonsillectomy and adenoidectomy [16].

In the majority of cases of non-syndromic single-suture abnormalities, a single intervention for the surgical correction of the head shape is the norm [4].Whilst there is considerable variation between different units regarding

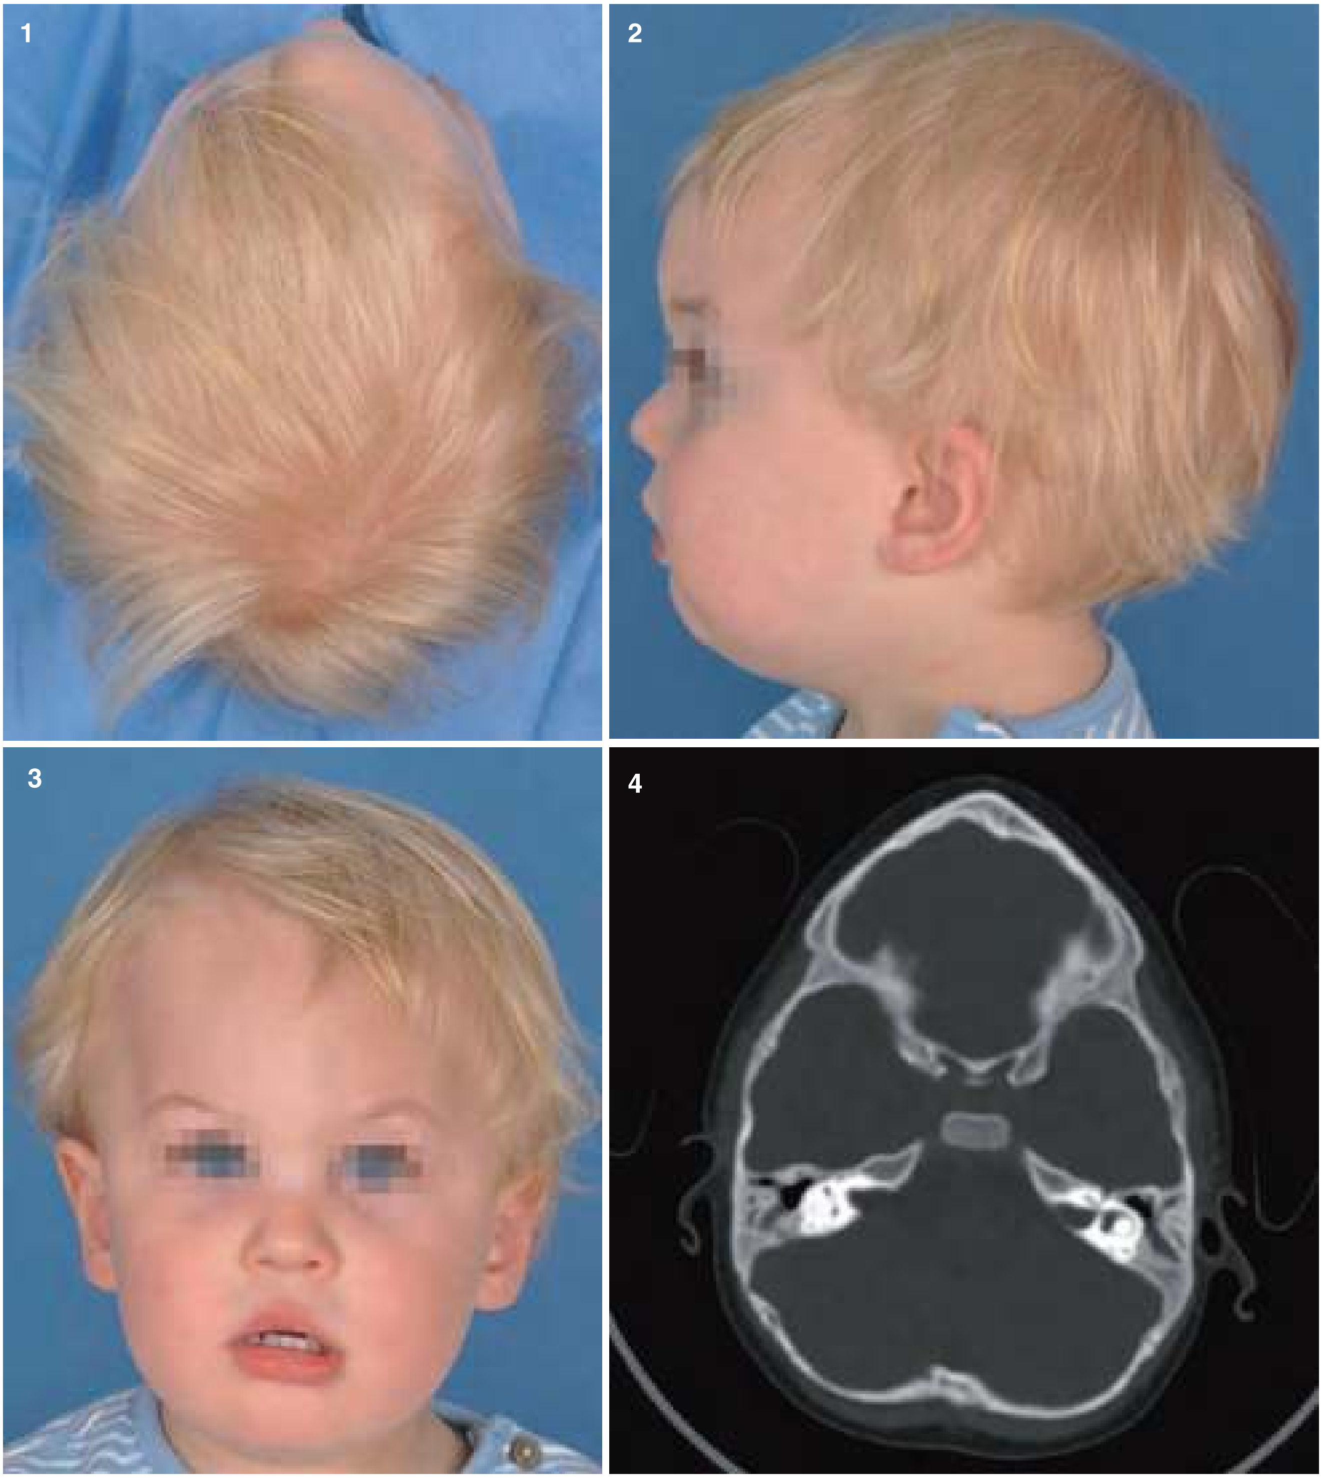

Fig. 79.3 (3.1–3.17) Case series of metopic synostosis. (3.1–3.3) Preoperative facial views of patient with metopic synostosis, age 23 months (late presentation), note pointed brow, triangular-shaped skull and hypertelorism. (3.4–3.6) Preoperative CT scan of the same patient with metopic synostosis—note it is not our usual practice to obtain preoperative CT in metopic synostosis; however this was taken due to the subtle (and late) presentation. (3.7–3.14) Intraoperative views of fronto-orbital remodelling. (3.7) Frontal bar after removal prior to remodelling. (3.8) Frontal bar and fontal bones after removal prior to remodelling. (3.9, 3.10) Frontal bar after remodelling with midline graft to correct hypotelorism. (3.11) Frontal bone osteotomised ready for remodelling. (3.12–3.14) Final views after fixation—fronto-orbital remodelling or anterior two-thirds remodelling. Note use of absorbable plates in load−/tension-bearing areas and absorbable sutures or stainless steel wires in less critical regions. Bone dust and bone dust putty (fibrin sealant mixed with bone dust) are used in resultant bone defects to encourage ossification. (3.15–3.17) Postoperative facial views of patient with metopic synostosis

timing and actual intervention, the Glasgow craniofacial service protocol is outlined in Table 79.3. See also Table 79.4 for an outline of the surgical procedures commonly carried out and the case series (Figs. 79.2, 79.3, 79.4 and 79.5) for an overview of treatment outcomes.

In the management of the syndromic cases, the treatment has to be more flexible and problem driven. There is considerable variation in the severity and comorbidities in this group of patients. Overall the aim is to minimise the number of surgical interventions; however re-synostosis, systemic problems, corneal exposure, airway obstruction and raised ICP are much more common in the group [14]. In the absence of additional pressing clinical issues, the syndromic synostosis cases can be managed as the non-syndromic cases in terms of the timing and extent of skull surgery.

Table 79.3 Glasgow protocol for the management of non-syndromic synostosis

Condition	Ideal age for intervention	Usual procedure
Sagittal synostosis	5–7 months	Total vault remodelling
Metopic synostosis	10–14 months	Fronto-orbital advancement, anterior remodelling ± hypotelorism correction
Unicoronal synostosis	10–14 months	Fronto-orbital advancement, anterior remodelling—Bilateral
Bicoronal synostosis	5–18 months	Posterior vault distraction
	10–14 months	Bilateral fronto-orbital advancement, anterior remodelling
Lambdoid synostosis[a]	10–14 months	Posterior vault expansion static or with distraction

[a]In the presence of elevated ICP

79.2.4 Management in Early Childhood (3–8 Years)

In this period the management is primarily of observation. The non-syndromic cases are followed up 6 weeks, 6 months and 1 year post-skull vault surgery with growth, particularly head circumference, development and vision being monitored. A final review is usually undertaken immediately prior to the child starting school. Some units have a much longer follow-up period; however we reserve longer follow-up for the small proportion of patients who encounter ongoing development problems or symptoms. This protocol should be modified if there is a less well-developed community-based health surveillance programme.

The syndromic cases are followed up more closely with a minimum of annual reviews. In addition to the parameters noted above, the development of OSA may be insidious, and therefore at every review this should be asked about specifically. Towards the end of this period, consideration can be given to performing either a midface advancement or hypertelorism correction. This decision should be primarily driven by clinical problems rather than purely aesthetics, though teasing, bullying and psychological issues can, and should, play a role in decision-making. The input of child psychologists is often very helpful in developing a treatment plan and choosing the optimal timing [17].

During this period it is also important to monitor dental development and try to optimise routine dental care. In addition, at some time the patient should be referred for a full genetic consultation, though the timing of this can be determined by the needs and desires of the family. Throughout the care of the patient development, psychological, educational, physical and speech and language development should be monitored and intervention initiated when necessary.

Table 79.4 Surgical procedures in craniofacial surgery

Procedure	Access	Technical notes	Illustrations
Fronto-orbital advance and remodelling	– Bicoronal stealth incision in the Alice band region – Anterior dissection to superior orbit for access to frontal bandeau inferiorly (may require osteotomies to free supraorbital nerves/vessels)	1. Design mapped out and bur holes made for access with matchstick craniotome. 2. Frontal bone removed (pre−/post-suture). 3. Frontal bandeau removed—Cuts from anterior cranial fossa with direct vision inferiorly via the superior orbit. 4. Frontal bandeau and frontal bone remodelled as necessary and secured in advanced position.	Illustration 79.8a, b
Sagittal remodelling Total vault remodelling	– Mid-cranial stealth incision for access to anterior and posterior calvarium – Start in prone position with careful eye positioning and intermittent relief and then turn supine – Dissection posteriorly to base of occipit and anteriorly to brow	1. Map out dural sinuses. 2. Draw plan for osteotomies and create bur holes for access with matchstick craniotome. 3. Remove occipital bullet and barrel stave (sun) (bone harvesting as required from inner table). 4. Sagittal suturectomy and lateral barrel staving of mid calvarium/moulding laterally as far anteriorly as permitted whilst prone. 5. Secure occipital portion with PDS. 6. Turn the patient. 7. Frontal craniotomy/remodelling and inner table bone harvesting as required. 8. Complete suturectomy and barrel staving anteriorly. 9. Secure frontal bone (resorbable plates). 10. Fill in areas of bony discontinuity with bone putty (bone dust and tisseal).	Illustration 79.9
Metopic remodelling	– Bicoronal stealth incision in the Alice band region – Anterior dissection to superior orbit for access to frontal bandeau inferiorly (may require osteotomies to free supraorbital nerves/vessels)	1. Design mapped out and bur holes made for access with matchstick craniotome. 2. Frontal bone removed (pre−/post-suture). 3. Frontal bandeau removed—Cuts from anterior cranial fossa with direct vision inferiorly via the superior orbit. 4. Frontal bandeau remodelled with interposing bone graft to increase width and flatten midline prominence. • Internal resorbable strut plate for strength. • Resorbable plates bitemporally ± bone graft in gap from advancement. • Brow resecured in midline (resorbable plate/PDS). 5. Frontal bone remodelling (sectioning and repositioning ± barrel staving). 6. ± barrel staving and moulding of mid calvarium 7. Frontal bone placed and secured (resorbable plates/PDS).	Same as Illustration 79.8b
Unicoronal	– Bicoronal stealth incision in the Alice band region – Anterior dissection to superior orbit for access to frontal bandeau inferiorly (may require osteotomies to free supraorbital nerves/vessels)	1. Design mapped out and bur holes made for access with matchstick craniotome. 2. Frontal bone removed (post-coronal suture). 3. Frontal bandeau removed—Cuts from anterior cranial fossa with direct vision inferiorly via the superior orbit. 4. Frontal bandeau remodelled and secured: • Internal resorbable strut plate for strength. • Resorbable plates bitemporally ± bone graft in gap from advancement. • Brow resecured in midline (resorbable plate/PDS). 5. Frontal bone remodelling (sectioning and repositioning ± barrel staving). 6. Frontal bone placed and secured (resorbable plates).	Asymmetric fronto-orbital advancement for unicoronal synostosis Illustration 79.10

Table 79.4 (continued)

Procedure	Access	Technical notes	Illustrations
Monobloc	– Bicoronal stealth incision in the Alice band region – Anterior dissection (separate pericranial flap) to superior orbit for access to frontal bandeau inferiorly (may require osteotomies to free supraorbital nerves/vessels) – Dissection to zygomatic arch bilaterally – Intraoral access posterior to hamulus for pterygomaxillary disjunction – Transconjunctival access to orbital floor	1. Design mapped out and bur holes made for access with matchstick craniotome. 2. Frontal bone removed (pre−/post-suture). 3. Access to anterior cranial fossa and superior orbit. 4. Cuts as per frontal bandeau cuts in anterior cranial fossa with direct vision from superior orbit. 5. Cuts at zygomatic arches bilaterally. 6. Inferior orbital cuts from inferior orbital fissure laterally and then superiorly to join superior orbit cuts and medially from inferior orbital fissure running superiorly to join superior cuts. 7. Osteotomes used to achieve pterygomandibular disjunction. 8. Smiths/osteotomes to propagate splits. 9. Fixation may be for: • Static advancement with plates at frontal bandeau butt joint posterior frontal bone bilateral zygomatic arches. • Distraction—Internal distractor at posterior part of frontal process of zygomatic bone and pins for the RED frame in the body of the zygoma and paranasally. • A combination—Static fronto-orbital advancement/remodelling (as for FOAR) with distraction of the Le fort III segment.	Illustration 79.11a, b
Subcranial Le fort III	– Bicoronal stealth incision in the Alice band region – Anterior dissection to superior orbit for access to frontonasal junction (may require osteotomies to free supraorbital nerves/vessels) – Dissection to zygomatic arch bilaterally – Intraoral access posterior to hamulus for pterygomaxillary disjunction ± anteriorly for placement of distractors – Transconjunctival access to orbital floor	1. Cuts in orbital floors avoiding lacrimal apparatus leaving medial canthal tendon attached to bone. 2. Zygomatic cuts may be made from above or below depending on access. 3. Osteotome used to achieve frontonasal disjunction and pterygomaxillary disjunction. 4. Smiths to propagate splits. 5. Fixation may be for distraction as shown (and as per monobloc) or static advancement with fixation at the zygomatic arch, frontozygomatic suture, frontonasal junction and intermaxillary fixation.	Illustration 79.12—subcranial le fort III
Posterior vault distraction	– Mid-cranial stealth incision for access to the posterior calvarium – Posterior dissection to base of occiput – Stealth mapping of dural venous sinuses	1. Posterior bullet osteotomy with matchstick bur and craniotome. 2. Dural mobilisation. 3. Positioning of 2/3 distractors and tunnelling anteriorly to exit either through the wound or anterior to it. 4. May incorporate foramen magnum decompression or insertion of telemetry can ICP monitor if required.	Illustration 79.13—Posterior vault distraction
Facial bipartition/orbital osteotomies	– Bicoronal stealth incision in the Alice band region – Anterior dissection (separate pericranial flap) to superior orbit for access to frontal bandeau inferiorly (may require osteotomies to free supraorbital nerves/vessels) – Dissection to zygomatic arch bilaterally – Intraoral access posterior to hamulus for pterygomaxillary disjunction and anteriorly to separate nasal septum and split palate – Transconjunctival access to orbital floor	As per monobloc with additional: 1. Separation of the nasal septum from the palate via an intraoral incision. 2. Midline osteotomy of the palate. 3. Midline removal of bone as required from glabella/nasal region. 4. Secure as per monobloc with additional midline fixation and a palatal splint. Box osteotomies of the orbits to achieve orbital movement separate from the maxillary movement involve the same cuts without disjunction at the Le fort I level	Illustration 79.14a, b

79.2.5 Management in Middle Childhood (8–12 Years)

During this period routine monitoring is necessary, and as the face and dentition develop, attention can be turned to managing the midface and occlusion. During the transition from the deciduous to permanent dentition, it is important to have an orthodontic assessment—so that a definitive orthodontic/orthognathic plan can be developed. One of the major factors that may prompt early midface surgery would be the development of OSA; thus regular questioning and targeted investigations at review appointments are necessary. In considering orthodontics it is important to be mindful of the fact that repeated courses of orthodontics will lead to root shortening and also potentially exhaust the tolerance and cooperation of the patient and his/her family [18].

In general, the routine correction of hypertelorism can be safely performed from about the age of 8 years; however this is determined by the chosen technique (facial bipartition vs box osteotomy) (illustration 79.14a, b) and whether an early midface advancement is necessary for the management of OSA [19]. As with all surgery aimed primarily at improving facial appearance, the indications, objectives and expectations of surgery must be discussed at length with the patient and his/her family and a consensus reached. The input from specialist child psychologists is often very helpful. The transition from primary to middle or secondary school is often traumatic, and interventions before this time can be very helpful from a psychological perspective, but it needs to be acknowledged and accepted that further surgery at the completion of growth may well be necessary [18].

79.2.6 Management in Adolescence and after the Completion of Growth

At this stage in development, definitive corrective surgery (when necessary) should be planned and an integrated orthodontic/surgical plan developed. In the syndromic cases, ongoing monitoring for functional and developmental issues is required, and as the child matures, the drive and the responsibility for decision-making will move towards the patient and away from their parents. Many adolescents at this stage are tired of multiple hospital appointments and are not keen on further interventions; in these circumstances it is important to work with the patient and their family to provide care but also respect the patient's wishes and desires. It is better to postpone treatment rather than have a half completed course of orthodontics with poor cooperation and the consequent complications and finally lose the confidence of the patient.

The planning of comprehensive surgery will need assessment in the following areas:

1. Skull shape—irregularities, defects.
2. Orbital position and symmetry.
3. Upper midface morphology.
4. Lower midface morphology.
5. Mandibular morphology.
6. Nasal form.
7. Soft tissue issues.

It is always best to offer and plan for a total correction in the first instance. The discussion around further transcranial surgery is often key to the decision-making. Many patients and families do not want to undertake any further transcranial surgery, in spite of the significant benefits, particularly for hypertelorism or dystopia corrections. None the less these procedures can offer significant improvements in the final result [19].

For residual skull defects of approximately 2 cm diameter or larger, it is usual to offer some form of reconstruction; this could be autologous (usually cranial bone), or alloplastic. Alloplastic reconstructions may be of a variety of materials and can be CAD/CAM designed or shaped intraoperatively. One of the most common residual defects following a fronto-orbital advancement is a degree of temporal hollowing; this can be effectively addressed with the use of mouldable hydroxyapatite synthetic bone material. This technique can be used to satisfactorily address minor skull irregularities and defects, and it is also possible to combine this technique with the use of alloplastic custom-made cranioplasties (e.g. titanium or PEEK) [20].

The assessment of orbital position is critical to deciding on what operative procedure to offer. The combination of hypertelorism and marked maxillary narrowing (particularly if the upper incisors are crossed), as is often seen in Apert syndrome, lends itself to correction with a facial bipartition; this technique can also be used early as the bone cuts do not result in damage to the dentition. The major drawback of this technique is that orbital asymmetries cannot be addressed. The more conventional box osteotomy is used to effect asymmetric movements, hypertelorism and dystopia corrections. The overall aesthetic outcome is often enhanced with nasal augmentation and soft tissue surgery, but the final improvement (particularly in severe hypertelorism cases) unfortunately often does not match the skeletal changes achieved.

The upper midface can be advanced, either as part of the bipartition procedure, transcranial Le Fort III (monobloc), subcranial Le Fort III or Le Fort II. These procedures can be performed conventionally with bone grafting and fixation with either absorbable or titanium plates and screws or with the use of distraction techniques. If distraction is being utilised, the devices can be a halo-based external device or buried devices. It is sometimes helpful to combine external distraction devices with buried devices which facilitate the early removal of the somewhat cumbersome halo device for the retention period [21]. In addition to advancement movements, it is possible to incorporate height changes, but rotatory movements (e.g. to correct the upper dental midline) are very difficult unless the symmetry is equal at all facial levels. Furthermore if the maxillary advancement required has a significant differential between the upper component and dental component, it is possible to combine a Le Fort III (transcranial or subcranial) or a monobloc advance with a simultaneous Le Fort I osteotomy. This additional level of movement allows for differential advancements and/or height changes as well as rotations at the lower level. See case series in Fig. 79.5 of Crouzon syndrome.

The mandible including the chin should be considered as one would for conventional orthognathic surgery, but caution should be exercised in setback procedures as correction of the occlusion to a retrusive maxilla may worsen or precipitate OSA.

Nasal deformity is best dealt with as close to the end of treatment as possible; the range of deformity is considerable; each patient should be treated on their own merits. In cases with severe deficiency, dorsal augmentation with alloplastic or autologous material may be necessary, and this can be refined with nasal tip surgery.

The final phase of surgery is the management of the soft tissues, and again a variety of techniques can be employed to improve the overall aesthetic result. As well as rhinoplasty techniques, facelifting, brow suspension, eyelid surgery, soft tissue augmentation with fillers or fat transfer and soft tissue reduction with direct excision or liposuction all have their place.

See Table 79.2 for an outline of the management of common clinical problems and Table 79.4 for an outline of surgical procedures.

Part XXI

Malignant Pathologies of the Oral and Maxillofacial Region

Premalignant Lesions and Conditions of the Oral Cavity

80

El Mustafa, Sat Parmar, and Prav Praveen

80.1 Premalignant Lesions

It is well established that oral cavity cancer develops in a two-step process and, consequently, that most malignant ulcers are preceded by a precursor lesions [1]. These lesions are typically red or white patches referred to altogether in the 2007 WHO consensus statement as the group of potentially malignant disorders (PMDs) [2] (Table 80.1). Clinical identification of PMDs offers a window for intervention: eliminating diseased mucosa and exclusion of occult invasive cancers. This is important from a clinician's perspective on several fronts. Firstly, it is important to be able to recognise high-risk lesions among a multitude of innocent oral conditions that present with similar features. Some conditions such as oral lichen plans may have a potential for malignant change, but the condition is so prevalent that it becomes impractical to monitor every single patient with the disease. To avoid additional burdens on clinical services, the oral physician or surgeon needs to make a decision as to which patients must be kept under review at a specialist centre and which may be safely referred back for ongoing follow-up in the community. Among those who are reviewed at a specialist practice, ongoing decisions are made at each visit, when to intervene and to what extent one should be aggressive with the treatment plan offered. On a second front are the difficulties of recognition of tumour recurrences following treatment. Surgical treatment and radiotherapy change the tissue appearance and texture irreversibly. Among these patients, it is known that a proportion would develop either a second tumour at the site of surgery or a new tumour in a neighbouring area. It is challenging enough to identify precancerous lesions in nascent tissue, and thus the clinician must be much more vigilant in recognising potentially cancerous new lesions in patients under follow-up posttreatment of head and neck cancer.

Table 80.1 Potentially malignant lesions

Potentially malignant lesions
Leukoplakia (idiopathic)
Proliferative verrucous leukoplakia
Erythroplakia
Oral submucous fibrosis
Oral lichen planus
Chronic hyperplastic candidosis

Further to these concerns, we know that premalignant conditions tend to develop in what is known as field change. This means that for any subsite within the oral cavity at which cellular nuclear damage resulted in a PMD (or even cancer), the adjacent mucosa is almost equally at risk of producing additional PMD lesions even if they appear normal to the naked eye.

Knowledge of the patterns and behaviour of PMDs (premalignant disorder) is thus an essential part of oral medicine and oral surgery practice.

The commonest PMDs are leukoplakia with an overall prevalence of 2.9% in the general population [3] and submucous fibrosis with a prevalence of nearly 11% in high-risk populations [4]. The risk for submucous fibrosis is specific to populations where paan use is prevalent unlike the risk for leukoplakia which is universally applicable. Lesions are considered potentially malignant rather than premalignant. Clinical behaviour is unpredictable; some lesions remain stable; others regress, but in up to 30% of cases, oral malignancy is diagnosed within 5 years of follow-up. Cancer may arise from the lesion itself or at a different subsite within the oral cavity reflecting the concept of 'field cancerisation' explained previously.

It is important to note that a role for primary prevention in patients with leukoplakia is not confirmed. For example, smoking is a risk factor for the development of leukoplakia,

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_80

but smoking cessation does not necessarily reduce the risk of developing OCC. There is, however, benefit in screening for potentially malignant lesions, and this was demonstrated in a recent review of the US SEER-Medicare database of head and neck cancer. Yanik et al. [5] reported better treatment and survival outcomes in patients who developed oral cell carcinoma whilst under follow-up for a premalignant lesion [5]. This correlated with the fact that oral cancers were identified at an earlier stage in this patient cohort. Patients without the benefit of such close observation tended to present with more developed or advanced tumour forms. A role for screening patients following treatment for head and neck cancer recurrence is not known, and thus secondary prevention is not currently known to be effective. It is likely, however, that the principle of recognising early tumours and potentially malignant lesions would still result in timely provision of therapy. Table 80.1 enlists premalignant lesions discussed in this chapter.

80.2 Aetiogenesis

Development of a malignancy is a complex multistep process resulting from failures in several regulatory cellular pathways. Dysplasia in oral cancer is usually the first step in the malignant down spiral. Dysplasia is a descriptive term used on microscopic assessment. It indicates that the tissue has accrued a significant population of abnormal cells that display a pattern of nuclear damage that is known to herald cancerous behaviour. These changes are summarised in Table 80.2. Usually but not always, these changes are followed by unregulated hyperplasia (cellular multiplication). The tumour cells have gained autonomy meaning they escaped nuclear and immune mechanisms that limit excess growth and prevent accumulation of damaged cells. The final step is loss of integrity of the basement membrane at the boundary between mucosa and submucosa; the dysplastic cells begin to invade into the surrounding tissues or directly gain access to vascular channels. Each of these steps is controlled by molecular pathways directed by gatekeeper genes and gene products.

Two cellular or microscopic changes broadly define oral premalignancy: *hyperplasia* which results from over activation of the retinoblastoma pathway and the development of various degrees of *dysplasia* due to mutations in the p53 gene. In health and normal physiology, genes along the retinoblastoma pathway activate transcription factors required for taking the cells from the indolent G1 to the active S phase. Overactivation of these genes leads to loss of control of orderly cell division resulting in epithelial hyperplasia. A product of the CDKN2A gene, the p16 protein, usually keeps this stage of cell cycle in check. This protein may become inactivated either because of a mutation/deletion/epigenetic slicing of the parent gene CDKN2A or through direct degradation by a viral product, the E7 protein, of the HPV virus (relevant to the development of oropharyngeal cancer). The retinoblastoma pathway may also be directly upregulated by amplification of the Cyclin D1 gene, a proto-oncogene of the locus 11q13 [6].

With each cell division, there is a probability of errors arising in the nuclear DNA resulting in a defective daughter cell. Most errors are corrected during cell division, or the cells are removed by immune mechanisms. Defective cells that have escaped these reparative measures may still be suppressed by transcription factors that induce apoptosis. Apoptosis is triggered through p53, a tumour suppressor protein. The protein p14 is an alternative reading frame of the CDKN2A gene responsible for initiating the p53 pathway. Direct degradation of p53 by the E6 viral protein (HPV-related cancer) or genetic mutations in the parent gene (in 60% of non HPV cancer) restricts protective physiological apoptosis leading to a shift in cell population and accumulation of dysplastic cells. The premise behind looking out for premalignant disorders is that oral mucosa will change appearance with the onset of dysplastic changes and that the extent of dysplasia does correlate with malignant potential. High-grade dysplastic lesions indicate treatment is required imminently, whereas mild dysplastic lesions may be observed and are even considered a feature of benign chronic inflammation. Dysplasia is classified according to several grading systems summarised in Table 80.3, the most common system in use being the one proposed by the WHO in 2005. Further

Table 80.2 Histological features of cellular dysplasia

Dysplastic changes
Irregular cell shape and orientation
Increased and abnormal mitoses
Nuclear pleomorphism
Coarse and clumped chromatin
Increased nuclear-to-cytoplasmic ratio
Prominent nucleoli
Dyskeratosis

Table 80.3 Grading systems for dysplasia

Definition	WHO 2005	Ljubljana system	Equivalent SIN (squamous intra-epithelial neoplasia)
Increase in the number of normal cells	Squamous cell hyperplasia	Squamous cell (simple) hyperplasia	
Atypical changes confined to the lower 1/3 of the epithelium	Mild dysplasia	Basal/parabasal cell hyperplasia	SIN1
Atypical changes to the middle 1/3 of the epithelium	Moderate dysplasia	Atypical hyperplasia	SIN2
Changes involve at least 2/3 of the epithelium	Severe dysplasia	Atypical hyperplasia	SIN3

genetic changes are involved in progression towards invasiveness, but these are not as well defined as these are outside the scope of the chapter.

80.3 Leukoplakia

Idiopathic leukoplakia is the most common premalignant disorder. Nearly one in every 10 cases of oral cavity cancer (OCC) is known to arise in leukoplakia (Fig. 80.1), usually within 3 months of diagnosis of the lesion [5]. These lesions are defined as 'white plaques of questionable risk having excluded disorders that carry no increased risk for cancer' [2]. Table 80.4 enlists white lesions without a known malignant potential. These are rare, and thus most persistent white patches are best treated with suspicion until further evaluation.

Clinical variants of leukoplakia include homogenous plaques, nodules, speckled erythroleukoplakia and a distinct subtype discussed separately: proliferative verrucous subtype. Leukoplakia is present in less than 1% of the general population [5] but with greater prevalence reported among those older than 75 years of age and tobacco users of all age groups [7]. Men are twice as much likely to develop leukoplakia compared with women. In the Indian subcontinent, in regions where betel is consumed, prevalence rates approach 5% [8]. The annual risk of malignant transformation is estimated between 1 and 2% [9]. Larger non-homogeneous

Epithelial dysplasia

lesions, particularly those on the tongue and floor of the mouth, are associated with the highest conversion rates to oral squamous cell carcinoma. Table 80.5 lists clinical risk predictors for malignant transformation.

Tissue biopsy is required to assess the degree of epithelial dysplasia, an independent and consistently reliable risk factor for malignant transformation. Liu et al., using a binary grading of dysplasia, found that patients with high-risk lesions (moderate/severe dysplasia) eight times as likely to be diagnosed with oral cancer as those with low-risk (no/mild dysplasia) lesions [10]. Histological evaluation may also identify other conditions that are clinically indistinguishable from idiopathic leukoplakia such as hyperplastic candidosis, oral lichen planus variants, lichenoid reactions and discoid lupus.

Categorisation into high- and low-risk lesions is helpful in identifying target areas for surgical removal and those that may be safely observed but closely followed up.

However, in populations with high incidence of oral cancer, studies have shown oral leukoplakia as foci of invasive cancer and have advocated surgical excision of these lesions.

Toluidine blue dye improves visual detection of high-risk mucosa [11] and helps determine the extent of peripheral margins required for complete excision. It is not established whether surgical intervention reduces the risk of subsequent cancer, but a resection specimen may upgrade the histological evaluation or identify areas of occult focal invasion. Recurrence following surgery is observed in 10% of cases [12]. Laser surgery is effective in controlling low-grade leukoplakia, but significantly higher failure rates of up to 9% were reported in high-grade lesions and erythroleukoplakia [13]. Recent reviews have examined photodynamic therapy as a treatment option particularly helpful in controlling widespread and multifocal leukoplakia [14]. Partial and complete response rates as high as 70–100% were reported, but the range of photosensitisers used and photo-irradiation protocols applied varied greatly between individual authors.

Medical treatments for oral premalignancy include systemic vitamin A, systemic beta carotene and topical bleomycin. These were shown to control premalignant lesions, but a 2016 Cochrane review concluded that relapse rates were high and that transformation into oral cancer was not effectively reduced [15].

80.4 Proliferative Verrucous Leukoplakia

Proliferative verrucous leukoplakia (PVL) is a distinct and aggressive form of leukoplakia with one of the highest known malignant transformation rates. It is typically diagnosed in elderly women (4:1 female ration) without a history of tobacco use [16]. Aetiology is thus largely unknown. Lesions often start as isolated flat white plaques but gradually spread to become diffuse and multifocal with a characteristic warty appearance (Fig. 80.2). There typically is no erosive component. The lesions tend to present on the tongue or buccal mucosa or well as the alveolar ridge. They can be mistaken for hyperplastic candidosis or frictional keratosis particularly in denture wearers. Histological appearance is dependent on the stage of the disease ranging from benign hyperkeratosis to dysplastic keratosis merging into verrucous carcinoma. Malignant transformation may also happen simultaneously at multiple foci, and this is one of the clearest manifestations of the field cancerisation concept introduced earlier. Verrucous carcinoma is a squamous cancer with well-differentiated histopathological architecture that displays very little cellular atypia.

PVL is a lesion that benefits from excision biopsy rather than an incisional sample (see biopsy discussion below) for it is estimated that 20% of verrucous lesions, if adequately sampled, would reveal foci of conventional pattern squamous cell carcinoma. Local control is, however, difficult with high recurrence rates following surgical excision and greater malignant transformation rates in excess of 70% [17]. It is also one of the most difficult lesions to follow up, requiring multiple biopsies to monitor behaviour over time.

80.5 Erythroplakia

Erythroplastic lesions (Fig. 80.3) are similarly defined to oral leukoplakia but as red velvety lesions following exclusion of other named entities. It is a rare disorder with prevalence

Fig. 80.2 Proliferative verrucous leukoplakia

Fig. 80.3 Erythroplakia

between 0.01 and 0.2% but a much higher transformation rate compared to leukoplakia, reportedly between 51 and 90% [16]. Clinical appearance tends to follow one of three patterns: the homogenous, granular and speckled types [12]. Most common subsides are the palate, the buccal mucosa and the floor of the mouth. Lesions are rarely multicentric and may present a similar clinical appearance to erosive and atrophic oral lichen planus, erythema migrans, stomatitis, candidosis, lymphatic malformations and desquamative gingivitis (e.g. vesiculobullous lesions and gingival lichen planus). Speckled erythroplakia and leukoplakia most likely refer to the same disorder with red appearance correlating to high-risk epithelial dysplasia. Treatment options are surgical excision, laser excision or evaporation as per leukoplakia with a lower threshold for application for wide local excision due to the higher risk of cancer development.

80.6 Submucous Fibrosis

Oral submucous fibrosis is progressive scarring disorder linked to the use of betel products (paan). Additional risk for oral squamous cell carcinoma is conferred by the addition of slaked lime to the betel quid or concurrent use of tobacco. The active ingredients in paan include arecoline, copper and polyphenol fragments (flavonols, tannins) which stimulate an intense acute inflammatory response characterised by a polymorphic infiltrate and vascular dilatation. This gives way to a chronic immune response and constrictive vascular changes that end with obliteration of blood vessels in the affected region. Over time, this leads to an epithelial to mesenchymal transition mediated by TGF-β [18]. Fibroblasts are activated, and collagen is deposited steadily replacing the submucous tissues with hyalinised cartilage almost devoid of cellular components. Several genes are known to associate with the risk of developing submucous fibrosis including MMP3 gene promoter region and CYP1A1/CYP2E1 genes,

Table 80.6 Histopathological changes in submucous fibrosis

Very early Stage I	Early Stage II	Moderate advanced Stage III	Advanced Stage IV
• Fine fibrillar collagen and marked oedema.	• Early junta-epithelial hyalinisation	• Moderately hyalinised collagen.	• Completely hyalinised collagen.
• Strong fibroblastic response.	• Moderate fibroblastic response.	• Predominantly fibrocytes, reduced fibroblasts.	• Hyalinised collagen devoid of fibroblasts.
• Acute polymorphic inflammatory cell infiltrate.	• Mononuclear and lymphocytic inflammatory cell infiltrate.	• Lymphocytic and plasma cell inflammatory cell infiltrate.	• Lymphocytic and plasma cell inflammatory cell infiltrate.
• Normal or dilated-congested blood vessels.	• Dilated-congested blood vessels.	• Normal to constricted vessels.	• Markedly constricted or completely obliterated blood vessels.

but the genetic basis for transformation into squamous cell carcinoma is not currently defined. Table 80.6 summarised the histopathological evolution and progression of submucous fibrosis.

Consumption of paan is common in Southeast Asia and the Western Pacific but is now also seen in Europe and North America. It is estimated that more than half a billion persons consume betel worldwide [19]. Early presentation reflects the early histological picture with non-specific inflammatory mucosal changes. The diagnosis becomes clearer when early changes are replaced by the characteristic hypo-vascular blanched appearance with a fibrous texture although these changes may be patchy or reticular causing potential confusion with unrelated mucosal changes (e.g. lichen planus). In general, submucous fibrosis tends to present in young adults (predominantly males) with worsening trismus (37.2% of patients), painful dysesthesia (25.9%), excess salivation (22.5% of patients) and recurrent ulceration. Clinical findings on examination are white patches particularly in the buccal mucosa (20.8%) and the palate (17.7%) followed by the floor of mouth and the retromolar trigone [20]. Clinical signs develop within 3–5 years following commencement of chewing betel preparations. Patients are 19 times as likely to develop oral cancer particularly with betel quid containing tobacco [4]. Malignant transformation rates are reportedly 4–13% [21].

Conservative and medical measures are considered for the early clinical stages. This includes physiotherapy, immune modulators steroids and promoters of blood flow such as pentoxifylline. Many other medical treatments are reported but none with definitive clinical benefit.

Surgical options are limited and complete excision unlikely, but surgery is usually indicated for local release of retromolar or buccal scarring to help relieve trismus. Release of trismus is usually necessary at the mouth opening of 25 mm and less and is achieved with incisions, local V–Y flaps and masticator muscle myotomy, resurfacing the defect with the buccal fat pad or other grafts.

Fig. 80.4 Oral lichen planus

80.7 Oral Lichen Planus

Lichen planus (LP) (Fig. 80.4) is a prevalent inflammatory much cutaneous disease affecting 5% of the population worldwide. The pathogenesis is not well understood but is essentially an autoimmune response to the epidermal basal cell layer mediated by cytotoxic T cells. Characteristically, T cells are seen to infiltrate into the lamina propria on microscopy and the damaged basal keratinocytes degrade into apoptotic residues known as civatte bodies (not pathognomonic for LP) [22]. Aetiology is unknown, but it is well recognised that appearances of lichen plans can result from a hypersensitivity reaction to nonsteroidal anti-inflammatories, angiotensin-converting enzyme inhibitors and dental amalgam. These reactions are more commonly referred to as lichenoid mucositis. In rare instances, the disease associates with viral hepatitis (B and C), but in most patients LP, there is no triggering factor. Stress is thought to be a contributing factor.

Commonly, oral lichen planus (OLP) presents as reticular white patterns on the buccal mucosa or the tongue known as Wickham's striae. Many varieties and presentations are recognised such as desquamative gingivitis, plaque form and an unusual form that presents with vesicular bullae. An erosive form is also recognised giving the appearance of the high-risk erythroplakia and mixed red and white lesions [23]. Some authors use the term erosive OLP to refer to the ulcerated type of lesion and erythematous OLP as the commoner type which affects atrophied buccal mucosa (usually seen with reticular lesions). Distribution is usually symmetrical, a feature it shares with discoid lupus.

It is not clear whether oral lichen planus (OLP), a relatively common benign condition, is an independent risk factor for malignancy. A meta-analysis of 7806 patients concluded that just over 1% of patients OLP develop oral cavity cancer [24]. The highest risk subsites were predominantly the tongue (51%) and the buccal mucosa (32%). Malignant transformation was three times as likely in females as it was in men. It is proposed that changes at lower-power magnification of oral leukoplakia resemble lichen planus or that lichenoid changes in epithelial dysplasia are common. Clinically, there is overlap between the clinical appearance of the various types of OLP and between erythroleukoplakia and verrucous leukoplakia. A diagnosis of OLP is more likely in symmetric lesions, but only a biopsy demonstrating epithelial dysplasia would confirm truly high-risk lesions. Correlation between malignant change and certain subtypes of OLP, namely, the erosive and plaque-like forms, has not been consistent. Interestingly a co-existence with proliferative verrucous leukoplakia has been noted by several authors [25, 26].

80.8 Chronic Hyperplastic Candidosis

Candida is present in the oral cavity in between 40 and 60% of healthy individuals. Association between *Candida* infection and cancer is through smoking, an independent risk factor equally for the development of chronic hyperplastic candidosis (CHC) and premalignant mucosal lesions. Once hyperplastic candidosis is established, these lesions manifest and behave similar to homogeneous or speckled leukoplakia with 15% risk of progression to epithelial dysplasia [27]. CHC is usually resistant to antifungal therapy, and thus surgery is indicated particularly for well-defined lesions.

80.9 Premalignant Conditions

Premalignant conditions are a disparate group of rare congenital and acquired disorders of immune regulation, inheritable genetic instability and infectious diseases. Table 80.7 enlists conditions that associate with mucosal SCC followed by Table 80.8 which also provides a summary of clinical features, site distribution and risk probabilities for conditions that associate with the cutaneous type of squamous carcinoma. Reports of malignant transformations are generally few and data concerning the natural history of OCC limited. Conditions that rarely associate with oral SCC such as Plummer-Vinson syndrome are not discussed here.

Table 80.7 Potentially malignant conditions: mucosal SCC

Potentially malignant conditions: mucosal SCC	Aetiology	Clinical characteristics
Dyskeratosis congenita (mucocutaneous variant) [28]	Multigene defects, telomere dysfunction and bone marrow failure. Sporadic de novo, autosomal dominant and X-linked recessive types	Triad: Nail dystrophy, reticular skin pigmentation, oral leukoplakia. Oral leukoplakia in 80% of patients. 40–5% malignant transformation into SCC
Syphilis	Spirochete infection	Verrucous type and speckled leukoplakia in tertiary syphilis. Usually in the lips, tongue or palate. 3–33% risk of transformation
Graft versus host disease	Complication of allogenic stem cell transplantation	Oral lichenoid, erosions and painful ulcers. Few case reports of cancer transformation
Acquired immune deficiency syndrome [29]	HIV virus	HPV positive oropharyngeal SCC. Kaposi sarcoma

Table 80.8 Potentially malignant conditions: cutaneous SCC

Potentially malignant conditions: cutaneous SCC	Aetiology	Clinical characteristics
Actinic cheilitis	Solar radiation	Diffuse, atrophic, ulcerative or keratotic patches in the lower lip. 6% risk of malignant transformation
Xeroderma pigmentosum	Autosomal recessive inheritance	Cutaneous-type SCC on the lower lip observed in young adults, age < 20 years
Discoid Lupus [30]		1.3–6.5% risk of developing SCC and BCC with lighter skin. Risk increased to 22% in discoid lesions. Locally aggressive lesions with high recurrence rates

80.10 Tissue Biopsy

A sample of tissue is required whenever a premalignant disorder is suspected. Dysplasia cannot be visualised on clinical inspection. It is true that some lesions such as the speckled red and white lesions are most likely to harbour dysplastic cells, but it is hard to characterise white patches as dysplastic or not on clinical examination alone. Most sites within the oral cavity are accessible for a biopsy under local anaesthetic. General anaesthetic may well be indicated in some cases depending on tumour site particularly in the oropharynx or in patients not compliant with awake procedures. A biopsy may be obtained either by using a scalpel blade or through a punch biopsy applicator with pre-set width.

A small amount of local anaesthetic is administered locally within the site of the lesion for it provides pain relief and vasoconstriction through the action of an additive. Concentrations of 1:50,000 to 1:200,000 epinephrine are used as vasoconstrictor additives typically to lidocaine. Other vasoconstrictor agents include felypressin typically combined with prilocaine as a local anaesthetic. Care should be taken in patients who take anti-platelets agents or anticoagulant medications. The oral mucosa has a rich blood supply, and bleeding from small biopsy sites may prove to be difficult to control.

Excision of the abnormal patch as a whole may be achievable in smaller lesions, but in large and extensive lesions, an incisional sample is indicated. The site for taking a biopsy in this case is important. A white lesion may contain within multiple foci, and a biopsy from a uniform looking area may miss an area of dysplasia or early invasive cancers. Within a white lesion, it is advisable to take a biopsy from a speckled area, an area where there is induration/thickening and an erosive patch or where there is frank ulceration. When there is ulceration, then removal of tissue from the centre of the ulcer may return tissue that is necrotic and hard for the pathologist to interpret. Thus, it is also advised to take a biopsy from the margin of the ulcer particularly if the margin is elevated or everted. A small extension to incorporate normal looking tissue is helpful to enable the pathologist to visualise pathological transition into normal background architecture and pick up subtle changes that may otherwise be difficult to interpret.

The full thickness of mucosa is required for complete assessment. Invasiveness is impossible to interpret without inclusion of the basement membrane in the tissue biopsy. Traditionally that may not have been crucial for at the highest end of the dysplastic spectrum severe dysplasia is also considered to be at least as intra-epithelial neoplasia and in most cases surgical excision would be indicated. However, recent modifications of the TNM classification system and the work of D'Cruz et al. have highlighted depth of invasion as an independent risk predictor for regional metastasis [31].

Thus a biopsy may not only identify the nature of the lesion and reveal unexpected invasiveness; it may also determine the next step in treatment whether surgical excision of the lesion is enough or whether the threshold for regional surgery (i.e. a neck dissection) is required as well.

Once the sample is removed, haemostasis is required with either bipolar diathermy or, in small sites, chemical cautery with silver nitrate that is useful too. Most biopsy sites lend themselves to primary closure with a resorbable suture, whereas particular sites such as the mucosa overlying the hard palate may be safely left to heal by secondary intent.

80.11 Conclusion

Clinical examination of the oral cavity must include active screening for mucosal changes that are potentially cancerous. This may take place in the primary care setting, in dental practice, for these lesions are mostly asymptomatic and the patients may not be aware of their presence. A high index of suspicion is required for it is well known that although some lesions associate with known risk factors (e.g. oral submucous fibrosis), many lesions do not (e.g. verrucous leukoplakia). Clinical features may be ambiguous with some lesions that are red, erosive or speckled lending themselves to easier recognition compared with faint leukoplakia and subtle early changes in long-standing lichen planus. A low threshold for biopsy is recommended unless the lesion is demonstrably consistent with candidosis (i.e. may be clinically wiped off) or in the case of striated lichen planus that has remained consistent and well defined. Clinical photography is helpful in establishing objective documentation lesions for it is likely that the patient would be reviewed by different clinicians during follow-up. Once identified and histology is characterised, then lesions require stratification into high-risk and low-risk categories in order to determine the long-term plan for the patients, namely, surgical removal versus clinical observation, and the appropriate recall intervals for future follow-up. As discussed above, the treatment options are diverse and are tailored to the size of the lesion and degree of epithelial dysplasia. Although surgical removal does not eliminate the risk of malignant change entirely, early identification and close follow-up of premalignant lesions offer the best chance for achievement of good local control if and when oral cancer develops.

81 Oral Squamous Cell Carcinoma: Diagnosis and Treatment Planning

Vijay Deshmukh and Kishore Shekar

81.1 Background and Incidence

The incidence of oral and oropharyngeal SCC is on the rise. Each year approximately 263,000 new cases of oral cancer are detected worldwide, and 127,000 people die of the disease [1]. In India it is the third most common cancer and accounts for almost 40% of deaths. Among men it is the second most common site, and in women it is the fourth in India [2]. In 2012, the incidence rate for male was 10.1/1,00,000 and for female 4.3/1,00,000 [3].

81.2 Introduction

Oral carcinoma commonly called as the oral squamous cell carcinoma (OSCC) occurs as an ulceroproliferative lesion of the oral mucosa affecting any site starting from the lips to the oropharynx. The commonest sites are gingivobuccal sulcus of mandible followed by the tongue and floor of the mouth. It should be understood that Indian cancer is much different to other parts of the world. The habit of the tobacco chewing (smokeless tobacco) and pan masala, i.e., a mixture of the tobacco, betel nut, and unknown chemicals used for the color and flavors, is the commonest cause. Classical Indian cancer is the gingivobuccal sulcus (GBS) of the mandible due to the placement and holding of the tobacco-lime mixture, in the area. Over the last three decades, pan masala has become popular, due to the easy availability in pre-mixed packed. This maybe chewed or kept in the oral cavity, i.e., GBS, which leads to continuous action of the contents on the oral mucosa. The constant irritation leads to fibrosis and with time results in submucous fibrosis.

81.3 Etiology of Oral Carcinoma

Etiology of oral SCC is multifactorial. Local irritants contribute significantly to the conversion of a premalignant process to invasive carcinoma. Damage to the epithelial layer followed by the basement membrane and submucosa secondary to chemical and mechanical injury leads to fibrosis of the mucous membrane.

The prominent etiological factors are:

1. Tobacco consumption—All forms of tobacco smoke as well as smokeless have carcinogenic potential. Evidence for smokeless tobacco causing oral and pharyngeal cancer was evaluated and confirmed [4]. India is the third largest producer and consumer of smoked and smokeless forms of tobacco. Tobacco-related cancers account for nearly 50% of all cancers among men and 25% of all cancers among women with the burden of tobacco-related cancers in 2001 estimated to be nearly 0.33 million cases annually. It has been predicted that an incidence of sevenfold increase in tobacco-related cancer is expected between 1995 and 2025 resulting in an increase by 220% of cancer deaths simply related to tobacco use [5]. In India chewable tobacco is consumed in various forms. The traditional form is called the pan (Figs. 81.1, 81.2 and 81.3). Local form of smoking tobacco is called as bidi, which is a crude form of cigarette. This is considered to be more carcinogenic. It commonly causes carcinoma of the palate, oropharynx, and larynx.

Fig. 81.2 Pan masala (gutkha) pouches. Ready to eat mixture of tobacco, betel nut, lime, catechu, and unknown chemical coloring and flavoring agents

Fig. 81.3 Pan-betel quid. Betel leaf coated with lime-catechu-flavored tobacco-betel nut. It is rolled, wrapped, and pinned with clove. Most commonly chewed in Indian subcontinent

2. Alcohol—Alcohol is considered to be causally associated with oral cancer. As heavy alcohol drinkers are frequently heavy smokers as well, a synergistic effect with cigarette smoking is implicated in oral cancer [6–8]. Excess alcohol consumption is associated with nutritional deficiencies. This acts as an aggravating factor.
3. Betel nut chewing (areca nut)—Chronic chewing of the betel nut leads to abnormal fibrosis of the oral-pharyngeal areas. Betel nut is the endosperm of the fruit of *Areca catechu*. It is consumed in various forms. It is used fresh or dried or may be cured before use by boiling, baking, or roasting. The abrasive mechanical property causes attrition of teeth and physical damage to the mucosa. This sandpaper action makes the mucosa more susceptible to the chemical properties of beetle nut. In India alone 38 different combinations of areca nut with tobacco have been documented (Fig. 81.1). The number of patients with a pan masala chewing habit (68.0%) was higher than the number of patients with betel nut (17.4%) or betel quid chewing habits (14.6%). The chewing of pan masala is associated with earlier presentation of oral submucous fibrosis (OSMF) as compared to betel nut chewing [9]. Pan masala (Fig. 81.2) is the artificial mixture available in small pouches having contents of tobacco, betel nut, spices, coloring and flavoring agents, preservatives, as well as unspecified agents. This has proven to be highly carcinogenic. Consumption of this mixtures leads to OSMF which is a precancerous condition. Development of precancerous lesions like leukoplakia in preexisting fibrosis potentiates carcinoma conversion. Betel nut is also consumed with a pan (Fig. 81.3) a freshly prepared mixture on the betel leaf with tobacco, slaked lime, catechu, and clove. This is chewed over a longer time and remains in contact with oral mucosa causing mechanical and chemical irritation. The important flavonoid components in areca nut are tannins and catechins. These alkaloids undergo nitrosation and give rise to N-nitrosamine which might have cytotoxic effect on cells [10].
4. Nutritional deficiencies—Dietary deficiencies of vitamin A, folate, riboflavin, iodine, and iron add to the risk of cancer. High dietary fiber; vitamins C, E, and A; and selenium offer protection against cancer [11, 12].

5. Poor oral hygiene and traumatic injury of dental origin—Poor oral hygiene is often associated with gingivoperiodontal infections raising bacterial colony count leading to a constant inflammatory response. This together with traumatic tooth injury can lead to a carcinogenic effect.
6. Viral infections—The role of human papillomavirus (HPV) in pharyngeal cancer is well established. However its effect on the oral cavity is still being researched. Globally, HPV infection is relatively more common in OSCC patients [12].

81.4 Precancerous Situations of Oral Cavity

Precancerous situations can be broadly divided into precancerous conditions and precancerous lesions. Precancerous condition's most commonly seen in India are oral submucous fibrosis (OSMF) and oral lichen planus. Precancerous conditions can be associated with the precancerous lesions (please also see Chap. 80 on premalignant lesions and conditions).

81.4.1 Precancerous Conditions

Precancerous conditions make every part of the oral cavity susceptible to cancer conversion as is seen in oral submucous fibrosis (OSMF). The phenomenon simulates field cancerization. Development of a second primary despite adequate treatment of the first is common. Sometimes two primaries at distant anatomical sites are noted in extensive long-standing OSMF.

81.4.2 Oral Submucous Fibrosis (OSMF)

Oral submucous fibrosis is a chronic insidious disease of the oral mucosa characterized by loss of mucosal elasticity and excessive fibrosis (Figs. 81.4, 81.5 81.6 and 81.7). It is always associated with juxta-epithelial inflammation and progressive hyalinization of lamina propria [13]. Oral submucous fibrosis (OSMF) is predominantly seen among betel quid chewers and pan masala chewers in India. OSMF generally starts at the RMT (retromolar trigone), anterior faucial pillars, and the adjoining area of the soft palate. It extends to involve the buccal mucosa, commissure, lips, and rima oris. Resulting trismus is due to mucosal and muscle fibrosis in the masseter and pterygoids. Figures 81.8 and 81.9 shows the traumatic ulcers caused in buccal mucosa and RMT area in OSMF cases mainly due to the limited mouth opening and fibrosis. In such cases early dental intervention or extractions

Fig. 81.4 OSMF (oral submucous fibrosis). Note fibrosis affecting RMT, faucial pillars, buccal mucosa, as well as rima oris

Fig. 81.5 OSMF (oral submucous fibrosis). Note fibrosis affecting RMT, faucial pillars

Fig. 81.6 OSMF (oral submucous fibrosis). Note fibrosis affecting lower lip and blanching of mucosa. Note pale nails due to anemia

Fig. 81.7 Bald tongue in OSMF. Has high malignant potential

Fig. 81.8 OSMF with traumatic ulceration from last molars

Fig. 81.9 OSMF with traumatic ulceration from last molars

may be delayed due to the difficulty in access to the posterior teeth due to trismus. Such chronic traumatic ulceration may undergo malignant change as seen in Fig. 81.10.

81.4.2.1 Molecular Pathogenesis of OSMF

Time and constant irritation lead to inflammation with mucosal atrophy. It can thus be considered that induction of oral mucosal inflammation by betel quid is a critical event in the pathogenesis of OSMF. Cytokines like interleukin-6 (IL-6), tumor necrosis factor (TNF), interferon-a (INF-a), and growth factors like TGF-b are synthesized at the site of inflammation.

TGF-b1 is a key regulator of extracellular matrix (ECM) assembly and remodeling. TGF-b1 increases collagen production and decreases its degradation [14]. OSMF has characteristic clinical presentation depending on the stage of the disease. The majority of patients have intolerance to spicy food, roughness of oral mucosa, and varying degrees of difficulty in opening the mouth.

OSMF is a well-recognized potentially premalignant condition of the oral cavity. The transformation rate is as high as 7.6% over a period of 10 years [15]. In this group, primary malignancy develops in the buccal mucosa extending to involve the retromolar trigone. This is unique in the context

Fig. 81.10 Malignant transformation in posterior buccal mucosa in a case of OSMF, accompanied by chronic trauma form tooth

of the Indian subcontinent, as pure tobacco chewing habit has decreased and is replaced by the gutkha chewing habit. Tobacco-lime preparation used to be kept in the GBS or the floor of the mouth for longer period. This led to leukoplakia and/or erythroplakia, followed by malignant transformation. The current preparation is not constantly placed in the GBS but chewed for long time and swallowed. The chemical effect leads to OSMF and field concretization.

81.4.3 Oral Lichen Planus

Oral lichen planus (OLP) tends to often present bilaterally as white striae on the buccal mucosa. Any mucosal site in the mouth may be involved. Other sites, in decreasing order of frequency, may include the tongue, lips, gingivae, floor of the mouth, and very rarely palate [16].

Six clinical forms of oral lichen planus are recognized [17]: reticular, erosive/ulcerative, papular, plaque-like, atrophic, and bullous. Atrophic/erosive lichen planus is associated with a risk of cancerous transformation [18]. Patients with OLP tend to be monitored closely to detect any potential change early.

The rate of malignant transformation in individual studies ranged from 0 to 3.5%. The overall rate of transformation was 1.09% for OLP.

81.4.4 Precancerous Lesions

Precancerous lesion is a pathology of the oral mucosa which has a tendency to transform into the squamous cell carcinoma. The commonly prevalent lesions are leukoplakia erythroplakia, carcinoma in situ, and smoker's palate.

81.5 Diagnosis of Oral Squamous Cell Carcinoma (OSCC)

Diagnosis of oral squamous cell carcinoma is not a challenging task except in the cases of an unknown primary. History of risk factors, classic clinical appearance of an indurated ulcer, involvement of lymph nodes, and destruction of bone are common features in advanced disease.

81.5.1 Clinical Features of Oral Carcinoma

Oral squamous cell carcinoma often presents as an indurated ulcer, exophytic growth, indurated non-ulcerative patch (endophytic), or a combination of the above appearances. Figures 81.11, 81.12, 81.13, 81.14, 81.15, 81.16, 81.17, and 81.18 shows the various clinical presentation of SCC in tongue. Fig. 81.19 shows multiple primary tumors arising in case of OSMF.

Important parameters to be recorded at the primary site in clinical examination are site of the tumor; size; extension to involve adjacent structures like the skin, muscles, bone of maxilla and/or mandible, and skull base; and extensions into compartments such as the paranasal sinuses, nasal cavity, orbit, pterygoid space, masticatory compartment, and infratemporal fossa. Regional spread to the lymph node basin in the neck needs clinical and radiologic correlation. Evaluation of distant metastasis to lungs and bones forms a part of the staging process.

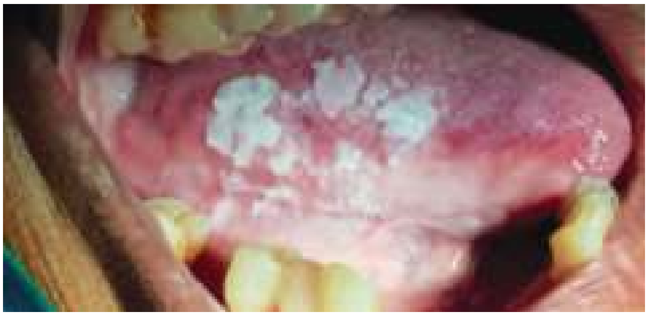

Fig. 81.11 Precancerous lesion of the tongue—diffuse leukoplakia. Lesion has a potential to undergo SCC

Fig. 81.12 OSCC of the tongue—inverted margins. Lesion not associated with any habit. These lesions often can have genetic predilection and behave aggressively

Fig. 81.13 OSCC of the tongue—everted margins. Lesion can behave aggressively often associated with tobacco-related habit

Fig. 81.14 OSCC of the tongue—exophytic growth. Lesions have nonaggressive behavior with better prognosis

Fig. 81.15 Another case of OSCC of the tongue—exophytic growth. Lesions have nonaggressive behavior with better prognosis

Fig. 81.17 OSCC of the tongue—non-ulcerative patch. Lesion is frequently associated with smoking

Fig. 81.18 OSCC of the tongue—verrucous growth. Lesion generally has dormant behavior with better prognosis

Fig. 81.19 Intraoperative picture. Multiple primary tumors—SCC in OSMF. Rt.GBS/BM—resected, with Tongue-Rt. side. Either of these can be considered as Second Primary Tumour (SPT)

81.6 Imaging in OSCC Diagnosis

The minimum radiologic investigation for the primary site and neck should include imaging from the skull base to the clavicle. Staging of the chest is to detect both metastatic disease and synchronous tumors. MRI and/or CT with contrast is considered to be the gold standard. In poorer socioeconomic background, one could consider ultrasound scan of the neck as a staging modality. This will however not adhere to the current international guidelines. In our units the minimum standard is a MRI of the neck (including the primary) and CT chest. A double-contrast CT of the neck is as valuable as a MRI. Radiologic examination provides a greater accuracy in the staging process. Prognosticators such as depth of invasion and extracapsular spread in lymph nodes can be studied with good accuracy.

Where there is involvement of bone, a MRI and CT will provide better definition for resection. Marrow signal changes can only be evaluated on a MRI. The CT provides

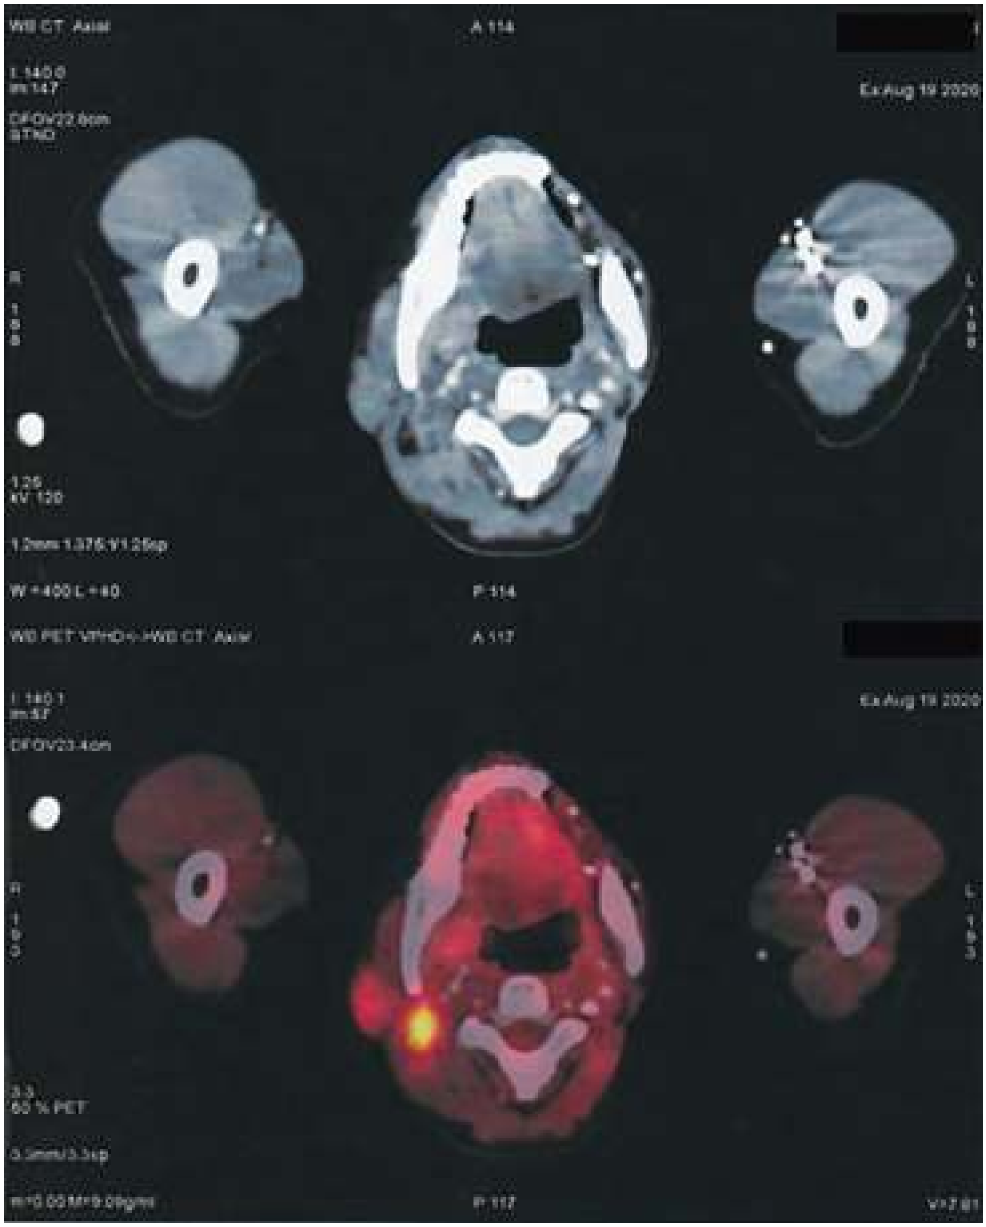

Fig. 81.20 PET-CT-SCC—Contralateral neck metastasis, at IIA, of second primary in Lt. Maxilla

better information on cortical erosion. In addition a thin slice CT helps in 3D planning prior to free flap reconstruction.

The role of a PET-CT is limited. Its primary indication is to detect an unknown primary prior to targeted biopsy. A further role for the PET-CT is in post-radiotherapy evaluation of the neck (Fig. 81.20).

MRI scans offer better accuracy of soft tissue extension of tumor. Studying fat planes between muscle groups allows for compartment resections in T4 tumors.

81.7 Tissue Sampling

Incisional biopsy is the gold standard in the diagnosis of squamous cell carcinoma. FNAC is used for the detection of lymph node metastasis. However with the increased accuracy in MRI and USS reporting, this modality is used less. Biopsy tissue should be taken from the most indurated portion of the tumor. Taking a biopsy from the summit or the center of an ulcer may yield a false-negative result. Scalpel, punch, and low-voltage electrocautery are all good options. Minimum size of the sampled tissue should be ideally 6 mm in all three dimensions. Mapping biopsy from multiple sites may be required at times to evaluate the extent of involvement and to prevent a false-negative result. This is especially the case when a tumor develops in the background of a premalignant lesion.

Deep biopsy is required to get estimation on the depth of invasion (DOI). In cases of exophytic lesions, tumor thickness may cause difficulty in getting deeper tissue; in such cases tumor margin area can be chosen. In order to obtain a good-quality oral biopsy, the clinician should avoid crushing the sample with the tissue-holding forceps, infiltrating anesthetic solution within the lesion, using an insufficient volume of fixing solution and taking insufficient amount of tissue in extension and depth. The specimen should be handled gently, avoiding any crushing, and introduced in the fixing solution such as 10% formalin.

In inaccessible areas, due to the site of tumor or reduced mouth opening, it is good practice to carry out an examination under anesthesia to evaluate the extent of the tumor. This also provides an opportunity for the lesion to be accurately biopsied in a more controlled environment of theaters.

81.7.1 Histopathology

Pathologist is expected to report on the tumor grade—well-differentiated squamous cell carcinoma, Grade 1; moderately differentiated squamous cell carcinoma, Grade 2; or poorly differentiated squamous cell carcinoma, Grade 3. Well-differentiated tumors resemble normal squamous epithelium to a large degree (Fig. 81.21), poorly differentiated tumors exhibiting little or no histologic traits of the squamous phenotype, and moderately differentiated tumors having an intermediate morphology between the two ends of the spectrum. Higher grades have strong potential for recurrence and lymph node metastasis [19].

Several prognostic indicators have consistently demonstrated a correlation with disease-specific survival, local and regional recurrence, and lymph node metastasis in numerous single or multicenter studies. The prognosticators are depth of invasion (DOI), pattern of invasion (POI), perineural invasion (PNI), lymphovascular invasion (LVI), and extranodal extension (ENE).

81.7.2 Depth of Invasion/Tumor Thickness

It is important to differentiate between depth of invasion and tumor thickness. The DOI is a more predictable prognosticator compared to the latter. It is known that exophytic tumors (verrucous carcinomas being the prototype) or predominantly exophytic tumors have a good prognosis, whereas endophytic or deeply infiltrating tumors are aggressive [20]. Depth of invasion (DOI) is an important independent factor in prognosis with strong effect on disease-free survival and overall survival, correlating with propensity for nodal spread better than tumor size in oral cancer [21–25]. In the floor of the mouth, 1-cm-wide tumor infiltrating at 0.7 cm depth will likely have a worse outcome and carries a higher risk of neck metastasis than a 2-cm-wide tumor with microinvasion or superficial invasion (e.g., less than 2 mm in thickness) [26–28].

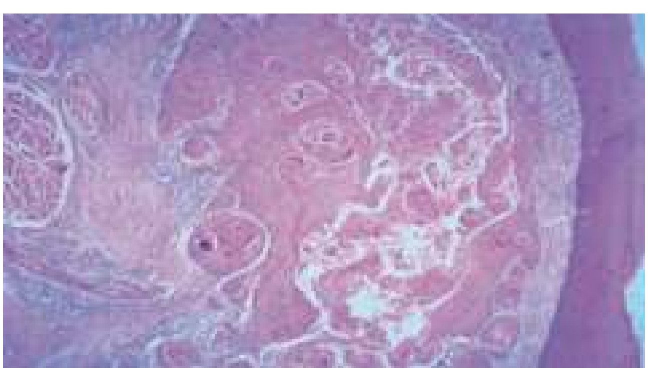

Fig. 81.21 Well-differentiated OSCC. H&E 10x

81.7.3 Pattern of Invasion

Pattern of tumor invasion is an important prognostic factor. Tumor interface abutting deeper tissues has better prognostic value as compared to multiple tumor satellites into the deeper tissues [20].

81.7.4 Perineural Invasion (PNI)

PNI presence is a soft indicator for local recurrence and decreased survival. Multiple studies have shown conflicting results [29]. However it is one of the most important predictors of neck metastasis [30] alongside DOI. PNI increases the rate of occult metastasis [31].

81.7.5 Lymphovascular Invasion (LVI)

Histopathological presence of lymphovascular invasion has poorer prognostic outcome. The presence of LVI is associated with nodal spread or occult metastases [23, 32–34]. Literature review has conflicting evidence regarding the importance of LVI.

81.7.6 Bone Invasion

It is common to see OSCC of GBS and retromolar trigone (RMT) invade the adjoining mandible, maxilla, and pterygoid column. This upstages the tumor to a T4.

The increased risk of local recurrence can be attributed to two factors—tumor character and margin status following resection. Invasion into the pterygoid spaces makes surgical resection difficult. Close margin is expected in these advanced tumors.

Mandible infiltration can be of periosteal fixation, cortical erosion, or medullary invasion. Deeper invasion has poor prognosis [35] (Fig. 81.22).

Fig. 81.22 OSCC with bone invasion. H&E 10X

81.8 Neck Assessment in OSCC

A positive neck node is the single most important prognosticator for disease-free survival at 5 years. Size, number of levels involved, fixation to adjacent structures, and extranodal extensions (ENE) are of significance in lymph node assessment of the neck.

In a N0 neck, the pickup rate of a sub-centimeter positive node is less than 50% on clinical examination alone. Use of radiologic examination increases the pickup rate to 90%. A staging neck dissection is the only modality that has a pickup rate greater than 98% [36–38].

A well-lateralized tumor often spreads to the ipsilateral neck. In 5% of patients, the first echelon can be the contralateral neck. Tongue cancers have the propensity for skip metastasis and contralateral spread. For all other regions of the oral cavity, the first echelon spread is at level I/II.

Depending on the literature one reads, the specificity and sensitivity between MRI and CT are confusing. The authors recommend that the radiologist choose the modality he has the greatest confidence in reporting. Ultrasound scan as a screening tool is useful in the outpatient setting.

Radiologic signs of nodal involvement are increases in size of the lymph node, obliteration of the fatty hilum, increased vascularity, an ill-defined outline, and intranodal necrosis. Ten millimeters or more in an axial section are considered positive for nodal involvement in the neck. However, false-positive or false-negative results of 15–20% are noted in the literature [39, 40].

81.9 Distant Metastasis

Distant metastasis needs to be suspected in lungs and vertebrae. Evaluation is done by CT alone or a PET-CT scan.

81.10 TNM Staging System

Cancer staging can be divided into a clinical stage and a pathologic stage. In the TNM (Tumor, Node, and Metastasis) system, clinical stage and pathologic stage are denoted by a small "c" or "p" before the stage (e.g., cT3N1M0 or pT2N0). This staging system is used for most forms of cancer. Accurate staging is critical as treatment is often based on clinical and radiologic stage.

Currently AJCC eighth Edition is used; this includes both the depth of primary tumor invasion and extracapsular extension of lymph node metastases. The AJCC eighth Edition OSCC staging system showed improved disease-free survival discrimination between overall stages and between T categories, while AJCC seventh Edition did not [19].

81.10.1 AJCC Eighth Edition Clinical Staging System

T—Primary tumor.
Tx—Primary tumor cannot be assessed.
Tis—Carcinoma in situ.
T1—Tumor ≤ 2 cm in greatest dimension, ≤ 5 mm depth of invasion (DOI not tumor thickness).
T2—Tumor ≤ 2 cm with DOI > 5 mm or tumor > 2 cm and ≤ 4 cm with DOI ≤ 10 mm.
T3—Tumor > 2 cm and ≤ 4 cm with DOI > 10 mm or tumor > 4 cm with DOI ≤ 10 mm.
T4—Moderately advanced or very advanced local disease.
T4a—Moderately advanced local disease.

Lip: tumor invades through cortical bone or involves the inferior alveolar nerve, floor of the mouth, or skin of the face (i.e., chin or nose).

Oral cavity: tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face). Note: Superficial erosion of bone/tooth socket (alone) by a gingival primary is not sufficient to classify a tumor as T4.

T4b—Very advanced local disease. Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery.

Regional lymph nodes (N) ENE—extranodal extension.

Nx—Regional lymph nodes cannot be assessed.

N0—No regional lymph node metastasis.

N1—Metastasis in a single ipsilateral lymph node, ≤ 3 cm in greatest dimension and ENE (−).

N2—Metastasis in a single ipsilateral lymph node, > 3 cm but ≤6 cm in greatest dimension and ENE (−); *or* mets in multiple ipsilateral lymph nodes, ≤ 6 cm in greatest dimen-

Table 81.1 AJCC prognostic staging groups according to the eighth AJCC edition

Clinical group	T	N	M
0	Tis	N0	M0
I	T1	N0	MO
II	T2	N0	MO
III	T3 T1 T2 T3	N0 N1	MO MO
IVA	T4a T1T2T3T4a	N0 N1, N2	MO M0
IVB	T4b Any T	Any N N3	MO M0
IVC	Any T	Any N	M1

sion and ENE *(−); or* mets in bilateral or contralateral lymph nodes, ≤ 6 cm in greatest dimension and ENE (−).

N2a—Metastasis in single ipsilateral lymph node >3 cm but ≤6 cm in greatest dimension and ENE (−).

N2b—Metastasis in multiple ipsilateral lymph nodes ≤6 cm in greatest dimension and ENE (−).

N2c—Metastasis in bilateral or contralateral lymph nodes ≤6 cm in greatest dimension and ENE (−).

N3—Metastasis in a lymph node >6 cm in greatest dimension and ENE *(−) or* metastasis in any lymph node(s) with clinically overt ENE (+).

N3a—Metastasis in a lymph node >6 cm in greatest dimension and ENE (−).

N3b—Metastasis in any lymph node(s) with clinically overt ENE (+).

Distant metastasis (M).

M0—No distant metastasis (no pathologic M0; use clinical M to complete stage group).

M1—Distant metastasis.

AJCC prognostic stage groups are provided in Table 81.1.

81.11 Treatment Planning for the Management of Head and Neck Malignancy

81.11.1 Introduction

The management of head and neck cancer has undergone a sea change since the 1980s. The most important change that has been to the benefit of both patients and clinicians is the emphasis on evidence-based practice, and this has led to the development of the multidisciplinary team (MDT) or the tumor board as it is also known as.

In the more recent past, a new thought process is the practice of realistic medicine. The emphasis is on a more personalized approach to patient care and changing our style to shared decision-making. This is an approach that has been rolled out across Scotland.

81.11.2 MAGIC: Making Good Decisions in Collaboration

The key questions to be asked are:

1. Is this test, treatment, or procedure really needed?
2. What are the potential risks and benefits?
3. What are the potential side effects?
4. Are there alternative simpler, safer treatment options?
5. What would happen if one did nothing?

81.11.3 The Start of Treatment Planning

The beginning of planning treatment starts on the receipt of a referral or patients' attendance. Patients with a history of a neck or salivary gland lump, non-healing ulcer of the oral cavity, bleeding, pain refractory to analgesia, hoarseness, and dysphagia are seen in the clinic within 2 weeks. Clinical examination should include the examination of the tongue base, tonsils, larynx, and nasopharynx with flexible nasoendoscope.

Developing a one-stop clinic helps in avoiding delays, and this has a significant impact on patients' psychological well-being. The one-stop clinic includes a biopsy on the same day for visible lesions and an ultrasound-guided core biopsy of neck lumps. The results of these preliminary investigations should be available in a week, setting up for a second meeting.

81.11.4 The Second Meeting

The second meeting or breaking bad news is perhaps the most important consultation in treatment planning. Patients are invited to attend the clinic with members of their family. Consultation is held in a quiet atmosphere in the presence of a clinical nurse specialist. It is important to be factual and honest. Unrealistic expectations should not be given. One must also bear in mind the impact the diagnosis will have on patients and their families. Empathy is very important. A good rapport with the patient and their family is invaluable.

81.11.5 Staging Scans

The minimum staging scans for head and neck cancer include a MRI and/or CT neck and CT chest. The rationale for staging is localization of the tumor and detection of regional and distant lymph node metastases. This has an importance in both the extent of therapeutic intervention and the disease-specific survival.

81.11.6 Localization of Primary Tumor

The localization of the primary tumor helps in the decision-making regarding the resectability of the lesion with clear margins. Tumor resection with a R1 margin is considered a futile procedure, and at the best it is palliative and at its worst just a “big biopsy.” Anatomical areas of interest in localization are the skull base with particular interest to the carotid canal, involvement of the infratemporal fossa, the extent into the orbit, and in the case of tongue tumors proximity to the tongue base and larynx. Involvement of any of the above structure carries a very high risk of a positive or close margins resulting in increased risk of recurrence. Adjuvant treatment would then be inevitable. Functional outcomes are poorer.

MRI of the soft tissues is our preference for localization of the tumor as it helps in planning anatomic resection by determining the depth of infiltration. This can be in the form of compartment resection—medial masticatory compartment resection for retromolar, soft palate, and posterior tongue tumors. Anatomical resections in tongue tumors uses muscle planes to identify margins and vascularity of the remainder tongue. The muscle groups most important to this are the mylohyoid, styloglossus, and stylohyoid. With tumors extending to the infratemporal fossa and skull base, a key landmark is the styloid. Prestyloid resections are considered straightforward, and a R0 margin is to be expected. Tumors in the poststyloid space carry the risk of a close margin.

Tumors involving the mandible and maxilla, in our practice, have a CT and MRI. The MRI helps in determination of marrow signal change and gives an aid to planning resection margins. The CT has a two fold advantage. CT helps localize cortical breach and complements the MRI in planning resection. It has also the added advantage of obtaining 3D models which helps in planning bone reconstruction with a free flap.

For malignancies of the salivary glands, our first line of investigation remains an USS-guided core biopsy followed by a full staging of the neck and chest with MRI and CT, respectively. Tumors of the skull base and infratemporal fossa have both MRI and CT for localization of the primary.

For patients with suspected recurrence, especially under a free tissue flap transfer, the preferred modality is a PET-CT. PET-CT allows for a functional evaluation of the suspect area. In areas of previous surgery, the MRI has higher false-positive rates due to loss of fat planes and the inability to differentiate from scarification. A double-contrast CT scan may give better definition of a recurrence; however both specificity and sensitivity are low. The CT may give better spatial resolution. However false-negative results are high in glottic tumors and in mucosal disease with superficial spread with CT.

The role of PET-CT in our practice is limited to neck lumps with unknown primary, small malignancies and in recurrent SCC. The major drawback for a PET-CT is poor anatomical depiction. Anatomical resection is not possible with a PET-CT alone. PET-CT adds little value in patients who have had recent surgery, i.e., biopsy. This invariably gives rise to a hot spot in inflamed tissue. However, it is more sensitive than CT and MRI in detecting small malignancy. In more than 30% of cases, the PET-CT picks up malignancy not identified by other modalities, and the majority of these are at the tongue base and supraglottic space.

Direct evaluation by examination under anesthesia and pan endoscopy provides probably the most accurate assessment for localization and planning surgery.

81.11.7 Evaluation of the Neck

There are numerous papers regarding the sensitivity and specificity of different evaluation techniques—clinical examination, duplex ultrasound scan, CT scan, MRI, and PET. It is agreed by all that clinical examination of the neck provides the least reliable results of all and an adjunct investigation is necessary. It is the opinion of the authors that both CT and MRI give equally reliable results. The decision to which modality suits an individual team the best is reliant on the expertise of the head and neck radiologist in reporting the scans. In our own clinical practice, we feel that the MRI scan provides a good diagnostic value for staging the neck. In T1 tumors where there is a N0 neck clinically and radiologically, the evidence for staging neck dissection is limited. In cases where the MRI is equivocal, an USS with a FNAC (fine needle aspiration cytology) may be indicated. The USS would evaluate the lymph node for size criteria, presence of necrosis, and the absence of normal hilum. Lymph nodes that are rounded and greater than 1 cm in the neck are regarded to be pathologic until proven otherwise.

The role of USS should not be easily dismissed with the advent of cross-sectional imaging. The USS has many advantages. The spatial resolution of a good USS is better than that of a CT or MRI. Taking account of shape, contour, echogenicity, grouping, internal architecture, necrosis, and pattern of Doppler vascularity enhances the accuracy of US for nodal metastases to greater than 90%.

The USS is a cheap and quick modality that can be used. There is no radiation exposure. Its use as a surveillance scans cannot be surpassed in today’s economic constraints. The one major drawback we have noted in our practice is that its sensitivity and specificity are highly operator dependent. It cannot detect retropharyngeal, retrotracheal, and mediastinal lymphadenopathy. In these instances a CT or MRI gives better information.

PET-CT has a limited role in the staging of the neck. PET-CT is a useful tool to look at post-chemoradiation treatment response and to evaluate the neck following radiotherapy with residual neck mass. In the head and neck, misregistration of PET to CT can cause difficulty in reporting and increase false-positive results.

81.11.8 The Role of Sentinel Node Biopsy

The presence of metastatic disease to the neck is an important prognostic factor for disease-free survival in head and neck cancer. Recent papers by Anil D Cruz et al. have shown that patients who had an elective neck dissection fared much better than those on the watchful waiting strategy in both T1 and T2 tumors [29].

Sentinel node biopsy relies on the fact that metastases to the regional lymph nodes follow a predictive pattern in most cases. Migration of cancer cells is often to the first echelon node. It is therefore predicted that if the first echelon node is negative, the more distal node is unlikely to have cancer cell migration. Validation studies involving elective neck dissection have shown that there is 95% detection rate in sentinel nodes. The first echelon node in most oral cancers is at level I or level II. In a well-lateralized tumor, the first echelon node more often than not is on the ipsilateral side.

The indications for a sentinel node biopsy are:

1. T1/T2 tumors which are node negative on staging scans.
2. To assess the need for bilateral neck dissection in tumors close to or just crossing the midline.
3. To clarify the need for contralateral neck dissection in large tumors.

Proponents of SLN biopsy claim the following advantages: reduces the morbidity of elective neck dissection, more accurate staging of the neck, and better prediction in those who have an unpredictable pattern of metastatic disease, therefore guides decision-making, helps identify skip metastases and micrometastases, and saves time and expense.

It is the opinion of the authors that sentinel node biopsy is a very good adjunct. Recent meta-analysis and systematic reviews suggest that high sensitivity, negative predictive value, and accuracy of SNB make this a valid diagnostic tool. NICE (National Institute of Clinical Excellence) guidelines recommend that a SLNB should be offered to all patients with T1 and T2 tumors with a node-negative neck. A word of caution, however, for T1 and T2 tumors with a tumor thickness greater than 5 mm, an elective neck dissection may still be indicated.

81.11.9 The Multidisciplinary Team

Following completion of all diagnostic requisites, the findings are discussed at the weekly MDT or the tumor board meeting. The MDT has a core group of clinicians and healthcare professionals. The MDT comprises of maxillofacial surgeons, ENT surgeons, oncologist, speech and language therapist (SALT), dietician, clinical nurse specialist (CNS), head and neck radiologist, head and neck pathologist, restorative dentist, and cancer audit officer to collect data. We have two clinicians from each of the subspecialties at our MDT. The MDT should not be regarded as a forum to advance individual pride or agenda. This is a group that helps balance evidence base in the management of patients and makes a realistic recommendation of treatment strategy.

The responsibility of the MDT is to protect and facilitate the patients' pathway through cancer treatment. The first and foremost recommendation made by the MDT is the treatment intent—curative or palliative. This is followed by the treatment strategy—surgery or radiotherapy ± chemotherapy (Refer Chap. 84 to read about Adjunctive therapy in oral cancer).

At our MDT, the nature of surgery or the form of reconstruction is rarely discussed. The certainty of achieving tumor clearance and potential morbidity associated with the treatment form the majority of the discussions. Speech and language team assess the need for potential future PEG (gastrostomy) or nasogastric feed. Where there is a high index of suspicion that a PEG feed will be necessary, this is done pre-treatment. Dieticians help in planning feeding regimes both pre- and postoperatively. The restorative dentist offers an opinion on unrestorable teeth that need to be extracted at the time of surgery or prior to chemoradiation to reduce the incidence of future osteoradionecrosis.

81.11.10 Planning Reconstruction

The choice of reconstruction is numerous (Refer Chap. 82 to read about principles of surgical management of oral cancer. Chapter 85 deals with the access osteotomies to maxillofacial region while Chaps. 86 and 88 deals with soft and hard tissue reconstruction respectively). The preferred choice is dependent on the following factors:

– Patient's overall health to withstand long surgery.
– Associated postoperative functional deficit if no reconstruction is carried out.
– Skill of the surgeons.
– Socioeconomic factors.

The best form of reconstruction is to try and substitute like for like. A simple but effective way of looking at reconstruction would be:

- Flaps for lining the defect in T2 defects—radial forearm free flap, anterolateral thigh perforator flap (ALT), medial sural artery free flap, submental flap, nasolabial flaps.
- Flaps that are required for increasing bulk or low volume—anterolateral thigh flap, pectoralis major flap.
- Flaps for major resection which require high volume—rectus flap, latissimus dorsi flap.
- Flaps for lining the pharynx—radial forearm free flap, ALT, pectoralis major flap.
- Skull base defects that require a long pedicle—rectus abdominis flap, ALT, or latissimus dorsi free flap.
- Bone reconstruction—fibula free flap, DCIA (deep circumflex iliac artery) flap, scapula flap.
- Composite defect—combination of the above or scapula flap.

81.11.11 Conclusion

A good functional MDT that practices evidence-based medicine with a realistic approach that is patient centered will be an effective oncology team that will deliver high-quality care for patients.

82 Principles of Surgical Management of Oral Cancer

Sushma Mehta and Moni Abraham Kuriakose

82.1 Introduction

Management of oral cavity cancers in a curative intent setting mainly involves surgery. The other treatment modalities such as radiotherapy and chemotherapy are most commonly used as adjuvant treatment based on the histopathological features. However, it is to be noted that surgery alone is insufficient to treat oral cancer. Chemotherapy is either concurrent with radiotherapy or in very rare scenario used as induction therapy. The primary cancer treatment and risk factor reduction are of utmost importance to improve effectiveness of the primary treatment and to prevent development of second-primary cancers.

Ablative surgery has evolved over the years with the attempt to extirpate the tumor in its entirety with the understanding of the molecular tumor biology, pattern of tumor invasion of the tumors, as well as availability of better instrumentations.

With the advent of endoscopic assisted and robotic-assisted neck dissection, the branch of oral oncology has truly made progress, thus improving visualization and three-dimensional navigation; however it is still in its infancy and needs further research to understand the benefits over the conventional methods.

This chapter outlines details of ablative surgery and rationale for addressing neck (node positive/node negative) in patients with oral cavity cancers.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_82) contains supplementary material, which is available to authorized users.

82.2 Initial Evaluation and Staging

Initial evaluation as for any other medical condition includes history, a clinical examination and investigations to form a diagnosis. The other two important aspects influencing management of oral cavity cancer (mainly squamous cell carcinoma) are habit history and performance status. Table 82.1 describes the performance status scales.

Staging of the disease is particularly important as it helps the clinicians in better communication in a scientific forum and forming a treatment plan for a patient. Various phases in management of oral cancer include accurate diagnosis, appropriate treatment plan, and execution of the advised treatment with relevant reconstruction, rehabilitation, and surveillance. So, to help clinicians in decision-making, there are several guidelines that exist. As these guidelines have a more generalized approach, it is the clinician's knowledge

Table 82.1 Performance status scale: Zubrod scale and Karnofsky scale

Performance Status Scales [1]	
Zubrod scale	Karnofsky scale
"0" normal activity	"100" normal; no evidence of disease
	"90" able to perform normal activities with only minor symptoms.
"1" symptomatic and ambulatory cares for self	"80" normal activity with effort; some activities
	"70" able to care for self but unable to do normal activities
"2" ambulatory >50% of the time; occasional assistance	"60" requires occasional assistance; cares for most needs
"3" ambulatory ≤50% of the time; nursing care needed	"50" requires considerable assistance
	"40" disabled; requires special assistance
	"30" severely disabled
"4" bedridden	"20" very sick; requires active supportive treatment
	"10" moribund

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_82

and understanding and experience which will help in tailoring the treatment plan to each individual distinctly. This individualized approach cannot be implemented unless there are multidisciplinary tumor board meetings, which are crucial for clinicians practicing oncology and hence provides team-based practice keeping the patient in mind [2–4]. This is best done before initiating the treatment.

To be able to know the extent of disease and decide the intent and modality of treatment, imaging plays a very important role. Precise imaging information is needed to determine the locoregional extent, erosion, and involvement of underlying bone and marrow space, lymph node involvement and to rule out distant metastasis—especially to the lungs. However the dilemma that most clinicians face is which is the imaging modality of choice for different clinical scenarios. In the following section, we attempt to provide indications of each imaging type available, which probably will help the clinicians in deciding what suits their needs.

Plain radiography is restricted to evaluation of pathological fractures or initial benign lesions. Contrast-enhanced computed tomography (CECT) is considered as the most popular, easily available, and cost-effective diagnostic imaging. It is the imaging modality of choice to know the presence of bone erosion and lymph node characteristic. Bony expansion is usually a feature of slow-growing/benign disease process; however destruction of bone and replacement by the tumor depicts the aggressiveness and hence is a feature of malignant process (Figs. 82.1, 82.2, 82.3 and 82.4).

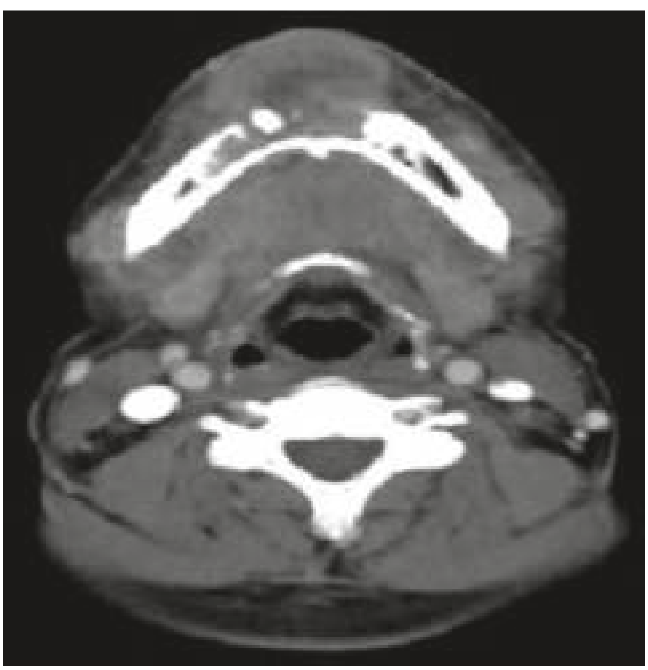

Fig. 82.1 Axial section of contrast enhanced CECT showing an ill-defined heterogeneously enhancing mass lesion along the mandibular alveolus involving the central lateral incisors and canines with erosion of body of mandible

Fig. 82.2 Sagittal section of the patient same as Fig. 82.1 to depict the extent of bony erosion and involvement providing a guide for the osteotomy

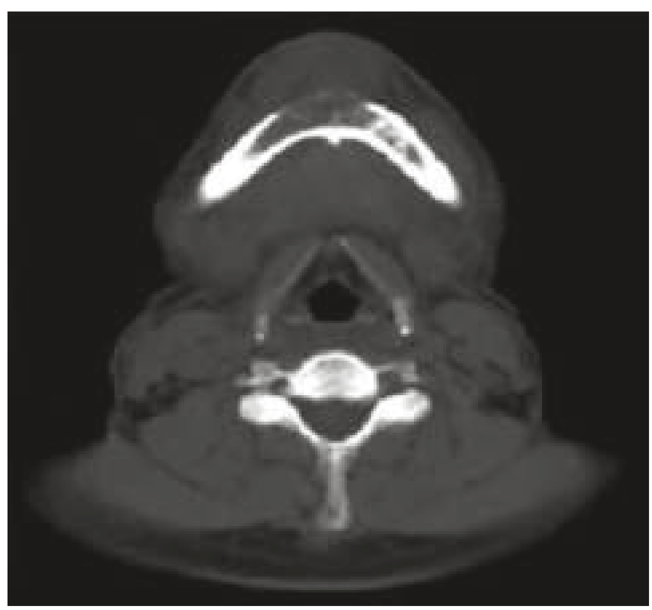

Fig. 82.3 This is axial section in bony window for exact extent of bony erosion

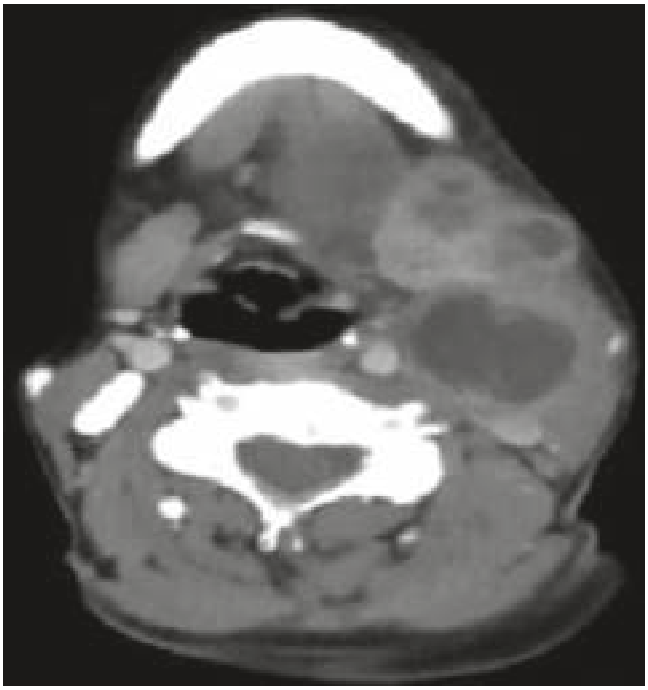

Fig. 82.4 Axial section—contrast-enhanced computed tomography. A heterogeneously enhanced conglomerate of the lymph nodal mass at left level II with cystic areas highly suspicious of metastatic lymphadenopathy. The mass has partially compressed internal jugular vein and pushed it posterolaterally

Magnetic resonance imaging (MRI) is usually indicated as an adjunct as it has better soft tissue delineation. It is also used for assessing dural invasion (linear or nodular), medullary bone involvement, and perineural invasion. Radiographic assessment of tumor extent is invaluable for treatment planning. In case of tongue cancers, MRI has gained popularity for assessment of tongue cancer especially as it is helpful in identifying tumor thickness, involvement of the contralateral side, and involvement of extrinsic muscles. With recent addition of depth of invasion in the AJCC classification for staging, MRI has proven its role. As for buccal mucosa tumors, assessment of masticatory muscles involvement is crucial because it has historically been considered unresectable. However, according to Liao, infranotch lesions are still amenable for resection with favorable oncological outcome.

As oral cancers usually metastasize first to the lung, pre-operative chest imaging is a part of initial pre-operative work-up. This can be in the form of either plain film or 3D imaging such as computed tomography (CT). Fluorodeoxyglucose positron emission tomography (FDG-PET) scan has emerged as the imaging modality of choice in patient with recurrence and high clinical suspicion for distant metastasis (Figs. 82.5, 82.6, 82.7 and 82.8).

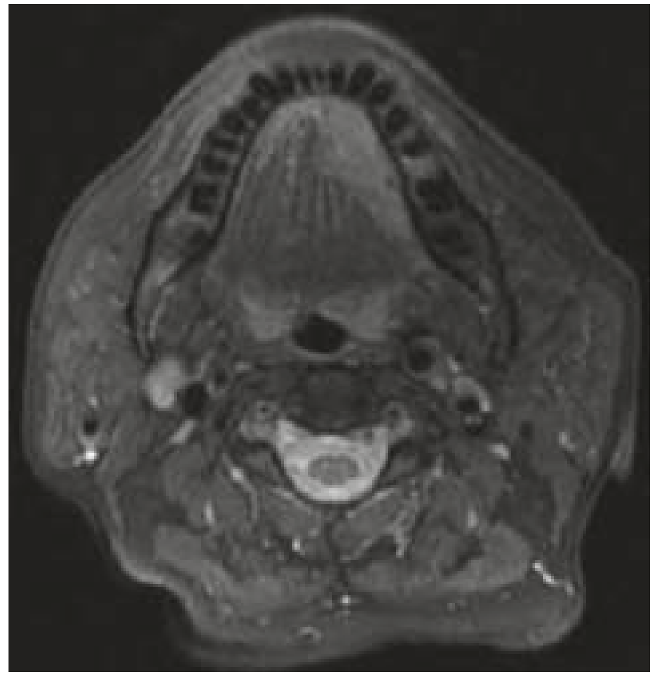

Fig. 82.5 The contrast-enhanced T1-weighted MRI images depicting hyperintensity involving the left lateral tongue with extension till the midline and involving tip of the tongue

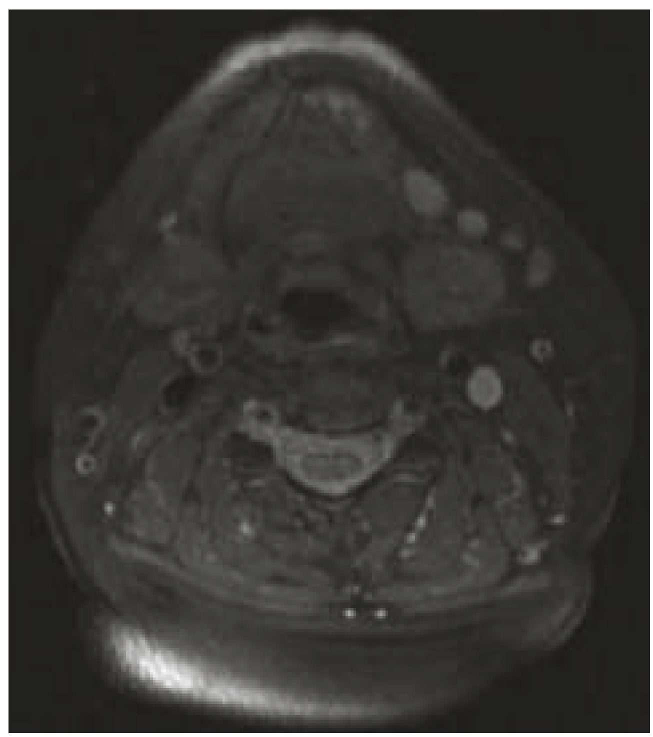

Fig. 82.6 Axial section of an MRI (T2-weighted) showing multiple lymph node metastasis at level IB

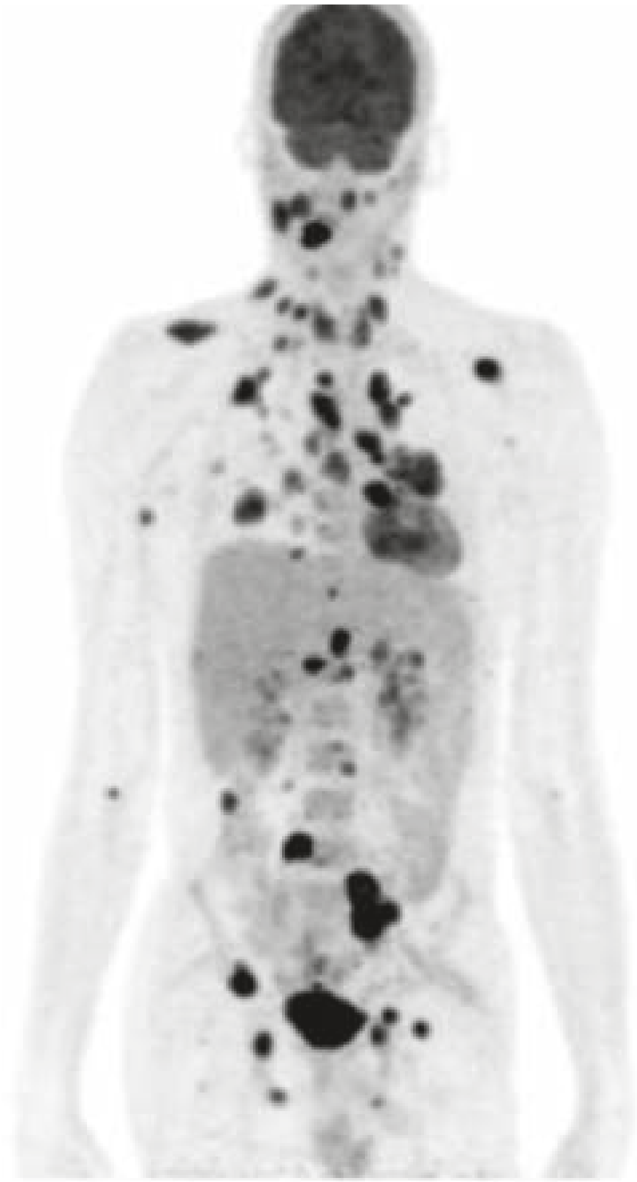
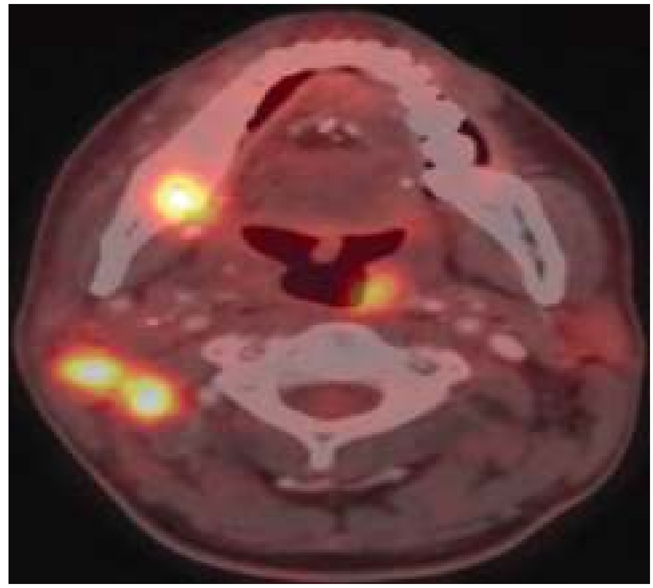


©Association of Oral and Maxillofacial Surgeons of India

Fig. 82.7 This is the whole body image of PET-CT scan depicting uptake in the multiple areas suggestive of metastatic disease

It is to be noted that any suspicious lesions in PET-CT scan needs to be corroborated with tissue diagnosis (direct or guided) as there are a subset of lesions with false-positive findings; however, PET-CT is considered to have the highest negative predictive value approaching 100%. Although as per the NCCN guidelines, PET-CT has to be advised for all stage III and IV disease, it is usually reserved for patients with recurrent or second primary disease in a resource-constrained setting [5, 6]. Tables 82.2 and 82.3 provide imaging considerations in oral cavity tumors.

Baseline follow-up imaging is usually done after 3 months, and CECT has established its role in ruling out recurrence/residual disease. To avoid misinterpretation, it is important that the concerned imaging radiologist is familiarized with postoperative sequelae of tissue changes or changes that occur following radiotherapy such as nonspecific tissue thickening, edema, or fibrosis and various bony and soft tissue reconstruction methods to facilitate interpretation.



©Association of Oral and Maxillofacial Surgeons of India

Fig. 82.8 FDG PET-CT images to show FDG avid lesion in the right lower alveolus and ipsilateral level II lymph nodes along with uptake in the right nasopharynx. All the lesion have a similar standard uptake value (SUV) of 15 corresponding to the metabolic activity

Staging the disease is developed to provide ease of communication and helps in understanding the prognosis and planning the treatment. AJCC staging system has been followed for years and provides concise information on size characteristics and extent of primary tumor and involvement of lymph nodes. The recent eighth edition has features like tumor thickness, depth of invasion, and extranodal extension (clinical and pathological).

82.3 Category for Oral Cavity Cancer, Eighth Edition Staging Manual

Table 82.4 provides the categorization for oral cavity cancer [6].

82.4 Principles of Surgical Management

In majority of oral cavity squamous cell cancers, surgery has been the mainstay of treatment, and hence, the need to know intricate surgical aspects has to be emphasized. As there has been improved understanding of disease pattern, biologic behavior of the disease at the molecular level, and the poten-

Table 82.2 Imaging in oral cavity tumors

Radiological means	Indications	Advantages/ Challenges
Computed tomography (CT)	Mainstay for imaging primary disease.	• Bone details. • Obscured to dental artifacts. • Early perineural spread can be missed [7].
Magnetic resonance imaging (MRI)	• Assessment of primarily oral tongue, floor of mouth, and hard palate lesions or bone marrow involvement along with assessment of nasopharyngeal, parotid, sinonasal tumors. • Useful in providing information on encasement of carotid arteries. • Promising results in early detection of perineural extension and detection of dural involvement or intracranial extension.	• Better contrast resolution. Superior detection of tumor spread into bone marrow. • Swallowing artifacts [8].
Ultrasonography (USG)	• To identify lymph node metastases. • For assessment of tumor spread in tongue carcinoma, when MR imaging is contraindicated or unavailable [9].	
Positron emission tomography (PET)	• Diagnosis of an unknown primary tumor, assessment of distant metastasis, response to therapy, surveillance/ detection of recurrence. • Limited role in neck node evaluation.	• Better localization of activity to normal vs abnormal structures, better identification of inflammatory lesions [5].

Table 82.3 Imaging considerations for various sites

Neck nodes	USG-guided FNAC—100% specificity [10, 11]
RMT	• To look for bone erosion—Cortical bone or marrow involvement. • To detect spread of lesion along pterygomandibular raphae.
Palate	• To assess invasion of maxillary sinus, palatal bone, and nasal vault. • Depth of invasion dictates extent of resection.
Infratemporal fossa	• Pterygomandibular raphae provides pathway of spread of lesion into ITF. • CT & MRI are useful.
Tongue	• MRI is preferred; surrounding structure involvement will help in deciding the extent of resection [12, 13].
Bone invasion	• MRI is superior for evaluating medullary space of mandible but inadequate for assessing cortical invasion.

Table 82.4 Category for oral cavity cancer, eighth edition staging manual [6]: Definition of primary tumor (T)

T category	T criteria
TX	Primary tumor cannot be assessed
Tis	Carcinoma in situ
T1	Tumor ≤2 cm with depth of invasion (DOI)* ≤ 5 mm
T2	Tumor ≤2 cm with DOI* > 5 mm Or tumor >2 cm and ≤ 4 cm with DOI* ≤ 10 mm
T3	Tumor >2 cm and ≤ 4 cm with DOI* > 10 mm Or tumor >4 cm with DOI* ≤ 10 mm
T4	Moderately advanced or very advanced local disease
T4a	Moderately advanced local disease Tumor >4 cm with DOI* > 10 mm Or tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla or involves the maxillary sinus or skin of the face) Note: Superficial erosion of bone/tooth socket (alone) by a gingival primary is not sufficient to classify a tumor as T4
T4b	Very advanced local disease Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery
*DOI is depth of invasion and not tumor thickness	
T suffix	**Definition**
(m)	Select if synchronous primary tumors are found in single organ
Definition of regional lymph node (N) clinical N (cN)	
cN	Category cN criteria
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension ENE(−)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−) Or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−) Or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, and ENE(−)
N2a	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension, and ENE(−)
N2b	Metastases in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension, and ENE(−)
N2c	Metastases in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); Or metastasis in any node(s) and clinically overt ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in any node(s) and clinically overt ENE(+)
Note: A designation of "U" or "L" may be used for any N category to indicate metastasis above the lower border of the cricoid (U) or below the lower border of the cricoid (L). Similarly, clinical and pathological ENE should be recorded as ENE(−) or ENE(+)	
N suffix	**Definition**
(sn)	Select if regional lymph node metastasis identified by SLN biopsy only
(f)	Select if regional lymph node metastasis identified by FNA or core needle biopsy only
U	Metastasis above the lower border of the cricoid

(continued)

Table 82.4 (continued)

N suffix	Definition
L	Metastasis below the lower border of the cricoid
Pathological N (pN)	
pN category	pN criteria
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(−)
N2	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(+) Or larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−); Or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−) Or in bilateral or contralateral lymph node(s), none larger than 6 cm in greatest dimension, ENE(−)
N2a	Metastasis in single ipsilateral node 3 cm or smaller in greatest dimension and ENE(+) Or a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b	Metastases in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c	Metastases in bilateral or contralateral lymph node(s), none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); Or metastasis in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+) Or multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+); Or a single contralateral node of any size and ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+) Or multiple ipsilateral, contralateral or bilateral nodes any with ENE(+); Or a single contralateral node of any size and ENE(+)
Note: A designation of "U" or "L" may be used for any N category to indicate metastasis above the lower border of the cricoid (U) or below the lower border of the cricoid (L). Similarly, clinical and pathological ENE should be recorded as ENE(−) or ENE(+)	
N suffix	Definition
(sn)	Select if regional lymph node metastasis identified by SLN biopsy only
(f)	Select if regional lymph node metastasis identified by FNA or core needle biopsy only
U	Metastasis above the lower border of the cricoid
L	Metastasis below the lower border of the cricoid

Definition of distant metastasis (M)	
M category	M criteria
cM0	No distant metastasis
cM1	Distant metastasis
pM1	Distant metastasis, microscopically confirmed

tial aggressive nature, the need has arisen for several technical modifications in this era. Hence as surgeons, we have to evolve and adapt to the required changes to improve outcomes of ablative surgery (oncological and functional) in patients with squamous cell carcinoma of oral cavity.

For early-stage oral cavity cancers, especially tongue, it has been proven that both surgery and radiotherapy/brachytherapy offer similar outcome (single modality). For advanced lesions with extensive disease, multimodality treatment is required; surgery being the primary modality and followed by adjuvant radiotherapy +/− chemotherapy (depending on the histopathological evaluation) has been the standard of care.

82.5 Treatment Decision Algorithm [14]

Critical decisions which have to be made are as follows:

1. Intent of treatment—curative vs. palliative treatment.
2. Primary modality—surgical vs. non-surgical treatment.
3. Need for addressing neck in clinically node-negative patients.
4. Type of neck dissection in patients with metastatic lymph nodes.
5. Need for adjuvant treatment.
6. Type of adjuvant treatment.
7. Best supportive care.

Decision 1 Primary intent of treatment: This is the first and most critical decision-making point. All patients other than those with technically unresectable tumors, distant metastasis, poor performance status, and major comorbidities precluding surgery must be considered for treatment with curative intent. However, it is to be noted that surgical excision with positive margins portends poor prognosis. Palliative care is usually when patient has distant metastasis and given only to relieve symptoms and control spread. This is in the form of chemotherapy, radiotherapy or metronomics.

Decision 2 Curative modality of treatment: The primary treatment for patients with oral cavity cancers is surgery. However, in selected scenarios, non-surgical treatment may be considered. This includes primary radiotherapy for tumors of the commissure of mouth and lip tumors where surgery can cause significant esthetic and functional disability. In addition, significant comorbidities that preclude long anesthesia may necessitate the need for primary radiotherapy or chemoradiotherapy. However primary chemoradiotherapy has very limited role in treatment of oral cancers.

Decision 3 Management of neck in N0 stage: Even with no radiographic evidence of significant suspicious lymph-nodes, rate of occult metastasis reaches up to as high as 30% [15]. Presence of lymph node metastasis and the number of lymph nodes involved have a direct relation with the prognosis of the disease; decreasing the overall survival rate by 50%. Moreover, a significant subset of metastatic nodes of less than 1 cm can have extranodal extension [16]. This further worsens the prognosis. There is now level I evidence from a randomized control trial, that addressing the neck surgically irrespective of the lymph node status improves overall survival to about 84% when compared to 69% in patients who were selected for wait-and-watch policy [17]. Therefore, almost all the patients with oral cavity cancer should undergo elective neck dissection. A subset analysis of the same study did not show benefit for primary tumors of depth less than 3 mm. This may be considered in selected patients with cancers of lower nodal metastatic prevalence such as lip and buccal mucosa.

Decision 4 Extent of neck dissection in N+ve oral squamous cell carcinoma: Conventional teaching is that any patients with N+ve neck should undergo modified radical neck dissection covering levels 1–5. This has been questioned by several observational studies. Large cohort of patients who have undergone radical neck dissection for N+ve disease has showed less than 3% incidence of level V nodes [17]. This also was observed only when there were pathologically positive level IV nodes [18]. There are reports of oncologic safety for clearing level I–III lymph nodes for alveolus and buccal mucosal cancers and to clear level IV in addition to levels I, II, and III lymph nodes in patients with oral tongue cancers as they bore high risk of skip metastasis [19]. It is to be noted that when a patient is found to have pathological nodal metastasis, in general, it is recommended for adjuvant radiation that covers all levels of the neck with additional boost in the levels which are positive for metastasis.

Decision 5 Indication for adjuvant radiotherapy: Any patients with more than one of the high risk features should be considered for adjuvant radiotherapy.

> This includes (1) nodal metastasis without extracapsular extension, (2) perineural invasion, (3) lymphovascular invasion, (4) poor differentiation, (5) close margin (1–5 mm), and (6) depth of invasion over 1 cm.

But the absolute indication for radiotherapy is stage III and IV disease.

Decision 6 Indication for adjuvant chemoradiotherapy: Meta-analysis of two randomized trials has suggested that in patients with positive surgical margin (<1 mm) and neck nodes with extranodal extension would benefit from adjuvant chemoradiotherapy.

Decision 7 Best supportive care options: This is an important and critical decision. Once the decision for treatment with palliative intent is arrived at, the goal should be made clear with the treating team of doctors and the patient/patient attenders. Ambiguity at this stage may result in loss of trust between the treating team and the patient, causing delay in treatment and possible increase in morbidity. Although this decision is made in the multidisciplinary tumor board, it requires series of meetings with the family to convey the treatment goals. It is also essential to appreciate by treatment group that lack of active treatment does not mean stoppage of care, which needs to be provided by the same team till the end. The quality of death is equally important as quality of life.

The role of best supportive care is to palliate the symptoms the patients may have. In this situation, it is essential to balance the morbidity of treatment versus potential benefit the patient may receive. Often one may have ethical dilemma when faced with young patients with locoregionally advanced tumors. In this situation, temptation of surgery should be tempered. One should consider surgery as palliation to alleviate fungating ulcers or to close a cutaneous fistula. The goal of this surgery must be made very clear to the family. It is essential not to give false hope to the family, which will have deleterious consequence in the patient-physician relationship. In patients with good performance status, especially those who have not received previous radiotherapy, one may consider chemoradiotherapy with curative dose, with the goal to obtain durable palliation. In doubtful situations, induction chemotherapy followed by chemoradiotherapy could also be considered. Local radiation or re-radiation to a limited field may be considered for fungating ulcers. The dose, fractionation, and volume of radiation field need to be tailored for palliative purpose.

In patients with advanced metastatic disease, one needs to be very selective in recommending systemic therapy as the benefit is doubtful. Chemotherapy with targeted anti-EGFr treatment has shown improved survival up to 4 months, with significant morbidity associated with the regimen [20]. An alternate approach is chemotherapy at metronomic dosing regimen, especially the use of methotrexate and celecoxib [21]. Recent evidence of nivolumab, a checkpoint inhibitor, showing improved survival of about 3 months, and acceptable morbidity, is to be considered. However the cost of the treatment is a major deterrent for its wider application. Table 82.5 provides the indications for adjuvant RT and adjuvant CT + RT.

Table 82.5 Indications for adjuvant RT and adjuvant CT + RT

Indications for adjuvant RT		Indications for adjuvant CT + RT
Tumor factors	Nodal factors	
• Perineural invasion. • Lymphovascular invasion +pT3/T4 primary tumor.	• Multiple positive nodes (without ECE). • Positive level IV/V nodes.	• Extra-capsular nodal spread. • Positive margins.
• Bernier J et al. [22]		

82.6 Indications for Adjuvant RT and Adjuvant CT + RT

After various comparative studies, it has been concluded that in adjuvant setting, postoperative IMRT has to be given at dose of 60 Gy in 30 fractions to surgical bed and first echelon nodal stations and the high-risk regions receive a total dose of 66 Gy. It has to be remembered that for salvage surgery cases, concept of re-irradiation should be explained to the patient. A minimum of 12-month duration gap is required prior to re-irradiation to allow for the spinal cord recovery.

In cases with postoperative histopathological features like extranodal extension or positive surgical margins, patients are treated with concurrent chemoradiation (usually 100 mg/m^2 of cisplatin for a maximum of 6 cycles in India). Indication of chemotherapy as described is usually in adjuvant setting in oral cavity cancers.

However role of chemotherapy as induction therapy is evolving. Chemotherapy usually exerts its cytotoxic effects systemically and hence associated with side effects. The major drawbacks of chemotherapeutic agents used commonly are the adverse toxicities and cellular resistance. In an induction setting, most commonly taxanes, platinum, and 5FU are used as 3 cycle regimen (also refer Chap. 84 of this book on Adjunctive therapy in Oral Cancer).

Tumors of oral cavity which are considered technically unresectable are as follows:

- Erosion of skull base, sphenoid bone, and widening of foramen ovale.
- Encasement of internal carotid artery, >270 degree.
- Involvement of mediastinal structures.
- Involvement of prevertebral fascia or cervical vertebrae.

These are considered unresectable not due to surgical technicality but because of the inability to get negative margins and to achieve R0 resection. However, with the superior skills such as endoscopic-assisted surgeries which are associated with less morbidity, and better adjuvant treatment including chemotherapy, an attempt has been made to consider resection of tumors involving muscles of mastication and pterygoid plates especially with the anterior infratemporal fossa involved. Recent studies have shown that surgical resection of these tumors along with adjuvant treatment has shown survival benefit. Also studies from Tata Memorial Hospital, India have shown better outcome in patients who have undergone surgical resection following neoadjuvant chemotherapy.

82.7 Principles of Ablative Surgery

1. Adequate access to the tumor.
2. To achieve negative surgical margins.
3. Utilization of intraoperative frozen section for margin assessment.
4. Wide excision versus compartment resection.

The surgical approaches for tumors of oral cavity depends primarily on the site of tumor (anterior versus posterior), its size, and its proximity to bone (maxilla or mandible). The various approaches frequently used for oral cavity cancers are shown in Figs. 82.9, 82.10, 82.11, 82.12, 82.13, and 82.14 (Also refer Chap. 85 of this book on Access Surgeries and Osteotomies of the Maxillofacial Region).

Types of mandibulotomy is shown in (Figs. 82.15, 82.16a, b) shows marginal mandibulectomy and segmental mandibulectomy.

82.8 Sub-Site-Wise Surgical Management

82.8.1 Tongue and Floor of Mouth

The tongue is a muscular organ which is composed of intrinsic and extrinsic muscles and divided anatomically into the oral tongue (falls in oral cavity cancers) and base of tongue (BOT, sub-site of oropharynx). The tongue is innervated by the hypoglossal nerve, and vascularity is by lingual artery (branch of external carotid artery). Pathway of tumor spread from the oral tongue can be into the floor of mouth, mandible, or/and base of tongue via local extension, the lingual septum being the barrier to tumor spread. For tumors abutting the mandible, marginal mandibulectomy is indicated for negative surgical margin encompassing the tumor and at the same time preserving the mandibular continuity. Segmental mandibulectomy is usually done when there is mandibular erosion or paramandibular spread. Anterior segmental mandibulectomy is more commonly indicated in floor of the mouth cancers.

Fig. 82.9 Lip split incisions; (**a**) midline lip split (straight), (**b**) midline lip split with Z-plasty; (**c**) angle/commissure lip split; (**d**) straight midline with chin contour; (**e**) straight midline with chin contour and Z-plasty at vermilion and submental region

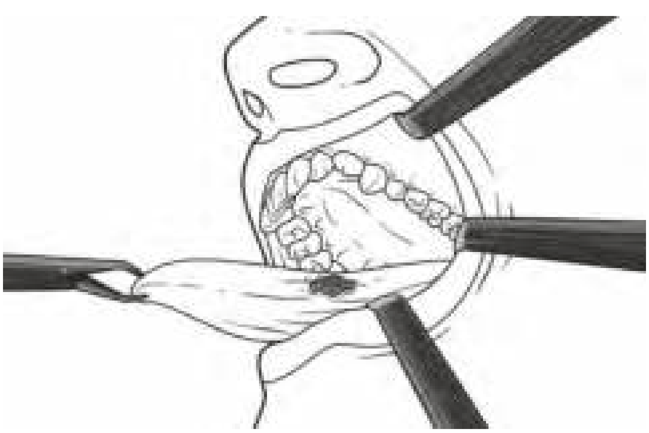


Fig. 82.10 Pictorial representation of excision of lesionally per-orally. This is usually indicated for T1–2 lesion in patients with adequate mouth opening

Lingual artery is an end artery, and hence clinicians have to be careful in resections involving more than two-thirds of tongue mass as this may jeopardize the vascularity and utmost care to be taken to preserve the neurovascular bundle.

There is a recent concept of compartment resection in patients with infiltrative disease where the adjacent extrinsic musculature and neurovascular bundle is excised in continuity to ensure negative margins. This was proposed by Calabrese [23], and all cases underwent access mandibulotomy; hence it is not commonly followed. Tumors of floor of the mouth are usually infiltrative and lymph node metastasis is seen bilaterally. According to Byers, the rate of lymph node skip metastasis at level IV is observed in about 10–15% cases. According to the study by Kowalski [24], tumors of floor of the mouth, tongue cancers crossing the midline, and advanced stage of the disease have a propensity of developing contralateral lymph node metastasis.

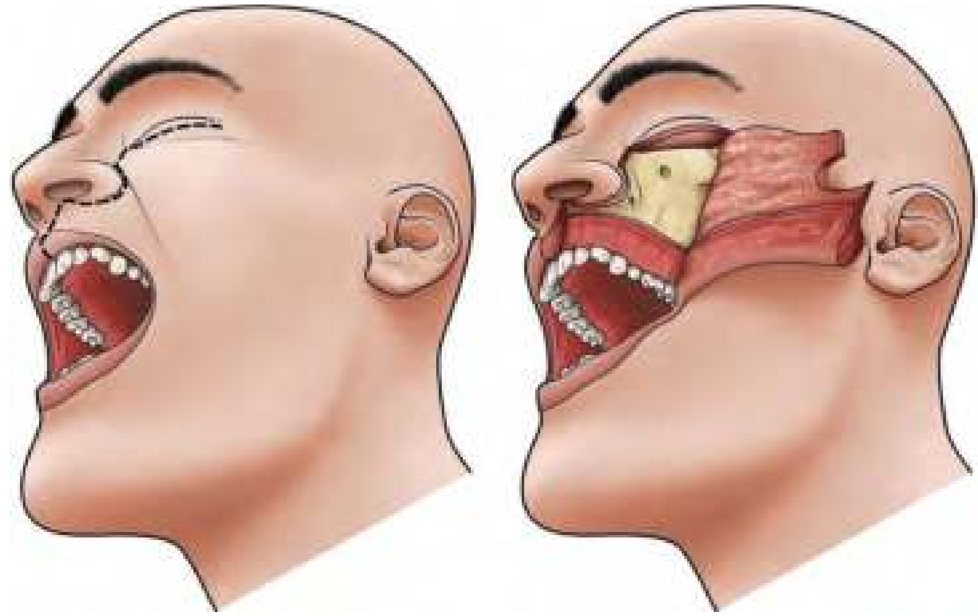

Fig. 82.11 Weber-Ferguson incision for tumors of maxilla not amenable to per-oral excision and not requiring infratemporal fossa access. The upper cheek flap is raised as shown

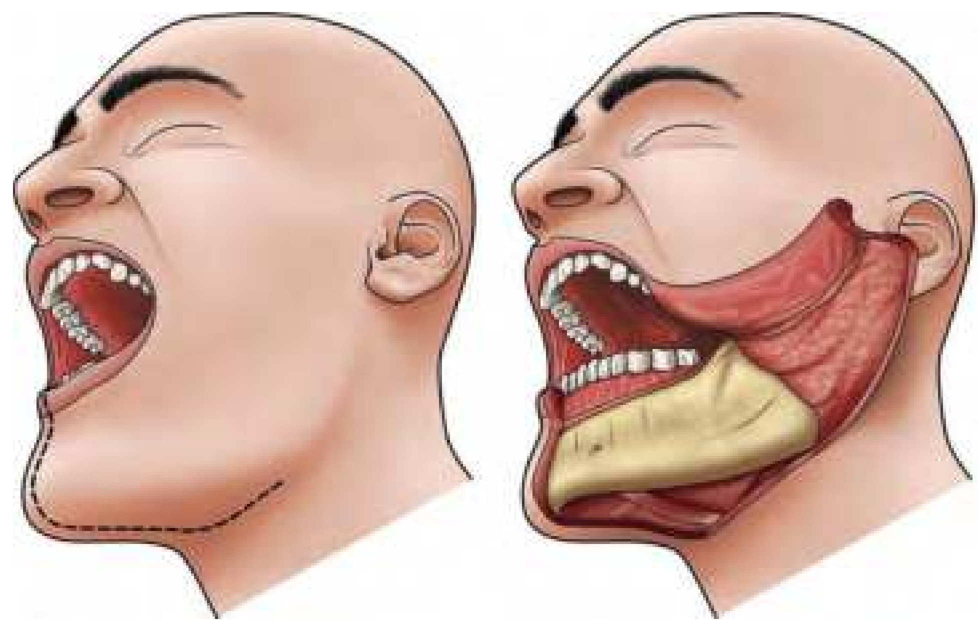

Fig. 82.12 A lower midline lip split incision continued and transverse neck skin crease incision followed by raising of a lower cheek flap. This gives the best access to infra-temporal fossa. The periosteum to be left on the mandible to preserve its periosteal blood supply. The mental neurovascular bundle has to be sacrificed

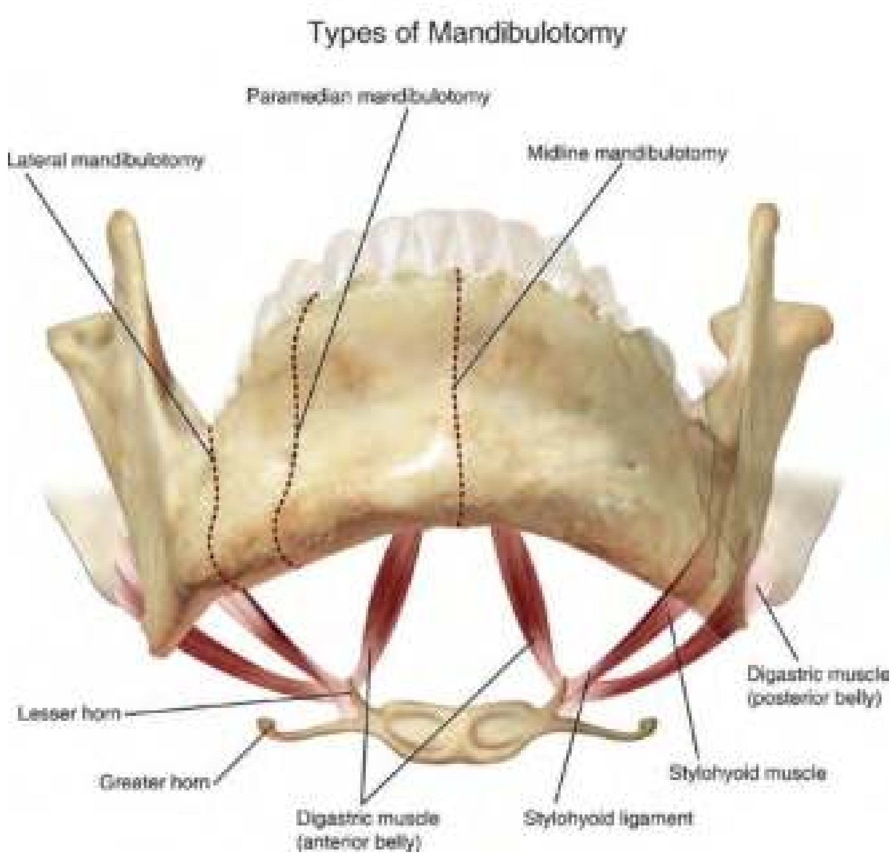
82.8.1.1 Surgery

Wide local excision (WLE)/adequate glossectomy procedure with adequate surgical margins has been the procedure of choice for early tongue cancers, and this is amenable with per-oral approach. Before planning resection, thorough knowledge about the extent of lesion is important, and palpation of induration provides a guide for the same. Ideal margin for resection of tumour is all 1–1.5 cm all around. Usually it is the deep soft tissue margin which is prone for being close or positive, and this can be avoided by palpation method. In many institutions, it is a useful practice to ligate the lingual artery in the neck before performing WLE for

Fig. 82.13 This picture depicts access mandibulotomies for tumors situated in the posterior tongue. The other alternative is pull through approach

Fig. 82.14 Visor flap provides best access for total and subtotal glossectomy

Fig. 82.15 Depiction of various types of access mandibulotomies



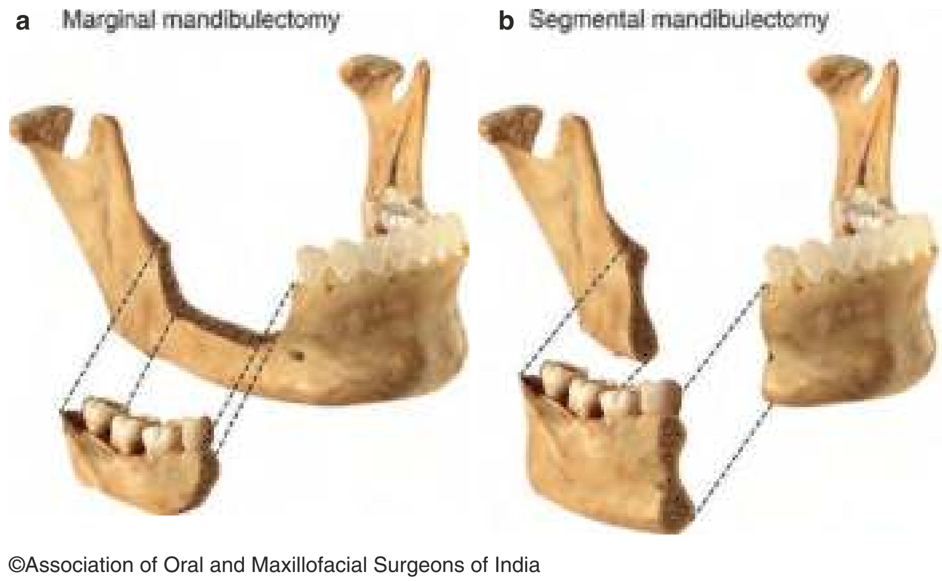


Fig. 82.16 Types of mandibulectomies (**a**) marginal and (**b**) segmental

adequate bleeding control and clean surgical field. The resulting defects of adequate glossectomy for early lesions are usually closed primarily avoiding tethering of the tongue. Excisional biopsy for suspicious lesions is highly discouraged even if the lesion is about 1 cm.

Moderately advanced cancers of the tongue and floor of the mouth (T2–T3) warrant classical hemiglossectomy which sacrifices the tip jeopardizing the tongue mobility resulting in compromised speech and swallowing. Majority of these tumors are excised by combinations of per-oral and pull-through approaches, without the actual need for lip-split or access mandibulotomy. The pull through technique helps in avoiding positive posterior margins as the resection is done under direct vision. All these patients require reconstructive surgery (lining or bulk), along with long-term tracheostomy and feeding tube (ryles tube/PEG) dependence. Free-flap reconstructions have become inevitable following resection of tongue cancers. Locally advanced (T4a) cancers (tumor depth > 20 mm, restricted mobility and hypoglossal palsy) of tongue warrant total glossectomy or near-total glossectomy. Standard total glossectomy procedure involves complete removal of anatomical tongue from mandible to hyoid and from the tip of the tongue upto the vallecula.

The following a is brief outlay of surgical steps: anterior belly of digastric muscle is first divided through the cervical neck incision followed by intra-oral crevicular incision. Then the genioglossus, geniohyoid is divided from the genial tubercle and mylohyoid muscle from the mylohyoid line from the mandible. At the contralateral retromolar region come the division of buccopharyngeal fascia, styloglossus muscle, and the palatoglossus muscle and incision at the vallecula. The same steps are repeated on the other side for total glossectomy. However in near-total/subtotal glossectomy, base of the tongue of uninvolved side is preserved. It is the extent of excision of the base of tongue which determines the postoperative swallowing function.

Tongue and the FOM lesions involving or abutting mandible pose a unique challenge. Resecting the segment of mandible increases morbidity and reconstructive challenge by many times. In such situations an attempt should be made to preserve the mandible whenever possible.

Removal of the level V lymph node is reserved in situations when level IV or V is involved or in N3 nodal disease. According to Kowalski et al., the indications for addressing contralateral lymph nodes are lesions of the tongue crossing the midline, floor of the mouth tumors, and locally advanced T3 and T4 tumors [24].

Reconstruction of the tongue requires a soft tissue flap with large volume to provide the adequate bulk which in turn is believed to aid in swallowing. The drawback of a reconstructed tongue is the impaired mobility resulting in compromised speech. The most commonly used flap is radial forearm free flap and anterolateral thigh free flap. The other uncommon examples for free tissue transfer are lateral arm flap, gracilis flap, and local flap such as FAMM flap and submental flap.

Reconstruction of tongue defect using radial forearm free flap (Figs. 82.17, 82.18, 82.19, 82.20 and 82.21).

82.8.2 Buccal Mucosa

82.8.2.1 T1/T2 Lesions

Surgical Steps: For Early Buccal Cancer Per-oral approach is adequate. It is important to ensure oncologic completeness and appreciate depth. Inadvertent injury to the buccal branch of facial nerve and to the parotid duct should be avoided. Facial artery, facial vein, and parotid duct (if encountered or injured) should be ligated. Mucosal incision around the lesion, with adequate margin, taking the buccinator muscle in specimen forms the deep soft tissue margin. These defects can be reconstructed with split thickness skin grafts/buccal pad of fat/local flaps such as nasolabial flap.

Fig. 82.25 Closure of the donor site

Fig. 82.26 Locally advanced T4a, left buccal mucosa lesion requiring composite resection with excision of the overlying involved skin

Advanced T3/T4 Lesions (Lesions with Skin Involvement/Bone Involvement/Involvement of Muscles of Mastication) Pre-operative clinical examination revealing a subtle skin puckering and imaging studies shows stranding of subcutaneous fat that is the early sign of skin involvement. If buccal space involvement is suspected, then buccal fat pad should be included in the specimen.

Fig. 82.27 Defect following composite resection and modified radical neck dissection; this defect was reconstructed with anterolateral thigh free flap

These advanced lesions require full-thickness cheek resection. The planning of incision may be a midline lip split or angle split, both of which will help in raising a lower cheek flap or when overlying skin is involved, an incision around the skin involved in continuity with the neck dissection incision. The muscle of mastication involvement warrants infratemporal fossa clearance (Figs. 82.26, 82.27 and 82.28).

82.8.3 Gingivobuccal Sulcus

Gingivobuccal sulcus (GBS) tumors are tumors occurring in the upper or lower GBS, usually seen to abut the bone adjacent (Fig. 82.29). These occur almost exclusively in Southeast Asia due to high incidence of chewing tobacco use. Due to the high propensity for local invasion and close proximity of bone, skin, and masticator space, presentation is often advanced, and outcomes are poor. If there is superficial erosion of bone or if the lesion is abutting the mandible, then the resection should include marginal mandibulectomy. Superficial cortical erosion in alveolar tumors is not considered as T4 lesion, and marginal mandibulectomy may still suffice. Although MRI is consid-

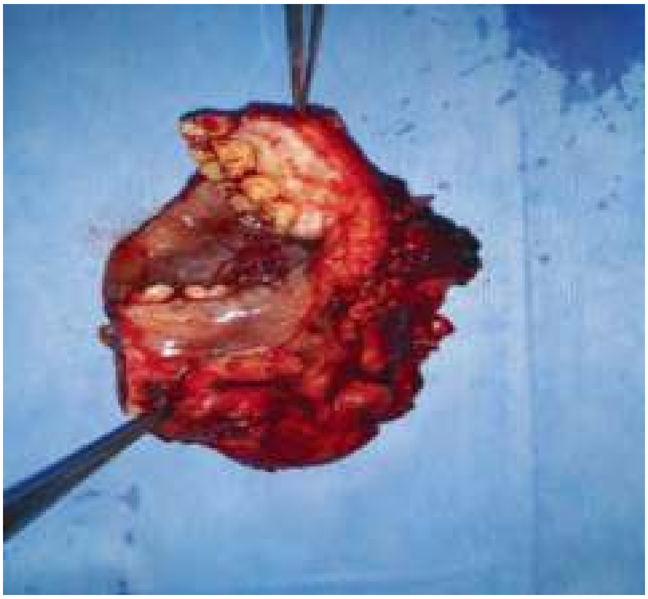

Fig. 82.28 Excised specimen in toto (Same case shown in Figs. 82.26 and 82.27)

ered most sensitive imaging modality to determine extent of bony involvement, periosteal stripping is by far the best method to determine extent of bony erosion and helps in decision-making regarding extent of mandibulectomy. GBS tumors usually present at an advanced stage with gross mandibular erosion, paramandibular spread, or overlying skin involvement (skin involvement is never seen in the masseter region as it is a tumor barrier). These findings preclude the use of marginal mandibulectomy, and hence patients often require segmental mandibulectomy and bony reconstruction.

82.8.4 Retromolar Trigone Carcinoma

Retromolar trigone tumors are rare but more aggressive malignancies with poorer outcome. Higher incidence of local recurrence has been reported in squamous cell carcinoma of the retromolar trigone (RMT) and posterior GBS carcinomas. This is attributed to to its higher propensity of infratemporal fossa (ITF) and pterygomandibular fissure involvement. Due to restricted mouth opening at the time of presentation, thorough clinical examination is hindered. For both oncologic and anatomic reasons, tumors with mandibular invasion are best managed surgically by segmental mandibulectomy including coronoid process of the mandible.

> The reason to preserve condyle is as follows: (a) it may be used for secondary reconstruction, and (b) as the condyle lacks medullary bone, it does not act as a pathway of spread and hence can be oncologically safe to preserve it.

Fig. 82.29 Classic example of a gingivo buccal tumor abutting the adjacent mandible

As a large proportion of the RMT tumors involve both the upper and lower jaw (Fig. 82.30), excision of ramus of mandible in the form of subsigmoid marginal mandibulectomy with at least an upper alveolectomy and ITF clearance (anterior ITF comprising masseter and medial pterygoid with or without pterygoid plates) is required. Selective neck dissection comprising of level I–V lymph nodes is usually performed electively for all stage cancers for purpose of staging.

82.8.5 Hard Palate

Tumors of the hard palate are less common when compared to tumors of the mandible, tongue, or buccal mucosa and are often of minor salivary gland etiology. Premaxilla provides support for the nose and midface; lesions involving anterior alveolus and hard palate will require bony reconstruction to prevent midface deformity. Lesions of the posterior alveolus and hard palate have a higher tendency to locally invade the orbital floor and skull base or through various neurovascular bundles (greater palatine foramen, sphenopalatine foramen, palatovaginal canal).

Lymph node involvement is very rare for salivary neoplasm of the palate, and neck dissection is reserved only for node-positive disease. However, maxillary alveolar carcinoma has a high propensity for occult lymph node metastasis

Fig. 82.30 Left retromolar trigone squamous cell carcinoma extending to involve lingual surface of mandible, soft and hard palate ipsilaterally

Fig. 82.31 Minor salivary gland tumour of the hard palate

(15–20%), and also in patients where neck is not addressed, they tend to present with nodal recurrences which are not salvageable in two-thirds of the cases; hence it is wise to consider elective neck dissection. The other point worthwhile and to be noted is that perifacial group of lymph nodes have to be cleared for effective disease control for the upper alveolus (Figs. 82.31, 82.32, 82.33 and 82.34).

Fig. 82.32 Defect following partial maxillectomy

82.8.5.1 Brown's Classification System for Maxillary Defects [25] (Fig. 82.35)

Vertical Component

- Class I, maxillectomy with no oroantral fistula.
- Class II, low maxillectomy.
- Class III, high maxillectomy.
- Class IV, radical maxillectomy.

Horizontal Component I, unilateral alveolar maxilla and resection of the hard palate;

(a) resection of less than or equal to half of the alveolar and hard palate, not involving the nasal septum or crossing the midline;

(b) resection of the bilateral alveolar maxilla and hard palate, including a smaller resection that crosses the midline of the alveolar bone, including the nasal septum; and

(c) removal of the entire alveolar maxilla and hard palate.

Fig. 82.33 Specimen in toto

Fig. 82.34 Defect reconstructed with conventional obturator placement

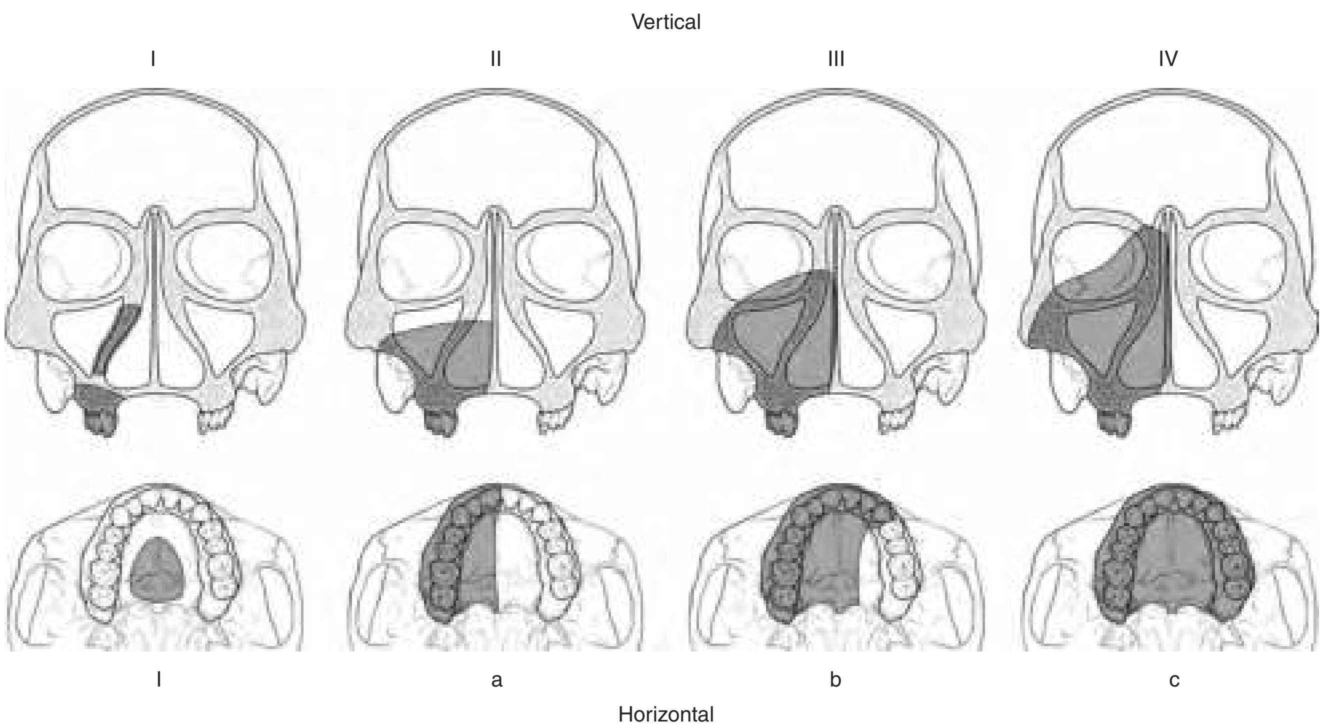

Fig. 82.35 Brown's classification for maxillectomy defects

82.8.6 Lip Carcinoma

Squamous cell carcinoma of the lip is most frequently associated with sun exposure as the risk factor. Lower lip is more commonly involved than the upper lip. Submental and submandibular nodal basins are the primary echelon drainage pathways; regional nodal metastasis occurs in only 10% of patients. Full-thickness excision with up to 1 cm margin is necessary. Lesions that involve less than one-third of the lip are managed with simple wedge excision and primary closure and hence offer acceptable oncologic and reconstructive results. For lesions larger than one-third but less than two-thirds, Abbe-Estlander or

Table 82.6 Treatment modalities of use in oral cancer

T1/T2 N0	Radiotherapy/brachytherapy vs. surgery
T3/T4 N0/N+	Surgery is mainstay of treatment followed by adjuvant therapy

Karapandzic flap can be utilized (refer Chap. 86 on Soft tissue reconstruction of the Maxillofacial Region). For defects more than two-thirds, free tissue transfer is preferred to achieve better cosmetic result and avoid microstomia and oral incompetence. To ensure oral competence, adjunctive procedures such as fascial sling, palmaris longus sling, or temporalis muscle sling can be used along with the adynamic soft tissue flap.

Table 82.6 describes the treatment modalities of use in oral cancer.

82.8.6.1 Management of the Neck in Oral Cavity

Introduction

Although skip metastasis can occur, lymph node metastasis usually follows a predictable fashion from the first echelon nodes to the second echelon nodes. Tumors of the oral cavity most commonly drain to levels I (submental and submandibular group) and level II (upper jugular group) in the neck. Level IA is between the two anterior belly of digastric muscle, and level IB is between anterior and posterior belly of digastric muscle on either side. The submental triangle drains the anterior portion of the oral cavity and hence can get involved in the tumors of the incisor region, the anterior floor of mouth, or anterior mandibular gingival/alveolar cancers. The level II nodes are found between the level of the hyoid bone inferiorly and anteriorly, the posterior belly of the digastric muscle superiorly, and the posterior border of the sternocleidomastoid muscle (SCM) posteriorly. In the jugular chain, the level III lymph node station is demarcated inferiorly by the omohyoid muscle as it crosses the internal jugular vein (IJV) and contains the mid-jugular lymph nodes particularly the prominent omohyoid node lying in close relationship to the muscle. Level IV (between the omohyoid muscle and the transverse cervical vessels, medially bound by the IJV) and V (between the posterior border of SCM and anterior border of trapezius muscle, further divided into levels A and B by the spinal accessory nerve) nodes are very rarely directly involved by early initial spread of oral SCC. In addition to these classical patterns of spread, buccal cancers may present with parotid nodes, and the posterior maxillary alveolus/hard palate may spread initially to retropharyngeal nodes. Tumors involving/crossing midline and tumors of the floor of the mouth generally require bilateral neck dissection.

82.9 Evaluation and Diagnosis

Evaluation of neck disease for the purpose of staging is best done by USG-guided FNAC, it being both highly sensitive and specific, simple, and cost-effective but observer dependent. Although palpation is most commonly employed, it has a very low accuracy ranging between 50 and 65%. The limitations of palpation method are obese patients or patients with previously treated necks; examination is more difficult. Imaging with CT scan or MR has been said to improve accuracy for metastatic neck disease to approximately 90%. Chaukar et al. found contrast-enhanced CT to give better concordance with histology in the N0 neck than either US or PET/CT.

82.10 Management

Evolution of neck dissection [26, 27]:

- 1906—George Crile described the classic radical neck dissection (RND).
- 1933 and 1941—Blair and Martin popularized the RND.
- 1967—Bocca and Pignataro described the "functional neck dissection" (FND).
- 1975—Bocca established oncologic safety of the FND compared to the RND.

Technique:

- The incision is made through the skin and deepened to divide subcutaneous tissues. Thus exposing the platysma (Thin pink muscle layer) which is incised in a single stroke.
- This is followed by raising of the subplatysmal flaps with the superior limit being the lower border of the mandible; anteriorly it is extends to the midline, posterior border of sternocleidomastoid (SCM) muscle posteriorly, and inferiorly till the clavicle [26].
- Neck dissection can be done either as an antero-posterior fashion or as a postero-anterior approach.
- Firstly the anterior belly of digastric muscle is identified, and mobilization of the fibrofatty tissue begins between the two anterior belly of digastric muscle and hyoid bone.
- In level IB dissection, marginal mandibular nerve is identified and preserved. The next step is to divide the fascia below the submandibular salivary gland, and the gland per se is retracted cephalad. This maneuver exposes the posterior belly of digastric muscle and helps in the identification of the facial artery. It is ligated close to the entry point at the posterior belly of digastric muscle and lower border of mandible. However full length of the facial artery may be preserved in case of full flap reconstruction [27, 28].
- The Sub mandibular gland (SMG), fibrofatty tissue, lymphatics and the prefacial LNs are mobilized off the mylohyoid and hence retracted it anteriorly.
- For the level II–IV lymph node dissection, the fascia over the SCM is raised till the posterior belly of digastric muscle superiorly. Level IIA dissection begins with identification of the Spinal accessory nerve (SAN) and Internal Jugular Vein (IJV) and removal of the LNs, lymphatics, and fibro-

fatty tissue between these structures, the deep limit of dissection being the prepectoral fascia. At any given point on time tractional injury to the SAN has to be avoided.

- This is followed by release of the fascia and tissue along the posterior border of SCM till the clavicle inferiorly; mylohyoid muscle retracted inferiorly and lateral border of IJV identified. Care is taken to preserve deep cervical plexus. Now the level II–IV tissue is retracted anteriorly and peeled off the IJV and continued in the anterior triangle of the neck till the midline, preserved the superior thyroid vessels and tributary of IJV.
- Level IIB is dissected between the posterior belly of digastric and postero-superior to the SAN, posterior limit being SCM.

This completes the selective neck dissection (Figs. 82.36, 82.37, 82.38, 82.39, 82.40, 82.41, 82.42, 82.43, 82.44 and 82.45).

Fig. 82.45 Composite resection with left hemimandibulectomy and selective neck dissection (Level I–IV) preserving the non-lymphatic structure

Table 82.7 Complications of neck dissection [29]

Immediate complications and management	
Hemorrhage	Controlled by ligation or direct cauterization. If hematoma, "milking" the drains may result in evacuation. It is best to return the patient to the operating room and explore the wound if there is suspicion of active bleed and/or there is evidence of hypotension. Blood and blood products to be arranged for blood transfusions. Coagulation profile
Nerve injury	SAN in the level II may be injured either tractional or due to vascular compromise. Vagus, lingual, hypoglossal, and marginal mandibular branch of the facial nerves should be identified and preserved. All attempts should be made to preserve the greater auricular nerve too
Increased intra-cranial pressure	This usually occurs when the internal jugular vein is ligated. When one internal jugular vein is ligated, the pressure rises by three-fold and when both are ligated it increases by five-fold. This usually is temporary and will normalize in 24 h. If it persists, head end elevation, steroids, and mannitol can be used
Pneumothorax	Rare Any tears in the pleura should be identified and closed and their integrity tested
Intermediate complications and management	
Pulmonary	Basal atelectasis and bronchopneumonia may occur in patients who are smokers and have pre-existing chronic obstructive lung disease
Deep vein thrombosis	This is seen in patients in geriatric age group, prolonged duration of surgery, bedridden patients, and patients with previous history of deep vein thrombosis, pulmonary embolism, myocardial infarction and thrombophilia
Chylous fistula	Intra-operative identification can be aided by placing the patient in the Trendelenburg position or adopting a forced Valsalva maneuver. Postoperative leaks are usually identified when feeding is commenced. Multiple approaches to the treatment of an established leak have emerged including nutritional, surgical, and pharmacological therapy
Carotid blowout	Damage to the adventitial layer during surgery may be another contributory factor. If risk of exposure is anticipated, vessels should be covered, e.g., dermal graft, fascia lata or levator scapulae muscle flap. This is particularly important in the post-irradiation subject
Delayed complications and management	
Lymphedema	When both the internal jugular veins are ligated, lymphedema often follows owing to interruption of the lymphatic drainage channels. There are massages advocated as a temporary measure

82.11 Complications of Neck Dissection

Table 82.7 provides a comprehensive view of the complications arising from neck dissection [29].

Sarcoma of the Maxillofacial/Head and Neck Region

83

D' Souza Jacob and Boyapati Raghu

83.1 Introduction

Sarcomas are uncommon malignant tumours with incidence of less than 5% of all head and neck malignancies in adults [1, 2]. They are more common in children, accounting for 30% of head and neck sarcomas [2, 3]. They arise from either soft or hard tissue mesenchyme cells. There is a male predominance and presentation is usually in the third and fourth decade of life in 70% of cases [4, 5].

Metastasis at initial presentation is seen in only 10% of patients, usually from high-grade primary lesions [6–8]. Despite this, prognosis tends to be poor, partly due to the proximity of vital neurovascular structures leading to difficulty in obtaining adequate surgical clearance. Moreover, majority of the sarcomas are poorly differentiated, a poor prognostic marker [9].

Sarcomas tend not be related to the use of tobacco and alcohol. Predisposition to the development of sarcomas is seen in some conditions [4, 8, 10]. Notable examples include association of osteosarcoma in patients with Li-Fraumeni syndrome, angiosarcoma with chronic lymphoedema and Kaposi's sarcoma with HIV infection. Additionally, exposure to chemicals such as vinyl chloride is well-recognised risk factors [10].

83.2 Classification

Broadly speaking, sarcomas can be classified into two categories: soft tissue and hard tissue (bone and cartilage) sarcomas. This, however, is an oversimplification since precise classification is fraught with significant difficulties. For example, fibrosarcoma and malignant fibrous histiocytoma are soft tissue sarcomas that arise in hard tissues [11, 12]. In contrast, chondrosarcomas are classified as soft tissue tumours. Additionally, some hard tissue tumours display extraosseous extension [1–3].

Ten or more main histological types and even more subtypes of sarcomas are described. Osteosarcoma, angiosarcoma and malignant fibrous histiocytoma make up the majority tumours in adults. In children, rhabdomyosarcoma is the most common sarcoma [1–3].

83.3 Staging

Soft and hard tissue sarcomas are staged using different systems (Tables 83.1 and 83.2). The American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) staging systems are used in most centres [13]. Other systems may be used in selected cases such as the Memorial Sloan Kettering system [14].

83.4 Natural History and Prognostic Factors

Head and neck sarcomas tend to show poorer response to treatment compared to sarcomas affecting the trunk and extremities [5, 6]. This is despite the low rate of lymph node metastasis at presentation (less than 10% of cases) and the modern multimodality treatment with surgery, radiotherapy and chemotherapy [4, 5]. Local and regional nodal recurrence is common and is more likely to result in death than distant metastatic spread [5, 8, 10].

The reasons for treatment failure resulting in disease recurrence are multifactorial. Adequate surgical margins are hard to achieve given the complex anatomy of the maxillofacial and the skull base regions (Fig. 83.1). The morbidity of radical resections is unacceptable, both functional and aesthetic. This is especially true for primary tumour larger than 10 cm at presentation [8, 9, 11]. Resections aimed at minimising morbidity risk positive or involved surgical

Table 83.1 TNM/UICC classification of soft tissue sarcomas

T classification	
Tx	Tumour cannot be assessed
T0	Tumour not evident
T1	Tumour size <5 cm
T2	Tumour size>5cm
N classification	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes evident
N1	Regional lymph node metastasis
M classification	
Mo	No distant metastasis
M1	Distant metastasis evident

Histological grading of soft tissue sarcomas

Gx: Grade cannot be assessed

G1: Well differentiated tumour

G2: Moderately differentiated tumour

G3: Poorly differentiated tumour

Staging:

Stage 1: Low grade tumour with no regional or distant lymph node metastasis.

Stage: 2 Intermediate, large or high grade, small tumour with no regional or distant metasta sis

Stage 3: High grade, large tumour or any tumour with regional metastasis.

Stage 4:Distant Metastasis identified

Table 83.2 TNM/UICC staging of bone sarcomas

Stage	Grade	Metastasis
1	Low grade < 8 cm	Absent
1b	Low grade > 8 cm	Absent
2	High grade < 8 cm	Absent
2b	High grade > 8 cm	Absent
3	Any grade, any size	Skip metastasis
4	Any grade, any size	Distant metastasis

margins and are an independent predictor of treatment failure and hence survival [5, 7, 8]. The grade of tumour is another prognostic factor. For example, the 5-year survival rates for high-grade tumours such as malignant fibrous histiocytoma, osteosarcoma and angiosarcoma are in the range of 60%. This is in contrast with low-grade tumours such as chondrosarcoma or dermatofibrosarcoma protuberance which show survival approaching 100% at 5 years [8, 9, 15]. There is optimism, however, with modern combined treatment modalities, for example, patients with rhabdomyosarcomas are showing better survival outcomes. Finally, sarcomas arising in previously irradiate tissues have poor prognosis due to a multitude of factors: delayed diagnosis; high-grade, inadequate surgical margins; limited option of adjuvant radiotherapy; and lack of proven chemotherapy regimens [10, 16, 17].

It is important to interpret the published treatment outcomes and survival rates with caution. Comparison between institutions is unreliable due to different study population, histological subtypes and follow-up regiments. Moreover, lack of standardisation in reporting leads to institutional bias of a selected treatment modality. Reported overall survival for bone sarcomas approach 80% at 2 years and 74% at 5 years [18, 19]. Radiation-induced sarcomas perhaps have the worse survival outcomes, as low as 25% at 5 years [19, 20].

83.5 Principles of Treatment

It is difficult to draw firm treatment guidelines for head and neck sarcomas because they are a rare group of heterogeneous tumours. The treatment philosophies vary between institutions due to multitude of factors as discussed previously in this chapter. Meta-analysis outcomes are therefore controversial and unreliable to draw firm conclusions. Furthermore, there are no randomised controlled trials [20, 21]. Despite this, there is consensus that early surgical resection with appropriately

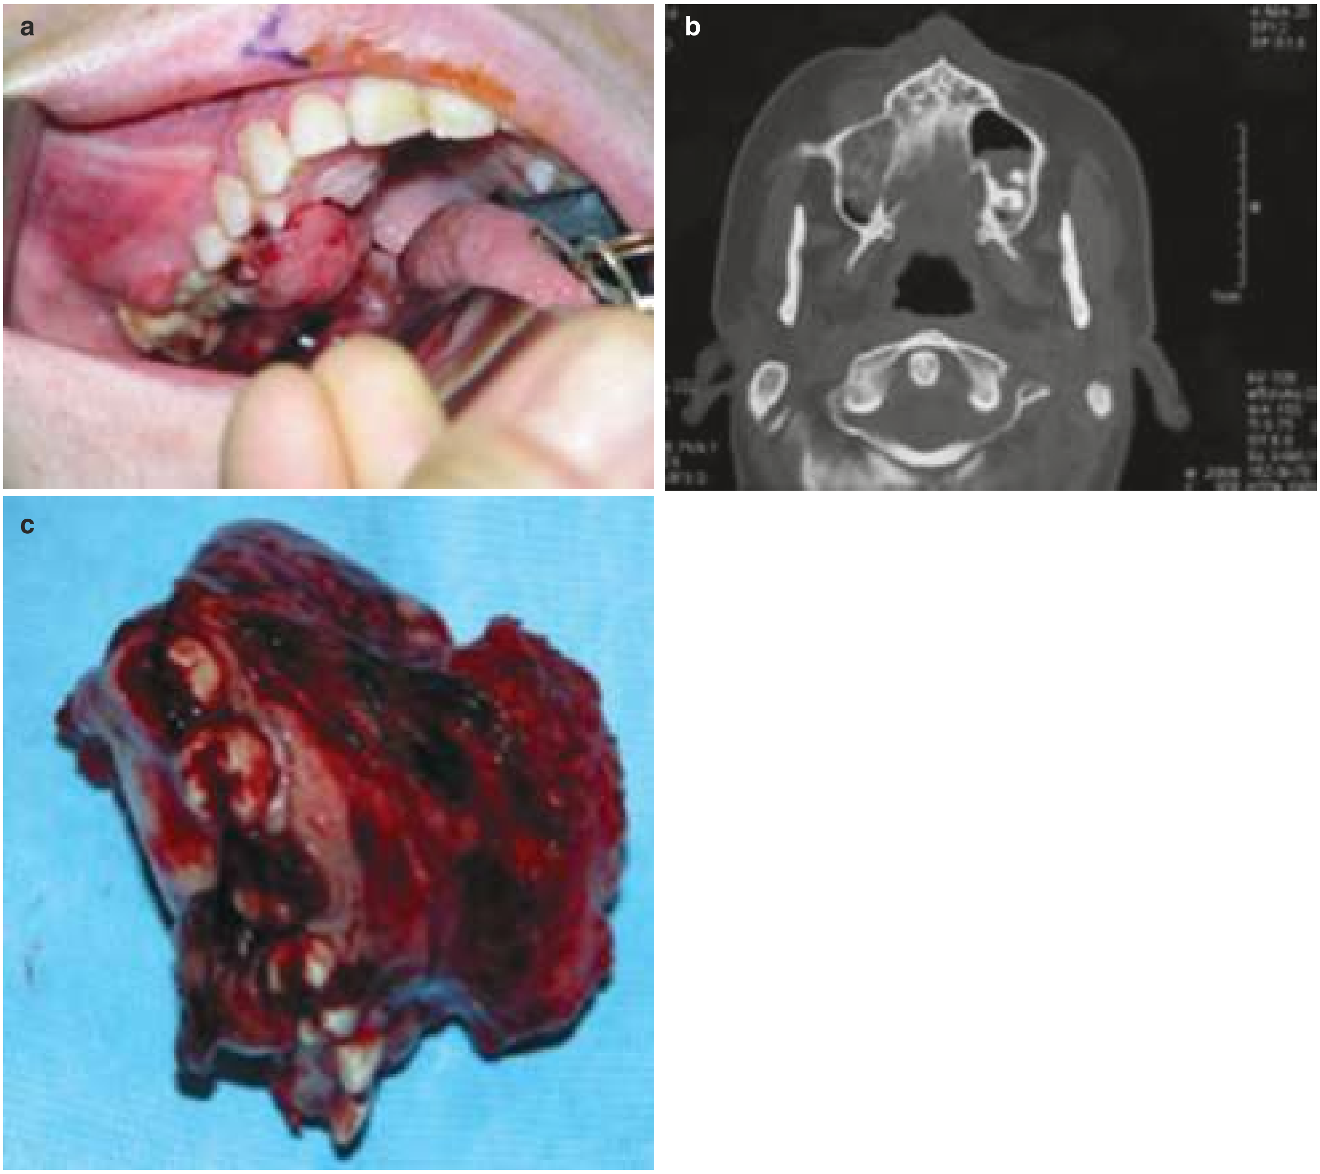

Fig. 83.1 (**a, b, c**) Osteosarcoma of the right posterior maxilla. Photograph showing osteosarcoma of the right maxilla. The extent of bone destruction from the tumour is seen in the scan. The resected specimen confirms the loss of the hemi-maxilla

timed adjuvant therapies can help improve outcomes. Needless to say, the role of multidisciplinary input/tumour board is vital.

Surgical resection of the tumour is the favoured primary treatment modality for patients with sarcomas of the hard tissues [22, 23]. Surgery is often preceded by chemotherapy on a neoadjuvant protocol [19, 22, 23]. The intention is to reduce tumour bulk and hence morbidity by minimising tissue loss. Elimination of micro-metastatic disease, mainly pulmonary deposits, is of added benefit. The role of adjuvant radiotherapy is limited to patients with positive surgical margins who often are not candidates for further resection [19, 24]. Further resections may not be feasible due to anatomical complexity or in those who have undergone complex reconstruction. Note should be made of the evolving role of radiotherapy in Ewing's sarcoma.

The size of the tumour at presentation often restricts the use of surgery in patient presenting with soft tissue sarcoma. Adjuvant radiotherapy is an indication when the resection margins are positive; the tumours are of intermediate or high grade and in cases of recurrent disease [12, 16, 24, 25]. The feasibility of introducing neoadjuvant chemotherapy or preoperative radiotherapy should be considered with diligence in patients with advanced disease at presentation with a view to reduce morbid resections [25, 26]. When surgery is not feasible, the role of palliative radiotherapy alone or in combination with chemotherapy should be considered.

83.6 Principles of Surgery

83.6.1 Hard Tissue Sarcomas

There is a consensus that achieving tumour-free zone of tissue at the resection margins maximises the chance of cure. However, what defines adequate margin remains debated. The current recommendation is resection of the tumour with a 2–3 cm macroscopic margin in patients who receive neoadjuvant chemotherapy aiming to sterilise the microscopic deposits around the main body of the tumour [24–28]. It is important to plan the resection on scans obtained prior to the neoadjuvant chemotherapy. This is because both the tumour-killing effect of the neoadjuvant chemotherapy and tissue shrinkage are unpredictable. Furthermore, one should aim for compartmental excision (Fig. 83.1) that allows for removal of all potentially involved structures beyond the radiographic margins such as intra-osseous extension of the tumour via marrow spaces [2, 19, 24]. Although this approach is radical, for instance, resection of the hemi-mandible to include disarticulation of the condyle in ramus tumours, the chance of surgical clearance can be maximised to 85% or greater [2].

83.6.2 Soft Tissue Sarcomas

Similar to hard tissue sarcomas, adequate surgical margins predict survival outcomes, both disease-free and overall survival. The recommendation is for 1–3 cm macroscopic margins [24, 29, 30]. Achieving this may be limited due to anatomical constrains and an infiltrative pattern of tumour spread that tends to characterise soft tissue sarcomas. One published series reported adequate surgical clearance in 85% of osteosarcomas vs. 64% soft tissue tumours [2]. The 2-year overall survival estimate for bone tumours (51 patients) was 91% vs. 67% for soft tissue tumours (50 patients) [2]. The 5-year overall survival estimates were 73 and 56%, respectively. These results were statistically significant. Other series with different patient cohort have reported 5-year overall survival rates of 74 vs. 57% for bone and soft tissue sarcomas, respectively [31, 32].

83.7 Clinical Assessment

Patients present with a wide range of signs and symptoms. These may range from indolent lumps to rapidly growing and locally destructive lesions (Figs. 83.1 and 83.2). Pain

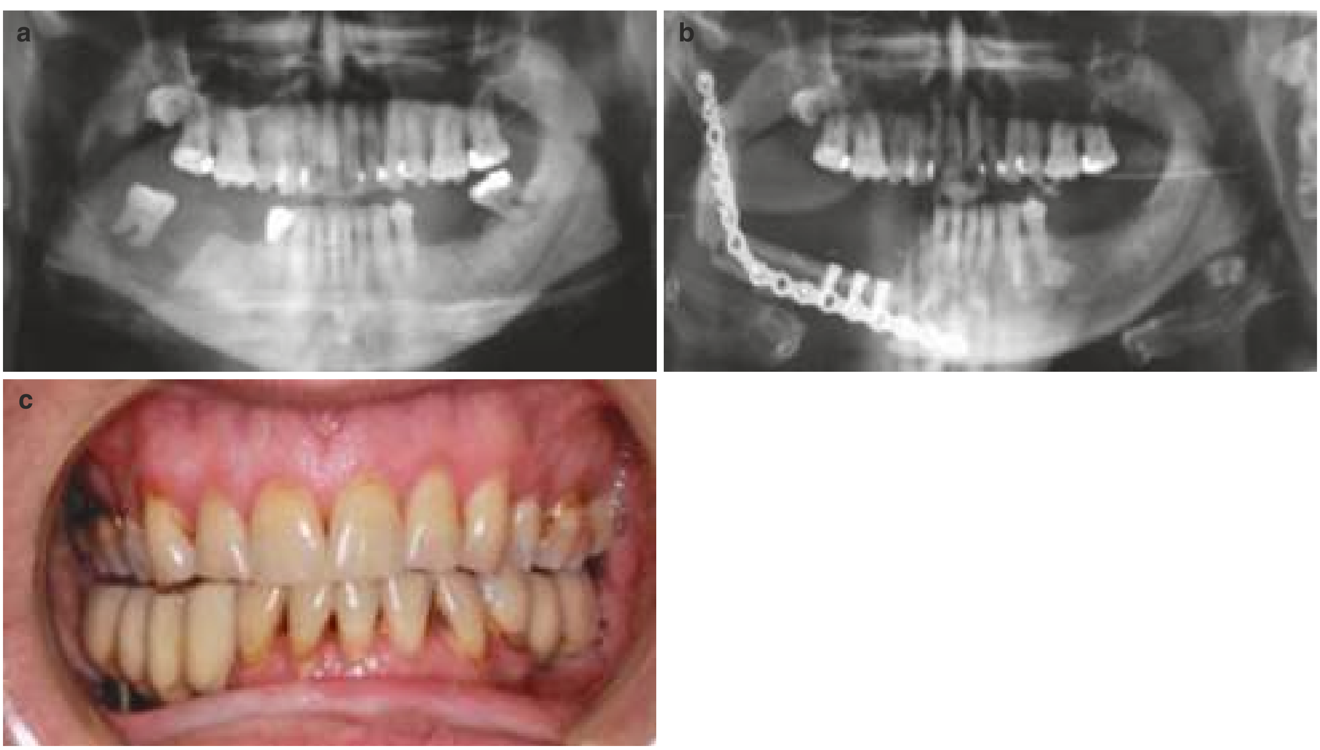

Fig. 83.2 (**a**, **b**, **c**) Osteosarcoma of the right posterior mandible. Plain radiograph showing tumour destruction of the right posterior mandible. A fibula free flap and dental implants are used for rehabilitation

is variable and there is a tendency for nocturnal bone pain [1, 4].

There may be a mass at the primary site, ulceration, sensory change affecting the skin or the mucosa, proptosis, epistaxis or nasal discharge, loosening of teeth and unexplained bleeding.

Involvement of the skull base by direct extension can lead to focal neurology. Metastatic lesions can present with a neck mass. Systemic symptoms tend to be non-specific such as malaise, loss of weight and appetite [8, 23].

83.8 Investigations

Magnetic resonance imaging (MRI) is usually the preferred investigation for primary lesions [30, 33]. They provide information regarding the nature of the primary tumour (solid, cystic, presence or absence of calcifications, internal vascularity, etc.). The relationship of the tumour to adjacent tissues can be accurately defined; this helps plan tumour resection [22, 34, 35]. Computer tomography (CT) scan of the facial bone may be used to complement the MRI scan, especially in patients requiring hard tissue resection and reconstruction (Figs. 83.1 and 83.2). The use of composite flaps with 3-D reconstruction with prefabricated plates is increasingly used in several centres [36, 37]. The use of dental implants has significantly improved outcomes following composite reconstructions (Fig. 83.2). CT scans of the thorax and upper abdomen complete the staging investigations. There is an evolving role for positron emission tomography (PET), both in the initial staging of the disease, the response to treatment and tumour surveillance [38, 39]. Blood tests include comprehensive baseline tests (full blood count, renal and bone profile) and serum alkaline phosphatase. Additional tests may be necessary, often dictated by individual patient profiles. Biopsy for tissue diagnosis must include an appropriate sample that in addition to routing staining provides tissue for immunocytochemistry [4, 12].

83.9 Osteosarcoma

Osteosarcomas are the commonest sarcomas of the bones in adults, representing 1% of all head and neck cancers. They do not show sex predilection. The peak incidence is between 20 and 30 years. However, tumours arising in area of Paget's disease of the bone are seen in older patient 60–70 years of age [25–27]. The mandible is the most frequently affected site, especially the angle/ramus region. In the maxilla, the tumour has a predilection to the alveolar ridge and sinus floor. Notable risk factors include chromosomal abnormalities (deletion of 13q14), germ line mutations (Li Fraumeni syndrome) and dysplasia of bone (Paget's disease and fibrous dysplasia) [25–28]. In some instances, these tumours arise in irradiated bone or de novo.

> Patient may present with asymptomatic intra-oral mass, loose teeth and toothache.
>
> Destructive lesions can cause soft tissue cheek swelling, sensory change, proptosis, nasal discharge or bleeding.

Three histological subtypes of osteosarcoma are recognised, namely, osteoblastic, chondroblastic and fibroblastic variants [31, 39].

However, myxoid pattern is the norm (Fig. 83.3). The chondroblastic variant shows binucleated cell characteristic of the lesion (Fig. 83.4) The degree of differentiation classifies them as stage I (well-differentiated and low-grade) to stage IV (poorly differentiated and high-grade). Regional neck metastases at presentation are rare, seen in less than 10% of patients at presentation. Distant metastases are seen in up to 30% of patients at presentation, mostly pulmonary [23, 27, 31]. On rare occasions, patients may present with rapidly progressive, fatal multifocal disease. Imaging reveals local bone. The well-documented finding of subperiosteal bone formation (Codman triangle) is uncommonly seen in head and neck lesions.

Whilst surgery, radiotherapy and chemotherapy are offered as single or multimodality treatments, well-established treatment regimens are lacking in consensus. Various drug combinations have been tried and tested, leucovorin, Adriamycin, cisplatin, ifosfamide and cyclophosphamide, with unpredictable response. One study has shown 2- and 5-year overall survival rates of 100 and 67%, respectively, in those treated with neoadjuvant chemotherapy and surgery. This compares favourably with patient treated with surgery alone showing poorer 2- and 5-year overall survival rates of 66 and 41%, respectively [19, 23, 31]. The role of

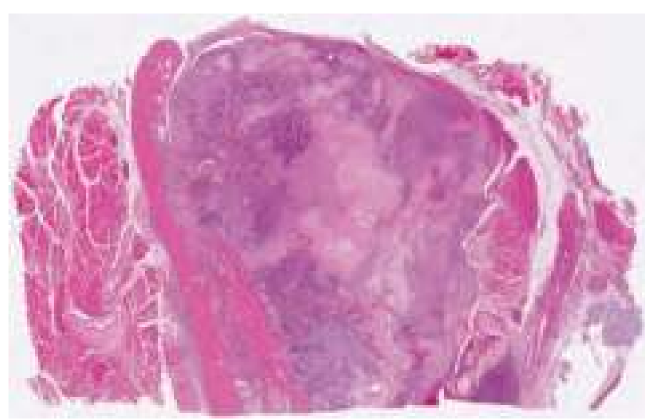

Fig. 83.3 Osteosarcoma-myxoid variant. H&E section of an axial slice through the masseter (far left), ramus of the mandible, tumour, medial pterygoid and palatal mucosa (far right bottom corner)

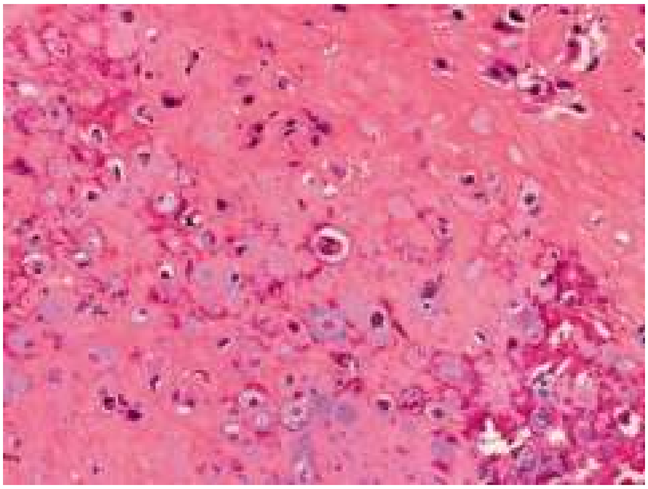

Fig. 83.4 Osteosarcoma-chondroblastic variant. Photomicrograph showing binucleated cells, characteristic of the chondroblastic type

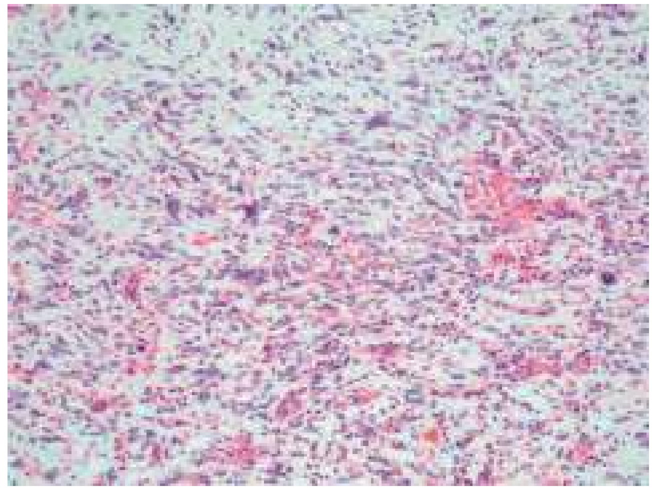

Fig. 83.5 Malignant fibrous histiocytoma. H&E section showing highly pleomorphic tumour cells with atypical mitotic figures amidst dense acute inflammation

adjuvant radiotherapy is applicable in patients with inadequate or positive surgical margins; however, doses in excess of 60Gy are necessary given their radio-resistant behaviours [8, 16, 31].

In addition to high-grade disease and large tumours at presentation, some additional factors have prognostic significance. For example, the expression of the p-glycoprotein confers multidrug resistance negatively impacting on prognosis. Osteosarcomas arising in Paget's disease and elevated alkaline phosphate levels have poorer prognosis [9, 25, 27, 32].

83.10 Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma is the commonest soft tissue sarcoma affecting the trunks and extremities. However, it is rare in the head and neck region, with less than 3% occurring here. It shows a male predilection with a 2:1 ratio and mostly seen between 40 and 60 years of age. The commonest subsite is the sinonasal tract. There is a strong link to ionising radiation exposure [11].

Histology shows highly pleomorphic fibroblasts mixed with abnormal histiocytes in a storiform pattern with a background dense inflammation (Fig. 83.5). Phagocytised neutrophils with large nuclei/nucleoli are commonly seen. Necrosis is an uncommon feature, but bizarre giant cells or atypical mitotic figures can be seen on most occasions [30, 34, 40]. The commonest subtype is pleomorphic; less common are giant cell and myxoid types. Immune positivity is seen with α-1-antichymotrypsin, vimentin and Ki-67 [11].

Wide surgical resection is the primary treatment, with consideration given to adjuvant chemoradiotherapy [17, 23]. Whist local recurrence is the norm, regional metastases to lymph nodes are rare. Positive margins predict for treatment failure locally and distant spread, usually to the lungs and liver [23, 33].

83.11 Liposarcoma

Although liposarcomas are second most common soft tissue tumours, less than 5% occur within the head and neck region. They show a slight male predominance, most commonly presenting between the ages of 30 and 60. Majority arise de novo rather than developing in a lipoma [24]. Patient may demonstrate risk factors such as repeated trauma, irradiation or genetic abnormality (NF-1 gene). The histological behaviour varies from high-grade (pleomorphic, round) to low-grade (myxoid) tumours. The myxoid variant shows lipoblasts arranged within a chicken-wire vascular network in a dense stroma (Fig. 83.6). The pleomorphic type shows significant numbers of highly atypical fat cells along with lipoblasts (Fig. 83.7). The epithelioid variant can be confused with carcinoma [40].

Whilst surgery remains the primary treatment modality, the role of adjuvant radiotherapy should be considered in patients with high-grade lesions and large tumours with positive resection margins. Published literature supports the use of adjuvant radiotherapy in reducing local recurrence from 60 to 40% [19, 20, 24].

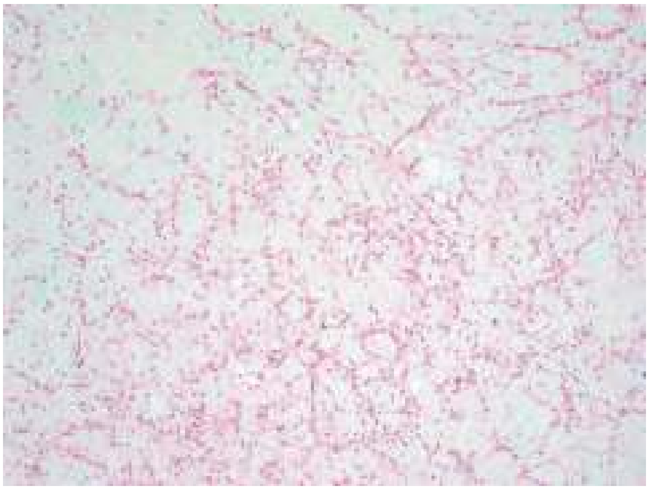

Fig. 83.6 Liposarcoma myxoid variant. H&E section showing myxoid tumour with lipoblasts arranged within a chicken-wire vascular network amidst dense myxoid stroma

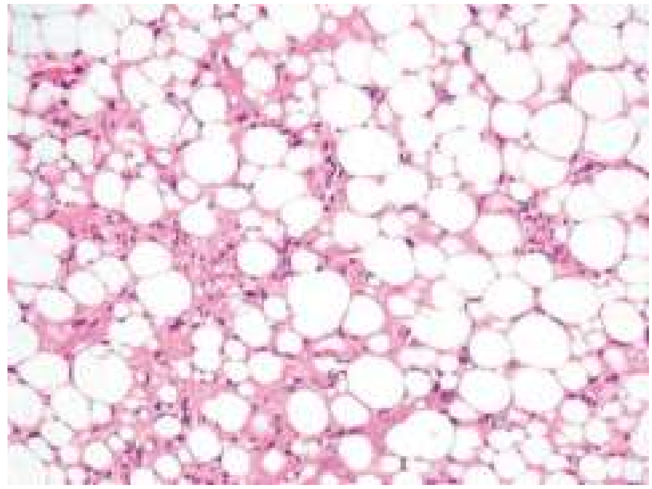

Fig. 83.7 Liposarcoma pleomorphic variant. H&E showing atypical adipocytes along with pleomorphic lipoblasts

83.12 Rhabdomyosarcoma

These are predominantly childhood tumours, usually affecting those below the age of 12 years [2, 4, 5]. They show slight male predilection. In contrast to adult sarcomas, up to half of all rhabdomyosarcomas occur in the head and neck sites. The favoured subsites are the orbits, the nasopharynx and the temporal bones [15].

Histologically, at least 70% of the tumours are of embryonal subtype; less commonly, the alveolar subtypes are seen (Fig. 83.8). Immune positivity to desmin, myoglobin and actin is well documented (Fig. 83.9). Cells show finely granular eosinophilic cytoplasm with cross striations with enlarged nucleus. More differentiated tumours may show elongated rhabdomyoblasts and occasional giant cells. Definitive diagnosis is based on myogenesis, multinucleated myoblasts, individual tumour cells with cross striations and dense eosinophilic cytoplasm [41].

Prognostic indicators include the location of the primary, age at presentation and metastatic disease. The survival rates have shown significant improvement: 71% in 2001 vs. 25% in the 1970s [15, 23, 31]. The orbital tumours show the best prognosis with 5-year survival rates exceeding 90% in children [15]. This contrasts with poor survival rates in adults at approximately 30%.

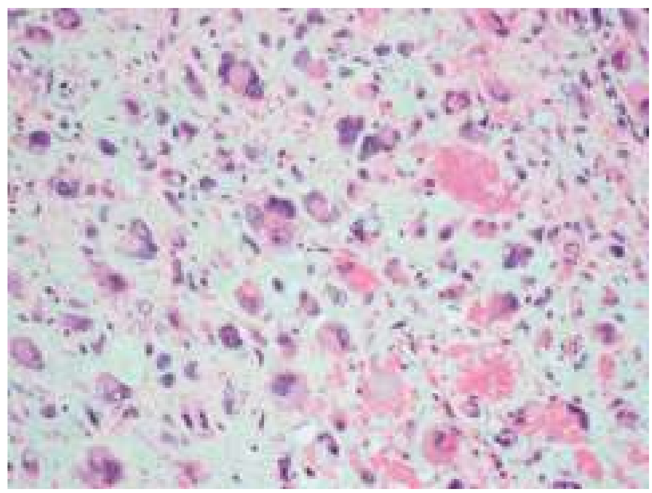

Fig. 83.8 Rhabdomyosarcoma pleomorphic variant. H&E section showing high-grade sarcoma with pleomorphic rhabdomyoblasts

83.13 Chondrosarcoma

Chondrosarcomas are malignant tumours of the bone or cartilage, and 10% are located in the head and neck [2, 8]. The larynx is the most commonly involved subsite, closely followed by the maxilla and mandible. The peak incidence is 30–50 years. At least 80% arise de novo. Secondary tumours arise in abnormal bone in conditions such as Paget's disease and fibrous dysplasia [40]. Rarely, extraosseous tumours are seen due to cartilaginous differentiation of primitive cells. Patient's symptoms depend on location and the extent of local tissue destruction. Despite slow initial progression, multiple metastases can develop rapidly [26]. Radiographic examination may show sunray speculation.

The degree of differentiation can range from well to poorly differentiated tumours. The common subtypes include myxoid and mesenchyme [26]. It is not uncommon for them

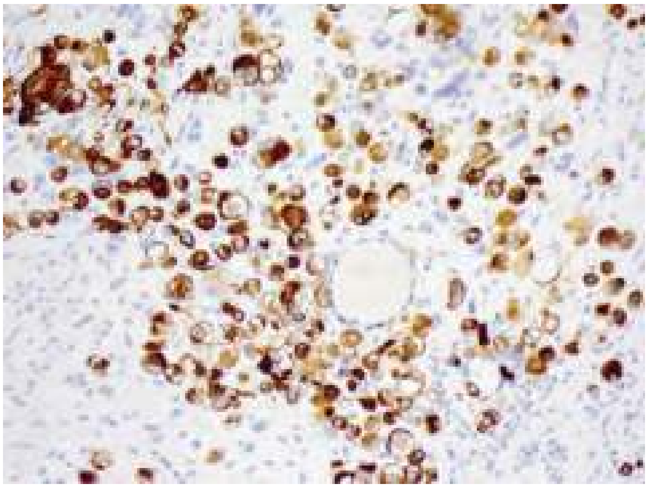

Fig. 83.9 Rhabdomyosarcoma. Showing expression of desmin in rhabdomyoblasts

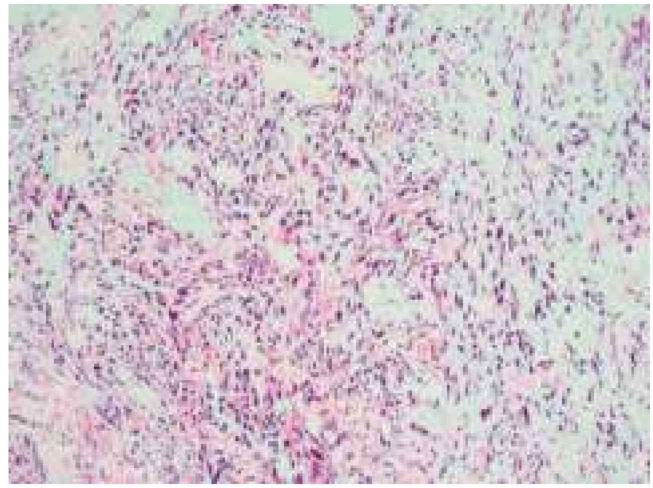

Fig. 83.10 Angiosarcoma. H&E section showing pleomorphic tumour cell lining interconnecting atypical vascular channels

to show histological similarity to tumours such as chondroblastic osteosarcoma and malignant fibrous histiocytoma. Additionally, low-grade tumours may show benign histology such as chondromatosis or osteochondroma.

Surgery remains the primary treatment modality, possibly driven by the belief that these tumours are radio-resistant. Additionally, irradiating areas such as the skull base can be carried out with conventional external beam photon therapy particularly with new techniques like Intensity modulation radiation therapy (IMRT). The role of proton beam therapy delivering high-energy irradiation has shown local control rates of 85–100% at 5 years [42].

The site of the primary tumour has implications for prognosis; for example, laryngeal primaries do better compared to nasopharyngeal primaries. High-grade and dedifferentiation confers poor prognosis due to early local recurrence and distant metastases. The 5-year overall survival rates are less than 50% vs. 80% or greater for high- and low-grade tumours, respectively.

83.14 Angiosarcoma

These tumours arise from the endothelial cells lining the vascular or the lymphatic system. They are most common above the age of 62 years and show male predilection with a ratio of 2:1. They can arise in several different sites given the wide distribution of the endothelium. Some lesions are localised and nodular, whilst others are diffused. Regional metastases are less than 20% of patients at presentation. However, distant metastases may be present in up to 45% of patients at presentation, mostly involving the lungs and liver [6–8]. The tumours show immune positivity for CD31. Histological examination shows anastomosing and infiltrating channels lined by multilayered endothelial cells with variable atypia (Fig. 83.10). Free-floating endothelial cells of 'fish in the creek' pattern with surrounding adnexae and dermal collagen can be a reliable feature [42].

Although surgery is the primary modality of treatment, diffuse lesions can make adequate surgical clearance a difficult task. The reported 5-year survival rates range from 12 to 40%. Predictors of poor survival include location of the primary tumour, size greater than 7 cm at presentation, high-grade and advancing age [1, 20, 23]. Local recurrence is seen in more than 50% of patients with inadequate or positive surgical margins, usually within 2 years. The role of adjuvant therapies is questionable in achieving adequate loco-regional control and improving survival.

83.15 Malignant Schwannoma

These are tumours arising in the nerve: peripheral or cranial. They usually affect the neck, followed by sinonasal areas. Involvement of the maxillofacial skeleton is rare. Although there is an association with von Recklinghausen's disease or neurofibromatosis type 1, sporadic tumours are well recognised [43]. Surgery remains the primary treatment modality. Tracking of the tumour along the nerve sheath limits the resectability, hence the need of adjuvant therapies, be it radiotherapy or chemotherapy.

83.16 Fibrosarcoma

These tumours often present as an asymptomatic painless mass between 30 and 40 years of age. History is positive for previous radiation exposure in at least 10% of patients.

Histological similarities are seen with malignant fibrous histiocytoma [6, 7, 44]. Surgery remains the mainstay of treatment, with adjuvant radiotherapy aimed at those with inadequate surgical margin and lessons that are high-grade. The reported 5-year survival rates are 80% or greater [22, 23].

83.17 Kaposi's Sarcoma

Human herpes virus 8 is implicated in the aetiology of these tumours arising in patients with AIDS. It is worth noting that Kaposi's sarcomas represent up to 80% of oral cavity sarcomas and have poor prognosis [25, 45].

83.18 Synovial Sarcoma

Contrary to the name, synovial sarcomas arise from the pluripotent mesenchymal cells, not the synovial cells. They show a male predilection and a peak incidence between 20 and 40 years. The common head and neck subsites are the hypopharyngeal and retropharyngeal areas. It is worth noting that up to 50% of patients have pulmonary metastases at presentation [5, 7, 15].

All histological subtypes (monophasic, biphasic, poorly differentiated) are high-risk tumours. Up to 90% of patients have chromosomal translocation (tX: 18) [21]. Prognosis tends to be poor with less than 20% of patients with metastasis at presentation alive at 2 years. Increasing age, size greater than 5 cm and poor differentiation predict worst prognosis [18, 22].

83.19 Ewing Sarcoma

These tumours arise in privative neuroectodermal cells and represent 5% of primary tumours. They are second most common malignant tumours of the bone in children. Subtypes include osseous and extraosseous. Metastases at presentation are seen in 20% of patients, mostly involving the lungs [46]. History may be positive of prior childhood malignancies treated with irradiation or chemotherapy. Most patients present with an enlarging mass that may be asymptomatic or painful. Destructive lesions due to osteolysis are evident on radiographs.

83.20 Conclusion

Sarcomas are aggressive tumours, fortunately rare in the head and neck regions except for rhabdomyosarcoma in children, which has shown good, improved outcomes with current treatment regimens. The primary treatment modality is surgery, often preceded by neoadjuvant chemotherapy and followed by postoperative chemoradiotherapy. Large tumours with a risk of positive surgical margins and histologically high-grade tumours are adverse features. Age is an independent prognostic factor in children and adults with sarcomas arising in Paget's disease for bone.

Treatment regiments are often institution-dependent and biased. Given the lack of randomised controlled trials and difficulty in interpreting meta-analysis, close cooperation and data sharing between centres can go a long way in improving treatment outcomes for this diverse group of patients.

84 Adjunctive Therapy in Oral Cancer

Amit Dhawan

84.1 Introduction

Oral cancer is the sixth most common cancer in the world, primarily caused by consuming tobacco and its products, alcoholism, nutritional deficiencies, poor oral hygiene, certain strains of human papillomavirus (HPV) and genetic predilection [1, 2]. Considering global incidence of oral cancer, more than 50% of overall head and neck cancer are occurring in Asian subcontinent with India having maximum numbers of these patients. According to some epidemiological studies in Asian Indian population, approximately 80,000 to 1,20,000 new patients of oral cancers are being diagnosed yearly, making oral cancer the third most common cancer in India after lung cancer [1]. Oral cavity cancers are primarily treated surgically owing to gross visual disease, easy accessibility, and less chance of obtaining the R1 resection (resection with positive margins). Retrospectively, all T1 and some of T2 lesions of oral cavity were treated with primary radiotherapy with curative intent, but the results were more promising with upfront surgery followed by some kind of adjuvant treatment depending upon the final histopathology report. Developing countries like India have nonstandardized oral cancer screening protocols due to which most of the oral cancer patients are missed at an early stage and are presented at an advanced stage (stage III–stage IV) with higher T stage (T3–T4) and dissemination of disease in the lymphatics of the neck which further reduces the prognosis for the survivability of the patients. There are other independent predictors on which prognosis of an oral cancer patient depends on like depth of invasion of tumor, involvement of lymph nodes in the neck (lymph node ratio), pattern of invasion of tumor, extranodal extension, and presence of positive margins after surgery. In the recent past, advanced-stage (stage III–stage IV) oral cancer was primarily managed by upfront ablative resection and neck dissection followed by postoperative adjunctive radiotherapy depending upon the other predictors of prognosis. This dual modality approach of followed by radiotherapy has given promising results in advanced-stage cancers, but the overall survival benefit came out to be as low as 40% [2–5].

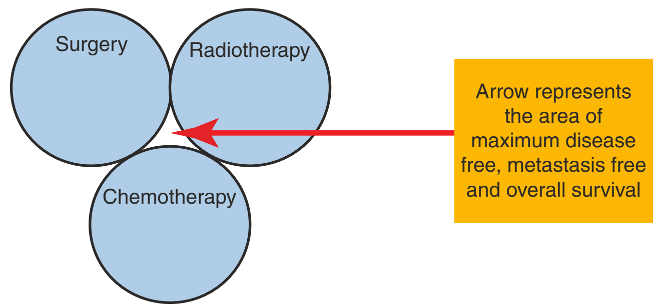

Fig. 84.1 The three major treatment modalities available for the treatment of oral cancer

In 2004, two large-scale trials were conducted, Radiation Therapy Oncology Group (RTOG) 9501 in America and European organization for Research and Treatment of Cancer (EORTC) 22,931. The results of these trials had provided the new insights for the management of advanced head and neck squamous cell carcinoma. The evidence from these landmark trials confirms the use of chemotherapy to the adjuvant radiation regime in the treatment of advanced-stage squamous cell carcinoma patients [5, 6].

The addition of chemotherapy may result in better locoregional control, overall survival, and metastasis-free survival in these patients. The three major pillars of treatment for oral squamous cell carcinoma are surgery, radiotherapy, and chemotherapy. To get the maximum survival advantage from these treatment modalities, all the three treatment modalities have to be used as an adjunct to each other [2, 3] (Fig. 84.1).

84.2 Basic Principles of Radiotherapy

When the radiation is used for the purpose of treatment, especially in the patients of oral cancer, it is referred to as radiation therapy or radiotherapy. Radiotherapy is frequently used in as an adjunctive therapy or adjuvant therapy, to improve both local-regional control and overall survival. Radiation therapy is thought to kill tumor cells via damage to their DNA. The amount of radiation is typically measured in the unit gray (Gy), which represents joules of energy per kilogram. The following gives the conversion between grays, radiation absorbed dose (rad), and centigrays: 1 Gy = 100 rad = 100 cGy [7, 8].

External beam radiotherapy refers to the treatment, when a targeted beam of energy in the form of radiation is directed from a machine placed outside the patient to an area to be irradiated located within the patient. However, a radioactive substance may be introduced directly within an existing tumor or tumor-bearing area which is referred to as brachytherapy. Arranging for a patient's radiation treatment involves a number of steps before treatment can commence, of which the first is a dental evaluation and appropriate dental care. After consultation, a patient is simulated, which usually involves obtaining a computed tomographic (CT) scan, while the patient is immobilized with a face mask. Afterward, the radiation oncologist outlines the disease on the scan (contouring). Then a medical physicist and dosimetrist devise a method to deliver the radiation safely to the patient while avoiding radiation to normal anatomical structures. At the time of treatment, the radiation therapists verify that the patient lines up appropriately before treatment can begin. Immobilization of the patient is carried out with a predesigned face mask made up of a thermoplastic material. It is to be noted that accurate positioning of the patient without movement and the ability to recreate the same position of the patient every time (up to 6 weeks) are important factors for overall effective radiation treatment of the patient [7–10].

84.2.1 Biology of Radiation Therapy

The current understanding of radiotherapy techniques makes use of radiobiological principles for better treatment planning and outcomes. These principles influence the response of both normal tissues and of tumor clonogens to ionizing radiation, and a basic understanding and application of these principles are vital to improve the narrow therapeutic ratio of tumor versus normal tissue damage.

The 5R' concept of radiobiology is as follows [9, 10]:

- *Reoxygention*: This refers to the process by which surviving hypoxic tumor clonogens become reoxygenated after a period of radiotherapy.
- *Repair*: This refers to the process by which tumor clonogens damaged by radiation may restore cell integrity to its full potential.
- *Redistribution*: Distribution of tumor clonogens to a more even cell age distribution after selective cell killing in certain phases of the cell cycle.
- *Repopulation:* This refers to the process by which tumor clonogens can replenish number of cells following a period of radiation therapy.
- *Radiosensitivity*: This refers to a dosage of radiation required to make a defined level of cell inactivation after radiation exposure.

84.2.2 Primary Radiotherapy

This is also called as radical radiotherapy. The indications of primary radiotherapy only include early-stage oral cancers like carcinoma of lip, ventral surface of tongue, and floor of mouth. According to some reports, primary radiotherapy is indicated for treating T1 and T2 cancers with proliferative character. It is believed that the local control and overall survival of the patients are similar in these cases without upfront surgery with an added advantage of preservation of cosmetic, anatomic, and functional integrity of the head and neck region. The literature supports the use of postoperative radiotherapy instead of preoperative radiotherapy even for small-sized tumors as the locoregional recurrence is reported to be slightly more in primary radiotherapy group as compared to postoperative radiotherapy group, but the survival advantage is not statistically significant.

After radiation therapy, the preferred method for assessment of tumor response, in addition to clinical and endoscopic examination, is a posttreatment positron-emission tomographic (PET)/CT scan at 12 weeks. In most patients with a complete response to therapy and negative PET scan results, routine neck dissection is not recommended in the postoperative setting.

84.2.3 Indications of Adjuvant Radiotherapy

The treatment for the stage III and stage IV oral cancer is complex. According to current National Comprehensive Cancer

Network (NCCN) guidelines, single-modality treatment with either surgery or radiotherapy is recommended for approximately 30% to 40% of initial stage oral carcinoma patients (stage I and II). Both modalities of treatment have resulted in comparable survival benefit in these patients. On the other hand, combined modality treatment is generally recommended for the approximately 60% of patients with locally or regionally advanced disease at diagnosis. The treatment in these individuals depends on factors such as site of the disease, stage, pathological findings, and presence of adverse features in the resected specimen. Several studies have classified the oral cancer patients into low risk, medium risk, and high risk [2, 3].

Postsurgical adjuvant radiotherapy is indicated according to the presence of adverse features on final histopathology.

The adverse features refer to extranodal extension, lymphovascular invasion, and perineural invasion.

Patients who are classified as high or intermediate risk of relapse benefit the most from the addition of postoperative radiotherapy.

The indications of adjuvant radiotherapy after primary ablative surgery in oral cancer patients are as follows:

- Stage III and stage IV oral squamous cell carcinoma patients.
- Positive surgical margins: presence of invasive carcinoma at the border.
- Presence of extranodal extension.
- Involvement of more than two levels of lymph nodes (multiple nodal metastasis).
- Perineural invasion.

Often, radiation to the head and neck involves the selection of different doses depending on the amount of disease in that area. Typically, gross disease receives a dose of 70 Gy. Areas at high risk of microscopic disease often receive a dose of between 60 and 66 Gy. Areas at low risk of microscopic disease typically receive a dose of 50–54 Gy. The areas designated at high risk and low risk will depend on the site of occurrence of disease, the stage, and presence of pathological adverse features. The most common fraction size is 2 Gy of radiation per day [10–13].

84.2.4 Effect of Radiation Treatment Delay

Postsurgical radiation delay has a profound effect on overall survival of patient. Tumati V et al. found an association between treatment delays and oncologic outcomes in patients treated with surgery followed by post-op radiotherapy in a total of 277 patients of oral and oropharyngeal carcinoma. On multivariate analysis it was observed that radiation treatment time had a significant impact on locoregional recurrence in these patients. The authors found out that delays in the postoperative radiation therapy >43 days were associated with statistically significant locoregional recurrences ($p = 0.02$) in patients with non-p16-positive cancers. Many investigators have studies in coherence with the above conclusions. An increase in distant metastasis appears to be the mechanism by which prolonged time to treatment initiation leads to worse overall survival [14].

84.3 Radiotherapy Techniques

Depending upon the indication and treatment plan, there are multiple techniques with which radiation therapy can be delivered to a patient undergoing treatment for oral cancer. The techniques of radiotherapy should deliver the calculated radiation dose to the patient as per treatment plan without much toxic effects to the normal tissues. Some of the radiation techniques are listed below (Table 84.1) [15–19].

Table 84.1 Radiation techniques

Radiotherapy technique	Indications	Advantages
Brachytherapy (a) Interstitial brachytherapy (b) Intraluminal brachytherapy	T1 and T2 tongue and floor of mouth cancers	Radiotherapy source placed directly into the tissues to be irradiated. Less chances of systemic toxicities and treatment interruption.
Conventional radiotherapy	For high-risk oral carcinoma patients	Well established with known pattern of response, local control, and toxicities
Intensity-modulated radiation therapy (IMRT)	Advanced approach to three-dimensional treatment planning and conformal approach. For dose calculated radiation delivery to target volume.	Allows for greater sparing of salivary glands, esophagus, optic nerve, spinal cord, and brain stem. Allows treatment to be delivered in single treatment phase. Offers the possibility of simultaneously delivering higher radiation to regions of gross disease and lower doses to areas of microscopic disease.
Image-guided radiation therapy (IGRT)	Advances in real-time imaging during radiotherapy	Targeted delivery of radiotherapy which spares the vital structures immediately adjacent to high-dose regions

84.3.1 Radiation Dosage and Fractionation Schedule

Radiotherapy schedule, conventionally, is followed for 5–7 days a week with defined breaks in the treatment for reoxygenation and repair of normal tissue cells of the body for target effectiveness of radiotherapy. According to the literature, the tumor cells repopulate in between the radiotherapy regime especially after fourth week, so unscheduled breaks between the course of radiotherapy are not recommended by the radiation oncologists. That's the reason different fractionation schedules have been advocated by the radiation oncologists for successful completion of the treatment without unnecessary treatment breaks which can have a negative impact on the final outcome of the patients [15–19].

- *Conventional fractionation*: Every week for 5 days Monday to Friday.
- *Hyperfractionation*: When more than one fraction of lower radiation dose is delivered to the patient in the same day, it is known as hyperfractionation. The advantage is the treatment can be completed in a shorter time than conventional fractionation, yet the same total dose is delivered with better disease control and without increase in the toxicity.
- *Accelerated hyperfractionation*: More than one fraction of radiotherapy is given everyday or radiotherapy is given more than 5 days per week, the disadvantage is the increase in the toxicity due to no treatment breaks.
- *Continuous hyperfractionated radiotherapy*: When the radiation fraction is delivered thrice daily for the whole week, it is known as continuous hyperfractionated radiotherapy. This uninterrupted radiotherapy regime finishes the total dosage of radiation in 12–14 days.

84.4 Complications of Radiotherapy

Though the dual-modality treatment (surgery and radiotherapy) has become a norm for the treatment of advanced-stage (stage III–stage IV) oral squamous cell carcinoma, there are some unavoidable toxic effects of radiation therapy which can affect the quality of life (QOL) of the patient. Radiotherapy has proved to be very effective in improving the locoregional control and overall survival of the patient, but there are short-term and long-term sequel of radiotherapy which sometimes limit the effectiveness of the therapy due to breaks in the treatment schedule. The intensity of the complications and toxic effects depends upon the dose of delivered radiation and the site exposed to the radiation therapy. Radiation techniques like intensity-modulated radiotherapy IMRT and image-guided radiotherapy IGRT are helpful in controlling the delivered dosage of radiation to the patient, thereby decreasing the rate of complications and increasing the response of the patient toward the therapy.

Depending upon the response to radiation, the complications have been divided into acute toxic effects or short-term sequel and chronic toxic effects or long-term sequel.

IMRT requires that the radiation oncologist outline the tumor, the areas at risk for microscopic spreading, and the critical normal structures on every CT slice (contouring). Outlining the gross disease (gross tumor volume [GTV]) and areas at risk of microscopic spreading (clinical target volume [CTV]) requires a thorough understanding of the anatomy of the region and is significantly more labor-intensive than prior two-dimensional or conventional radiation therapy techniques.

84.5 Acute Toxic Effects

84.5.1 Xerostomia

Xerostomia is also referred to as dry mouth. It is one of the most common acute and chronic side effects of radiotherapy. Xerostomia starts from the first week of radiotherapy and is a more common complaint in the first 2 weeks in those patients in whom submandibular salivary glands have been removed as part of the neck dissection. As far as possible, contralateral submandibular salivary gland should be preserved in uninvolved neck when bilateral neck dissection has to be performed. With the traditional radiographic techniques, parotid gland was not spared which resulted in more profound effects of dry mouth leading to halitosis, stasis of thick saliva, dysphagia, and cervical caries. Stasis of thick saliva leads to dysphagia like symptoms and even aggravation of mucositis earlier in the course of therapy.

Intensity-modulated radiotherapy technique and image-guided radiotherapy have revolutionized the concept of delivery of radiotherapy, thereby minimizing the risks of development of unavoidable side effects like xerostomia leading to more acceptable quality of life. A randomized controlled trial by Nutting et al. confirmed the reduction in postradiation xerostomia significantly. They compared intensity-modulated radiotherapy without taking parotid gland in the radiation field and conventional radiation therapy for all patients. About 83% patients developed grade II or higher xerostomia with conventional radiotherapy as compared to 29% of patients who were adopted for parotid sparing intensity-modulated radiotherapy [19].

Many investigators have assessed the relationship of radiation dosage to parotid and submandibular gland and severity of xerostomia at weekly intervals. The inference from these studies point toward the damage to plasma membrane of secretory granules of glands. Another observation was that the flow of saliva from submandibular and parotid glands considerably decreases up to less than 20% of pretreatment values by the end of the second week of radiation therapy. The recommendations are to use current radiotherapy techniques like intensity-modulated radiation therapy to spare the submandibular and parotid gland with lowest possible exposure. The treatment of xerostomia converges toward the usage of sialagogues, artificial saliva, and fluid therapy along with reassurance to the patient [20, 21].

84.5.2 Oral Mucositis

Oral mucositis due to radiotherapy and other systemic therapies in oral cancer treatment represents a major complication causing a wide spectrum of clinical signs and symptoms. Oral mucositis may hamper the quality of life, resulting from debilitating oral pain and bleeding from oral cavity, dysphagia, infections, and inability to chew food and may interfere with the ongoing radiation treatment, ultimately jeopardizing overall patient outcome. According to certain reports, third week of post-radiotherapy is the most crucial time when the mucositis begins to set in and the severity increases in the subsequent weeks. The severity and agony from mucositis is directly proportional to the total dosage of radiation delivered and the volume of irradiated tissue in a specified interval of time. Mild initial erythema to patchy mucositis (characterized by white patches of fibrinous exudate on an erythematous base) to confluent mucositis (where the exudative patches coalesce) are the presenting symptoms of progression of ongoing mucositis in the oral cavity. On the other hand, if there is an evidence of bleeding to touch from the oral ulcers, it is considered as severe to fulminant mucositis.

Confluent mucositis, common toxicity criteria (CTC) grade 3, is seen in 40–80% of patients receiving more than 60Gy (or equivalent), more frequently in those receiving concurrent chemotherapy or accelerated radiotherapy. The patients should be advised to keep good oral hygiene with 0.12% chlorhexidine gluconate along with sialagogues or artificial saliva which will have protective action for the underlying oral mucosa thus reducing the severity of symptoms and relieve the pain. A narcotic analgesic like tramadol is recommended for pain from mucositis. There are some reports which favor elemental zinc or zinc carnosine complex for relieving the symptoms of severe mucositis.

The role of nonalcohol-based mouthwash has been established by many authors for relieving the debilitating effects of mucositis. Topical steroids had been used in past for the treatment of mucositis in severe stages, but their use is constantly discouraged in the current settings. The radioprotectant drug amifostine has been investigated as a means of reducing the incidence of xerostomia and mucositis. The route of administration of amifostine is intravenous everyday prior to initiation of radiotherapy. Patient should be constantly monitored for hypotension and nausea postoperatively.

Moreover, WHO recommends the constant nutrition support to the patients undergoing radiotherapy which will have a positive effect on the recovery from acute mucositis. If oral route is jeopardized, the nasogastric feeding, PEG percutaneous endoscopic gastrostomy, and parenteral nutrition should be considered based on the severity of mucositis. Recovery of severe mucositis may not begin until 2–3 weeks after treatment completion then take up to 4–8 weeks to regain normal swallowing. The recovery is mostly complete; however, only <5% of patients may remain PEG dependent.

Other known acute toxic effects of radiotherapy are erythema of facial and skin of the neck, lethargy, loss of taste, and smell. Erythema of the skin takes about 7–10 days of complete remission after cessation of radiation therapy; however the skin remains photosensitive even after the completion of therapy [20–22].

84.6 Chronic Toxic Effects

There are multiple chronic toxic effects of radiotherapy enumerated in the literature by different authors and radiation oncologists (Table 84.2). It has been found out that the chronic effects of radiotherapy are more dependent on dosage than the acute effects of radiation.

84.6.1 Osteoradionecrosis of Maxilla and Mandible

Currently, one of the most serious long-term or chronic complications of radiotherapy to the head and neck region is osteoradionecrosis of the jaws. The associated morbidity of this complication and its subsequent treatment will include close observation and/or radical surgical resection followed by reconstruction with free fibula, deep circumflex iliac artery flap (DCIA), or a variety of pedicled and soft tissue free flaps depending upon the severity of necrosis and systemic condition of the patient.

The etiopathogenesis of osteoradionecrosis have been explained on the basis of current theory of Delanian and Lefaix [23]. It states that osteoradionecrosis of the jaws is a radiation-induced fibrosis with histopathological formation of phases which appear similar to those of chronic wounds. There is a histopathological picture of combination of dead or dying osteoblasts without replication of new osteoblasts and excessive proliferation of myofibroblasts. This condition is manifested as loss of trabeculae of existing bone and subsequent decrease in the quality and structure of underlying bone.

Among the risk factors for the development of osteoradionecrosis, total radiation dose delivered to the bone, in a specified period of time, remains the most important and crucial risk factor. The cumulative dose of radiation to the bone will

Table 84.2 Chronic effects of radiotherapy

Chronic toxicity	Risk factors	Prevention strategy
Osteoradionecrosis, mandible, maxilla	Primary bone surgery (marginal mandibulectomy), maxillary osteoradionecrosis is rare. Dentulous patients High radiation dose >65 Gy to the mandible. Traumatic extractions. Women > men. Conventional radiotherapy techniques. Age of the patient.	IMRT, IGRT, calculating the dose to be delivered to mandible. Proper dental consultation and rehabilitation before radiotherapy. Appropriate coverage of remaining bone with free vascularized soft tissue flaps
Trismus	Postoperative radiation to the masseter muscle and pterygoid muscles. Location of the tumor in the oral cavity. In case of maxillary tumors, reconstruction with temporalis flap pose greater risk of developing trismus after radiotherapy	Early institution of radiotherapy within 4–6 weeks of surgery Use of microvascular free flaps for reconstruction which provide extra soft and pliable tissue
Hypothyroidism	Irradiation of thyroid tissue at higher dose. Female patient	Dosage to the thyroid gland should be limited. Use of thyroid shield
Nerve injury (damage to spinal cord, optic nerve, vestibulocochlear nerve)	Radiation dosage >50–54 Gy pose more risk of development of nerve injuries	IMRT, IGRT, calculating the dose to be delivered
Radiation-induced cancers	Radiation-induced tumors are mostly sarcomatous and develop many years after institution of radiotherapy	Regular follow-up of the patient

produce an environment of hypo-cellularity and hypo-vascularity leading to the cause and effect relationship in the underlying bone. Maxillary bone is less susceptible to the development of necrosis than mandible as maxilla has a more porous structure of bone with more vascularity as compared to a single terminal inferior alveolar artery in mandible which undergoes fibrosis after high-dose radiation therapy. Moreover, muscles of facial expression and thick mucoperiosteum in maxilla prevent it from getting hypo-vascular in a shorter period of radiation therapy. Facial artery is notoriously unreliable to produce collateral blood supply to the mandible which is insufficient to prevent osteoradionecrosis. On the other hand, in case of post-neck dissection patients, the facial artery is most of the time ligated in the ipsilateral side during the clearance of level IB (submandibular) group of lymph nodes.

According to a comparative study conducted by Kuhnt et al. [22] on 776 patients with head and neck cancer who underwent intensity-modulated radiotherapy as radical radiotherapy for the treatment of head and neck cancer and as postoperative radiotherapy, the highest cumulative incidence of osteoradionecrosis was found to be 12.4%, and relative frequency was 6.6%. The interesting inference of this study is the actual risk for the development of osteoradionecrosis remains there for a lifetime of the patient and may increase by a factor of two in long-term survivors. There remains a highest risk for the development of osteoradionecrosis in patients who had undergone primary bone surgery during tumor resection (hazard ratio: 5.87 95% confidence interval) and in patients with tumor located in the oral cavity than other sub-sites in the head and neck region. This means the dental treatment including extractions and minor surgical procedures should be performed well before in the patients advised for adjuvant radiotherapy in which mandibular resection (marginal mandibulectomy or segmental mandibulectomy) has been advised. Moreover, it is prudent to cover the marginal mandibulectomy defect with the free flap or a soft tissue pedicled flap to maintain vascularity so as to prevent postradiation chance of osteoradionecrosis.

Gender, dentition (dentulous vs edentulous), and concurrent chemotherapy have no significant clinically relevant influence on the development of osteoradionecrosis. Males are found to have three times more risk for the development of osteoradionecrosis than women. According to a study conducted by Gabriela et al., 25% of patients developed refractory osteoradionecrosis which required some kind of resection and subsequent reconstruction when the radiation dose delivered were more than 66Gy at a daily fraction exceeding up to 2.2Gy as compared to no evidence of osteoradionecrosis at or below 65 Gy of radiation dose [24]. On the other hand, as the daily dose of radiation decreases to 1.8 and 1.9 Gy, and a total dose of 69–75.6 Gy, the rate was 19.6%. Daily dose of radiation is thus considered to be a most significant factor in determining likelihood of developing osteoradionecrosis especially in cases of oral cancer. The close proximity of the cancer to the mandible (with in 1 mm) receiving high dose of radiation remains the other risk factors for the development of osteoradionecrosis.

Prevention is better than the treatment of osteoradionecrosis. One study confirms the effectiveness of hyperbaric oxygen therapy in a very few number of patients. State-of-the-art radiotherapy techniques will limit the total absorbed dose to the mandible and potential sites in the oral cavity thus limiting the incidence of osteoradionecrosis [24, 25].

84.7 Principles of Chemotherapy

The oral cancer is considered as the sixth most common malignancy worldwide accounting up to 1,30,000 cases every year in a developing country like India. Due to poor screening facilities at primary examination level, lack of awareness among patients, and nonstandardization of public health sector, most of the cases are diagnosed when they have attained stage III and stage IV disease.

On the other hand, chemotherapy regimens for oral cancer treatment are evolving. There are multiple methods by which chemotherapy may be offered to the patients for the management of head and neck cancer to improve the overall outcomes in terms of survivability of patients.

Methods of providing chemotherapy for head and neck cancer patients are as follows:

- Single-modality treatment for palliation.
- As concomitant radiation therapy or concurrent chemoradiation (triple modality).
- As adjuvant therapy following surgical resection (dual modality).
- As definitive treatment for locoregionally advanced carcinoma primarily.
- As induction therapy or neoadjuvant therapy (NACT) before definitive treatment for prognostication of the primarily inoperable tumors.

Single-modality treatments usually have low efficacy in terms of locoregional recurrences. On the other hand, chemotherapy with or without radiotherapy poses the patient toward the risk of systemic toxicities and unwanted immunosuppression which may alter the overall result and outcomes of the patient undergoing cytotoxic therapy in any form [25–29].

84.7.1 Cytotoxic Chemotherapeutic Agents

While multiple cytotoxic drugs have been identified for the treatment of oral squamous cell carcinoma in addition to surgery and radiotherapy, some of the chemotherapy agents are listed below (Table 84.3).

84.7.2 Chemoradiation in Oral Cavity Cancers

Earlier it was thought that radiation therapy alone is effective for treating small T1 and T2 lesions of lower lip, floor of mouth, tongue, and palate within the oral cavity. After a decade, many centers adopted surgery alone for smaller lesions of oral cavity as primary treatment. Then a dual-modality approach (surgery followed by radiotherapy) was popularized for locally advanced carcinoma (stage III–stage IV AJCC eighth edition) of oral cavity. Hence, the dual-modality approach emerged as a conventional, widely accepted, and equally effective treatment option for the management of advanced (T3–T4) lesions. Conventionally, the combination of chemotherapy and radiotherapy, as primary treatment modality, had been reserved for those patients with unresectable disease or patients who refuse the surgical treatment.

It has been published by the RTOG trial reports that adjuvant radiotherapy improves the outcome of patients which received the surgical treatment for advanced-stage squamous cell carcinoma arising in the head and neck. At the same time, the disease-free survival and 5-year overall survival came out to be generally between 30 and 40% which is highly nonpromising. These trials also suggested that if the concurrent chemotherapy, using cytotoxic drugs, is added to the conventional postoperative radiotherapy regime, the effects of radiotherapy are intensified. This methodology of adjunctive treatment has significant amount of survival benefit than dual-modality treatment, and the chances of locore-

Table 84.3 Chemotherapy agents used in oral cancer

Chemotherapeutic drug	Mechanism of action	Toxicity and response
Platinum agents: Cisplatin, carboplatin, oxaliplatin	Inhibit DNA synthesis by forming intrastrand and interstrand cross-links between guanine-guanine pairs of DNA	Most active agent with response rates 20–50%. Dose rage is 80–120 mg/m^2 every 3–4 weeks. Renal toxicity, myelosuppression, neurological, and gastrointestinal toxicity (less with carboplatin)
Taxanes: Paclitaxel, docetaxel	Act by promoting the formation of tubulin dimers, stabilizing microtubules during cell division, and thereby leading to arrest of cells in G2/M phase of cell cycle	Particularly severe and life-threatening myelosuppression. Neutropenia, mucositis, and fluid retention Paclitaxel response up to 37% Docetaxel response 22–45%
5- fluorouracil: An antimetabolite	Depletion of nucleotides required for DNA synthesis and repair	Single-agent response is 15% Mucositis, diarrhea, myelosuppression
Methotrexate	Interferes with the use of folate used for DNA synthesis and repair inhibits dihydrofolate reductase (DHFR)	Most commonly used schedule is weekly intravenous bolus regime, using a dose of 40–60 mg/m^2. The objective response rate in this dose range is 10–30%
Cetuximab: a monoclonal antibody against human EGF receptor	It prevents binding of EGFR ligands, results in inhibition of function of the receptor	Significantly improved overall survival in head and neck squamous cell carcinoma patients Consistent severe acneiform skin rash

gional recurrences are likely to be less especially in high-risk patients postoperatively. In the last 10 years of research in the field of head and neck carcinoma treatment, the efficacy of triple-modality therapy has been justified in the literature for postoperative high-risk squamous cell carcinoma patients. Like RTOG a similar trial was conducted in Europe, the EORTC trial. This trial also reconfirmed the addition of adjuvant chemotherapy to the radiotherapy regime. The inference of this trial showed better rates of local control, disease-specific survival, and overall survival and significant decreased incidence of late toxic effects. Both these trials compared the addition of three planned cycles of concomitant cisplatin at 100 mg/m^2 every 3 weeks to radiotherapy (60–66 Gy, over 6–6.5 weeks, standard fractionation) with the same radiotherapy alone in patients with adverse feature of head and neck carcinoma. Therefore the concomitant therapy with cisplatin at 100 mg/m^2 every 3 weeks with adjuvant radiotherapy on day 1, day 22, and day 43 is the regimen of choice. The only limitations of these two trials were that these trials were not oral cancer specific. There are very few studies in the literature who have evaluated the concept of triple-modality therapy yet being site specific to oral cavity. Choi et al. retrospectively reviewed 861 patients with oral carcinoma treated in Korea from 1984 to 1996. Almost 63% of patients had stage III and stage IV cancer, and 36% had T3–T4 lesions. The authors concluded that triple-modality treatment (upfront surgery followed by postoperative chemoradiation) yielded a greater treatment response rate than dual-modality treatment [29]. On the other hand, Zhang et al. conducted a trial in oral cancer patients who received surgery followed by radiotherapy as a primary treatment modality. The trial found out that there is a 3.6 times more incidence to develop distant metastasis in surgery and radiation group as compared to surgery followed by chemoradiation group [3].

Box 84.1 Questions to be answered

Now the question arises.

1. Whether the addition of chemotherapy to the radiotherapy regime will improve the survival outcomes?
2. If the survival benefit is observed, does it have any effect on progression-free survival?
3. Is there any of incidence of chronic toxicities if the chemo radiation is used?
4. Does the technique of administering radiation have any profound effect in the outcome?
5. Whether the patients with adverse features (like: extranodal extension, lymphovascular invasion, and perineural spread) have improved outcomes with chemoradiation?

Explanation for Q1&2: Results of the recent study conducted by Stenson et al. revealed that patients who underwent chemoradiation as primary therapy for advanced-stage oral squamous cell carcinoma had a greater rate of metastasis-free and overall survival benefit with 66.9% disease-free or progression-free survival [30]. One of the recent single-institutional study conducted by Dhawan et al. on 128 patients of advanced-stage high-risk oral carcinoma shows an overall survival benefit of 10% in patients receiving chemoradiation as compared to patients receiving only radiation therapy after primary ablative surgery. This study was conducted in a subset of Asian Indian population to evaluate the benefits of multimodal therapy in the management of stage III/IV oral carcinoma [2]. Zhang et al. in their study showed a survival benefit of 11% in patients receiving chemoradiation as compared to radiation alone [3].

Explanation for Q-3: But the survival benefit doesn't come without a price to the patient. Along with improved survival comes the greater incidence of acute and chronic toxicities due to cytotoxic chemotherapeutic agents. The chances of recurrence always remain high even with the addition of chemotherapy due to the advanced stage and higher volume of the disease being treated. The recurrence potential of the lesion depends on the invasive pattern of tumor invasion at the first place and the presence of cancer stem cells in a given area. According to Pericot et al., high incidence of recurrence is associated with size of the primary tumor (T stage), and the difficulty in obtaining margins free of disease, after surgical resection. So obtaining a positive margin or a close margin (between 1 to less than 5 mm) after resection becomes an indication for administration of concurrent chemoradiation therapy. On the other hand, the development of myelosuppression, neutropenia, mucositis, and xerostomia is inevitable with triple-modality treatment [31].

Explanation for Q-4: The type of radiation (IMRT and routine radiotherapy) also affects the survival outcomes when used concurrently with chemotherapy as IMRT is more effective along with chemotherapy than with conventional radiotherapy.

Explanation for Q-5: Neck node involvement is also considered as an independent predictor of survival in oral cavity cancer. According to the literature, patients with nonpalpable disease in the neck or clinically N0 necks are having greater overall survival rate as compared to subsequent N stages. A recent study by Franceschi et al. found that among patients with involved neck nodes, survival rate was significantly lower when more than two levels of lymph nodes were involved, or when extranodal extension was observed. The adverse features which are found after final histopathological examination of primary as well as neck dissection specimen are currently addressed as extranodal extension, perineural invasion, and lymphovascular invasion. These patients are particularly at higher risk of disease progression and have higher death rates [32]. According to Zhang et al. [3], patients with extranodal extension and perineural invasion had improved disease-specific and metastasis-free survival in the surgery followed by chemoradiation group ($p < 0.05$). In a retrospective study conducted in 2016, authors found out that overall survival was significantly influenced by the type of modality and regional spread of disease. Chemoradiation after primary ablative surgery group had improved overall, disease-specific, disease-free, and metastasis-free survival compared to surgery followed by radiotherapy group even in patients with extranodal extensions, perineural spread, and lymphovascular invasion.

According to RTOG and EORTC landmark trials, there are some absolute indications for postoperative chemoradiation. These studies provided the base for the risk-adapted strategies in postoperative adjuvant therapy and *established extranodal extension and positive surgical margin as the absolute indications for adding concomitant systemic chemotherapy to adjuvant radiation*. However, proper patient assessment preoperatively is mandatory keeping in view the systemic toxicity due to chemoradiation.

Absolute Indications of Adjuvant Chemotherapy in Oral Cavity Cancers

According to RTOG trial, the definition of high-risk patients is as follows:

- Presence of tumor at the surgical resection margins—positive surgical margin.
- Extranodal extension.
- Clinical or radiographic involvement of level IV and level V lymph nodes.
- Stage of pT3 or pT4 with any N except T3N0 of the larynx.
- N2–N3 neck.
- Perineural invasion.
- Vascular embolism.

84.7.3 Induction Chemotherapy Before Surgery

Since 1982, during the days of early clinical trials on chemotherapeutic agents and their clinical advantage in head and neck squamous cell carcinoma, induction chemotherapy was thought to have potential benefits for treating head and neck cancers. Unfortunately, the higher response rates of these chemotherapeutic results have failed to result in statistically significant survival benefit. Induction chemotherapy before surgery is generally instituted in primarily unresectable oral cavity cancers at some centers. The efficacy of induction chemotherapy has yet to be proven in oral cancer treatment with regard to locoregional control and/or overall survival of these patients. The efficacy of induction chemotherapy to downstage oral cavity cancers was observed by a study conducted by Grau et al. in a prospective way with unresectable stage III–stage IV oral cavity cancers. They found out that disease-free survival at 5 years was 26% for patients undergoing resection and 22% for patients who received chemoradiation. Improved outcome is always at an expense of increased toxicity. There are other studies with comparable results which were carried out exclusively in oral cancer patients. Currently, induction chemotherapy cannot be recommended in resectable oral cancer patients for improvement in the survival [33].

84.7.4 Palliative Chemotherapy in Patients with Oral Cancer

Patients with recurrent and metastatic squamous cell carcinoma of head and neck are considered incurable with surgery or radiation. In these patients mainstay of treatment remains the systemic chemotherapy with cytotoxic chemotherapeutic drugs. Chemotherapeutic agents can be used either in combination regimen or as single agent in the management of metastatic oral cavity carcinomas. Radiation therapy with concurrent cetuximab, a monoclonal antibody to epidermal growth factor receptor (EGFR), has been shown to significantly improve overall survival rates compared with radiation therapy alone in the palliative setting. A direct randomized comparison of cetuximab versus platinum-based regimens is underway at many centers in the world. At present, platinum-based regimens (cisplatin, carboplatin) are preferred over other drugs, as long as patients can tolerate the regimen with acceptable complications [34–36].

84.8 Conclusions

Adjunctive therapies are included in the treatment regimen of oral squamous cell carcinoma to improve the disease-free, metastasis-free, and overall survival of the patients. Adjuvant radiotherapy is indicated in high-risk advanced-stage (stage III–stage IV) oral squamous cell carcinoma patients as dual modality. The complications and side effects of radiotherapy can be reduced by adopting advanced radiotherapy techniques like intensity-modulated radiotherapy, image-guided radiotherapy, and stereotactic radiotherapy. Concurrent chemoradiation therapy is adopted as primary treatment in patients with locally advanced oral cavity cancer whose disease is not amenable for surgical resection. Adjuvant chemoradiation is indicated in patients having postresection positive margins and with extranodal extensions or extracapsular invasion as a multimodality treatment. Consider cetuximab synchronously with radiotherapy in patients unsuitable for platinum-based chemoradiation.

85 Access Surgeries and Osteotomies for the Maxillofacial Region

Madan G. Ethunandan

85.1 Bicoronal Scalp Flap

The bicoronal flap was first described by Hartley and Kenyon [1] to access the cranium and popularised by Tessier [2] to provide additional access to the orbits and midface. Various modifications of the flap have been described and include a zigzag (stealth) incision [3], deeper plane of dissection in the temporal scalp region to avoid damage to the facial nerve [4, 5] and strategies to minimise alopecia [6].

The coronal flap provides access to the skull, anterior and middle cranial fossa, upper midface including the nasoethmoid region and orbits and temporal and infratemporal fossa.

The SCALP is an acronym consists of five layers: *S*kin, sub*C*utaneous connective tissue, galea *A*poneurotica, *L*oose areolar tissue and *P*ericranium. The first three layers are firmly attached to each other and are raised as a single layer, superficial to the loose areolar tissue (avascular plane of Merkel). The blood vessels and nerves run within the first three layers. The "perceived" complexity of the layers in the temporal region can be rationalised, if one was to consider the galea aponeurotica as a single layer which extends to the temporal region as the "temporoparietal fascia" (synonym—superficial temporal fascia/supra-zygomatic SMAS) and the pericranium extending as the "temporalis fascia" (synonym—deep temporal fascia) overlying the temporalis muscle. The deep temporal fascia divides about 2–3 cm superior to the zygomatic arch into a superficial and deep layers. The temporoparietal fascia, superficial layer of the deep temporal fascia and the periosteum of the zygomatic arch fuse together on the lateral aspect of the zygomatic arch and contain the frontal branch of the facial nerve. The superficial temporal fat pad is present between the superficial and deep layer of the deep temporal fascia, with the deep layer attached to the deep aspect of the zygomatic arch. Dissection deep to the galea and the temporoparietal fascia affords a relatively bloodless plane and maintains and preserves the blood supply and avoids damage to the nerves, including the frontal branch of the facial nerve. This "safe" plane of dissection can be between the temporalis muscle and the "undivided" deep temporal fascia or (more inferiorly) between the superficial and deep layers of the "divided" deep temporal fascia (Fig. 85.1a).

The frontal branch of the facial nerve crosses the zygomatic arch at least 8 mm (range 8–32 mm) in front of the external auditory meatus, at least 1 cm anterior to the superior attachment of the helix to the scalp, and runs no further than 2 cm above the frontozygomatic suture (Fig. 85.1b).

85.1.1 Procedure

The hair along the incision line can be parted or a small strip shaved. Local anaesthetic containing 1: 200,000 adrenaline is infiltrated above the galea for appropriate haemostasis (you know you are in the right plane if increased resistance is felt. If it is easy to inject, you are in the deeper loose areolar tissue plane). The incision is marked from the anterior attachment of the helix and carried over the vault to the opposite side, inside the hairline (Fig. 85.1c). It can stop at the midline, if only unilateral access is required. If repeated access is likely to be required to the cranial skeleton, it would be useful to incorporate a posteriorly directed "curve", just above the helical attachment to the scalp, to try and avoid injury to the anterior branch of the superficial temporal artery and maintain additional vascularity to the flap. A "bevelled" incision can be made parallel to the hair follicles to minimise alopecia, and a "zigzag" can be incorporated to reduce parting of the hair along a straight incision line. When designing the flap in male patients, the likely influence of male pattern baldness should be taken into account.

The incision commences at the vertex between the superior temporal lines and is made with a blade through the

Solid line—dissection between the (undivided) deep temporal fascia and temporalis muscle. (**b**) Position of the frontal branch of the facial nerve. (**c**) Skin marking for a coronal flap. (**d**) Pericranial flap raised as an extension of the deep temporal fascia incision (note same plane of dissection). (**e**) Incision marked on the undivided deep temporal fascia. (**f**) Periosteal tunnel created along the zygomatic arch, deep to the position of the frontal branch of the facial nerve. (**g**) Exposure of the lateral orbit and zygomatic arch. (**h**) Temporalis muscle retracted to expose the temporal fossa and lateral orbital wall

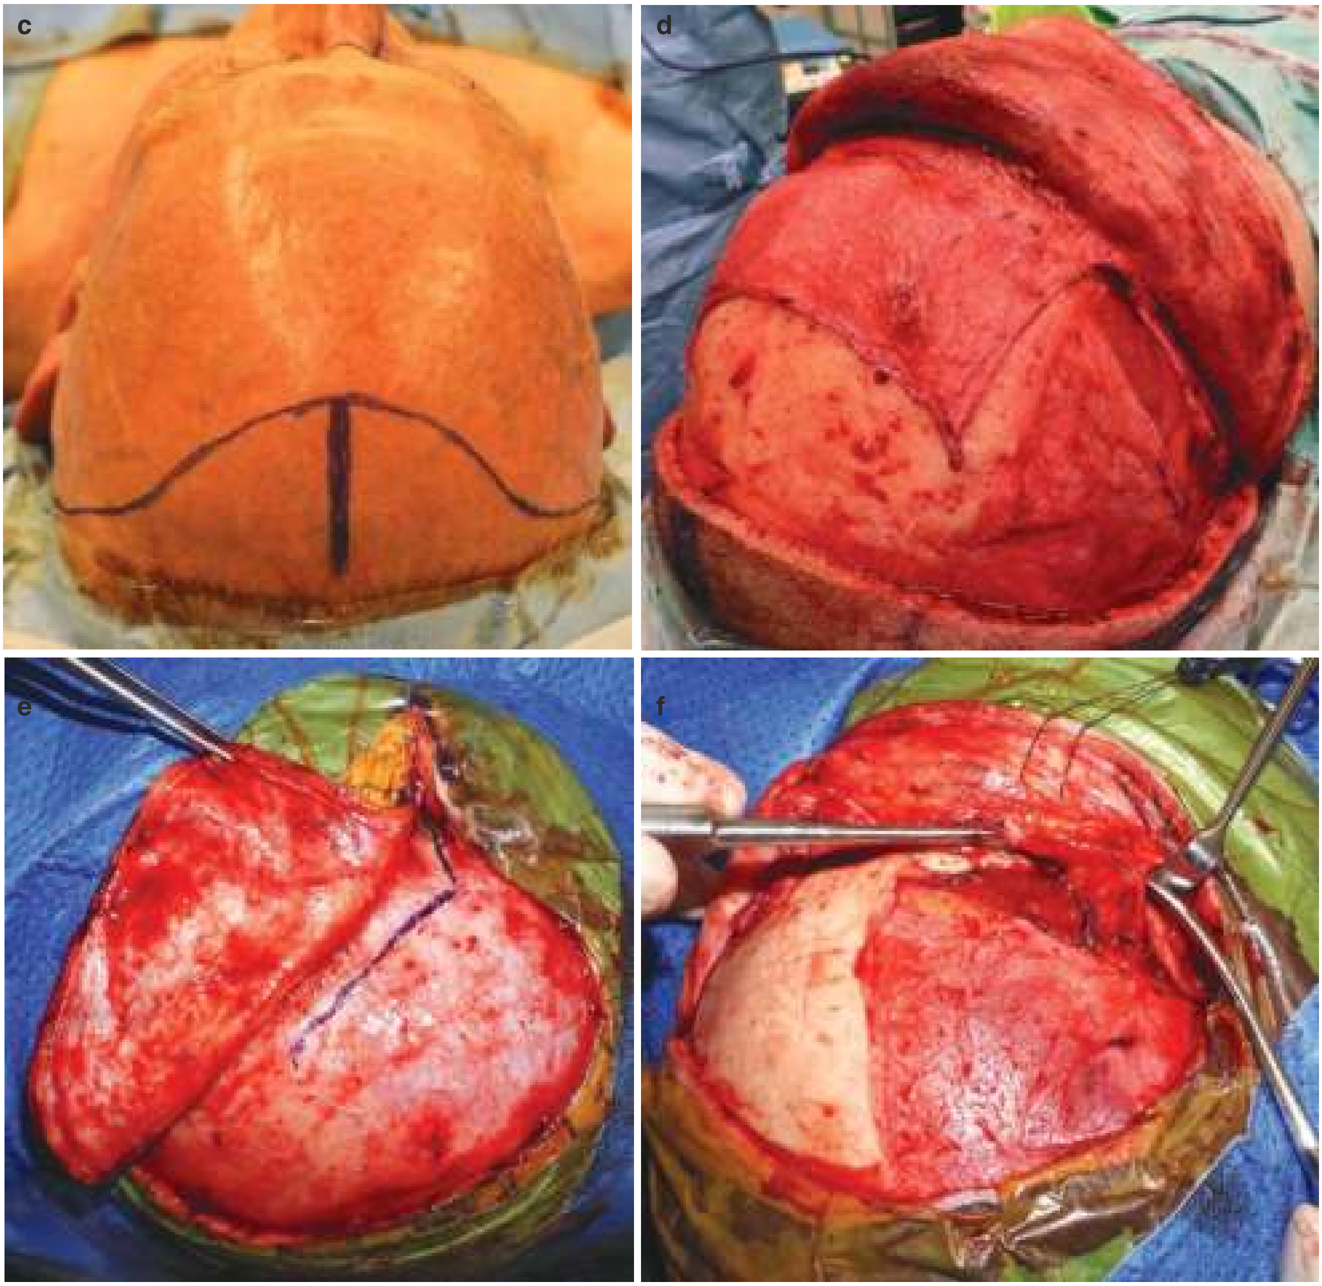

Fig. 85.1 (continued)

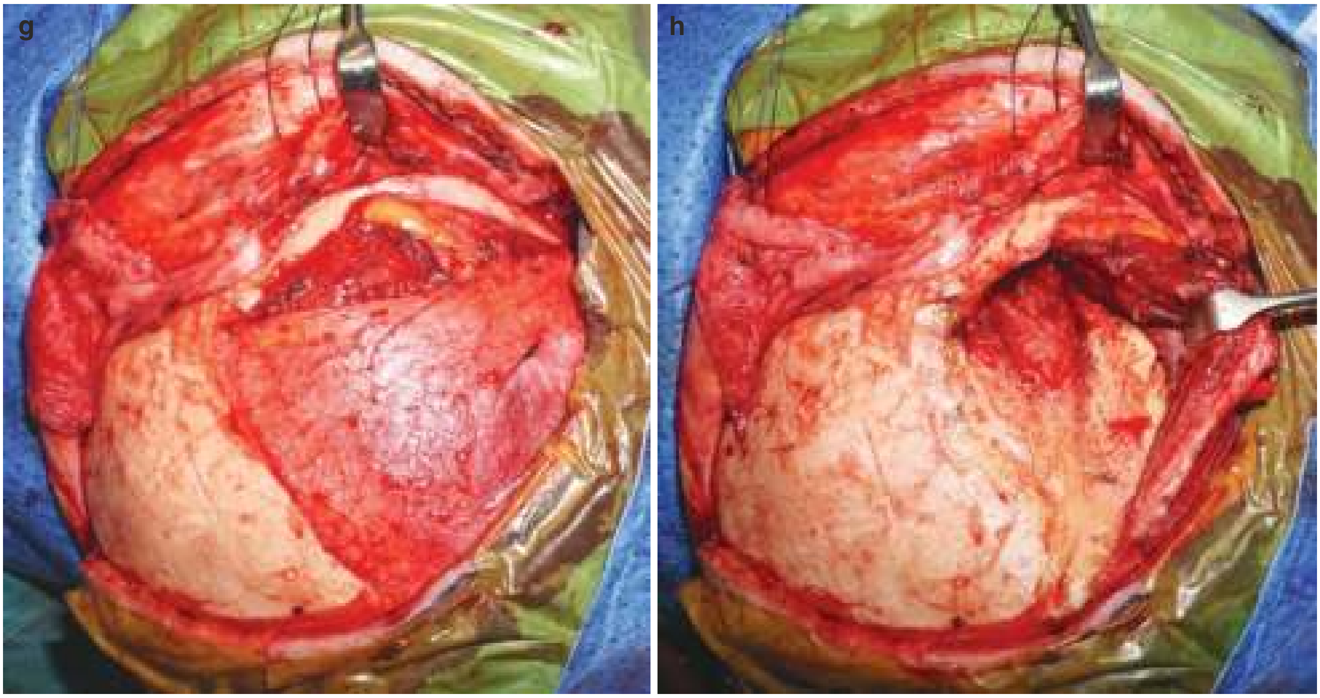

Fig. 85.1 (continued)

galea, up to the loose areolar tissue, and the superficial three layers are raised as a unit. Blunt scissors or a brain retractor can be used to undermine the incision line along this plane, down to the root of the helix, and with the brain retractor in situ, the incision is made down to it. This allows rapid elevation of the flap, without inadvertent damage to the underling temporal fascia/temporalis muscle. Dissection is carried inferiorly in the subgaleal plane. The pericranium is incised approximately 3 cm above the superior orbital rim, and the dissection continued subperiosteally. Resistance can be encountered in the frontozygomatic and frontonasal suture region and around the supraorbital neurovascular bundles. If the supraorbital neurovascular bundle is present within a foramen, rather than a notch, the foramen can be opened with careful use of a fine osteotome (divergent cuts to minimise damage and ease of release).

A pericranial flap could be easily incorporated, by extending the pericranial incision superiorly to the required length, between the superior temporal lines, as an extension of the temporalis fascia incision (Fig. 85.1d). If a pericranial flap is to be utilised, the subgaleal dissection should stop 2 cm above the supraorbital rim, to maintain the vascularity of the pericranial flap.

Exposure of the nasal bones and frontal process of the maxilla can be facilitated by a vertical periosteal releasing incision in the midline. The medial canthal ligaments can be detached from the anterior lacrimal crest, which provides excellent exposure of the medial orbit up to the optic canal and the medial floor up to the infraorbital nerve.

The detached medial canthal tendon must be "tagged" through the periosteum with a unresorbable suture on a round-bodied needle, for subsequent reattachment to a microplate. Subperiosteal dissection medially is now possible as far as the floor of the orbit.

The skin incision is extended inferiorly in a naturally occurring skin crease, to just below the cartilaginous meatus, if exposure of the zygoma, lateral orbit or temporomandibular joint is considered. This could be modified to follow the free edge of the tragus, to make this section less conspicuous. The dissection is carried forward medially following the cartilaginous meatus. At the superior attachment of the helix, the temporalis fascia is incised −1 cm above the zygomatic arch, and angled forwards to join the supraorbital periosteal incision 3 cm above the supraorbital rim (Fig. 85.1e). The incision is extended vertically in along the temporal fascia to the root of the zygomatic arch, which can be felt on palpation above the cartilaginous meatus. A pocket is created at the root of the zygomatic arch, deep to the periosteum and the soft tissues tented with a periosteal elevator to expose the arch. The soft tissues superior to the arch, on the surface of the temporalis muscle, can be transected down to the periosteal elevator to expose the zygomatic arch, zygoma and lateral orbit, without damaging the frontal branch (Fig. 85.1f, g).

Retraction of the temporalis muscle posteriorly provides additional exposure to the temporal fossa and the superior boundary of the infratemporal fossa (Fig. 85.1h).

Closure of the galea and meticulous haemostasis is essential, and drains and/or head dressing can be additionally utilised to prevent haematomas.

85.1.2 Potential Complications and Solutions (Clinical Pearls)

Alopecia: Use a knife for skin incision, meticulous haemostasis with judicious use of bipolar diathermy and tension-free closure.

Frontal nerve damage: Appropriate plane of dissection, care during retraction and the use of diathermy in the temporal/preauricular region.

Supraorbital/supra-trochlear nerve damage: Care during dissection in the supraorbital rim region and judicious use of fine/sharp osteotomes when deroofing the supraorbital foramen.

Clinical Tips

- Inject vasoconstrictor above the galea, make the incision in segments with a blade and use bipolar diathermy to achieve meticulous haemostasis and reduce blood loss.
- Consider making the incision parallel to the hair follicles and use bipolar diathermy "judiciously" to minimise alopecia.
- Start the incision in between the superior temporal lines to "easily" identify the appropriate plane of dissection.
- Stay deep to the galea in the temporal region to avoid injury to the frontal branch of the facial nerve.
- An easier and safer plane of dissection would be between the temporalis muscle and the deep temporal fascia.
- Stop dissection in the subgaleal plane, 2 cm above the supraorbital rims, if a pericranial flap is planned, to preserve its vascularity.
- Place deep sutures along the galea for "tension-free" skin closure but away from the skin surface to minimise "stitch" abscesses.

85.2 Midface Access

A modified Weber-Fergusson approach remains the most popular transfacial approach to the midface. This access was originally described well over 150 years ago by Weber [7] from Germany and Fergusson [8] from the United Kingdom. Various modifications have been incorporated over the years, and the more commonly used ones include the midline lip incision being placed on the philtrum [9], lateral eyelid extension [10] and medial eyebrow extension [11]. The original lateral rhinotomy incision was described by Moure [12], and a modification of the nasal component to lie along the nasal subunits was described by Thankappan [13].

A modified Weber-Fergusson incision provides excellent access to the ipsilateral maxilla and, with appropriate extensions, provides additional exposure to the nasal cavity, orbit and ethmoid (Fig. 85.2a). The "nasal" part of the incision can be utilised for a lateral rhinotomy access.

A Le Fort I down-fracture osteotomy can also be utilised to access the nasal cavity, maxillary antrum, pterygopalatine fossa and clivus. However, with the widespread use of endonasal endoscopic techniques, its use has become limited. The technique is similar to that utilised in orthognathic surgery and is outlined in the orthognathic surgery chapter.

An intraoral vestibular incision can be joined with bilateral piriform fossa and intercartilaginous and septocolumellar transfixion incisions to "deglove" the upper lip, cheek and soft tissues of the nose to provide access to the maxilla and nasal cavity [14, 15].

A maxillary swing procedure can be utilised to access the posterior maxilla, pterygopalatine/infratemporal fossa and nasopharynx. However, with the widespread use of endoscopic techniques, its role has also become limited. Its principal use is in the management of recurrent nasopharyngeal tumours, which cannot be accessed endoscopically [16].

The modified Weber-Fergusson commences with an upper lip split incision that is made along the philtrum and extended along the alar margins. A "V" can be incorporated along the nasal floor to improve localisation of the flap during closure. The incision is carried along the alar margin and extended superiorly at the junction between the nasal side wall and dorsal nasal subunit (Fig. 85.2a).

The intraoral incisions are made along the gingival crevice or buccal vestibule and are principally determined by the location of the tumour. A "V" can be incorporated in the lip mucosa to facilitate accurate approximation during wound closure. The cheek flap is elevated to expose the maxilla (Fig. 85.2b). The plane of dissection is principally determined by the extension of the tumour. A "tonsil" swab can be placed in the nasal cavity and soft tissues along the piriform rim transected to gain access to the nasal cavity and avoid inadvertent damage to the nasal septum.

Lateral extensions can be incorporated, if additional access is required to the orbits and zygoma. This is made along the subciliary/midtarsal skin crease and can be extended laterally along the crow's feet skin crease (Fig. 85.2a). Care is taken to elevate the skin flap "superfi-

Fig. 85.2 Midface access, (**a**) Marking for a modified Weber-Fergusson incision respecting the nasal subunits. Lateral lower and upper eyelid extensions (for total maxillectomy with orbital exenteration) and medial glabella extension (for additional nasal access). Red dotted lines with Lynch (superior) and crow's feet (lateral) extensions. (**b**) Exposure afforded by the incision. (**c**) Anterior ethmoid artery (arrow), exposed in the medial orbit along the frontoethmoid suture. (**d**) Lacrimal sac/nasolacrimal duct exposed in the lacrimal fossa

cial" to the orbicularis oculi muscle in the eyelid region to preserve function, and it is important to avoid "button holes" in the thin skin of the eyelids.

Superior extension (Lynch [11] modification) can be incorporated, if additional access is required to the medial orbit and ethmoids (Fig. 85.2a). The nasal sidewall incision is extended superiorly along the medial orbit at least, 5 mm medial to the medial canthus, up to the medial end of the eye brow/medial supraorbital rim. The incision deepened down to the bone and the frontal process of the maxilla, anterior lacrimal crest and frontonasal suture exposed. The medial canthal tendon is "formally" identified and detached. It is "tagged" with a 3.0 Prolene suture on a round body needle, for subsequent reattachment. The medial orbit can now be exposed with fine periosteal elevators. The frontoethmoidal suture (FES) in the medial orbit provides an excellent landmark for the position of the anterior and posterior ethmoid vessels and optic canal. These vessels are identified along the suture, skeletonised and ligated/diathermised (Fig. 85.2c). The optic canal lies posteriorly in superomedial orbit, in line with the suture. The number of ethmoidal vessels varies frequently [1–3] and the over-reliance of the distances between the vessels (24 mm, 12 mm, 6 mm) and the optic canal can be dangerous The FES can often lie "above" the cribriform plate, and its relationship to the anterior cranial fossa should be "critically assessed" in the preoperative scans. Osteotomies are best placed below the FES, if "unintentional" intracranial extension is to be avoided.

The lacrimal sac is identified inferiorly in the lacrimal fossa and can be dissected free for retraction or transection (Fig. 85.2d).

A medial extension, along the glabella skin crease, can be incorporated if additional access is required to the nasal bones, roof of the nasal cavity, or if a "nasal" swing is considered (Fig. 85.2a).

The lower eyelid extension can be combined with a similar upper eyelid incision, if a lid-sparing orbital exenteration is planned (Fig. 85.2a).

85.2.1 Potential Complications and Solutions (Clinical Pearls)

Unsightly scar: Use the modified Weber-Fergusson incision along the philtrum, nasal subunits with "v" in the nasal floor and lip mucosa—meticulous layered closure in layers and accurate alignment of the vermillion border.

Delayed bone healing (maxillary swing): Minimal soft tissue elevations along the osteotomy sites, pre-plating prior to completion of osteotomy, use fine saw blades and bur and copious irrigation.

Clinical Tips

- Inject vasoconstrictor, make the incision in segments and use diathermy to minimise blood loss.
- Extend the midline skin incision past the vermillion, prior to incorporating the mucosal "V" to facilitate accurate approximation of the vermillion.
- Tattoo or mark the vermillion, if you feel it would help in later approximation.
- Intraoral incisions and the plane of dissection are dictated by the location of the tumour.
- If a lower eyelid extension is planned, the plane of dissection is ideally above the orbicularis oculi muscle (if eye is preserved).
- Soft tissue "elevation" is kept to the minimum along the osteotomy sites, if a maxillary swing is planned.
- Formal identification and tagging of the medial canthus are necessary for later reattachment.
- Recognise the "orientation" value of the frontoethmoidal suture.
- Beware of using distances between the ethmoidal foramina and optic canal as the "sole" modality during deep dissection of the medial orbit.

85.3 Nasal Swing

This provides access to the nasal cavity, ethmoids and nasal roof and can be considered for bilateral lesions, when the nasal skin/bones can be preserved. Currently, with the widespread use of endoscopic techniques, its role, as a "sole" access to these lesions, is restricted. It is often used for additional access, as part of a wider resection.

A modified Weber-Fergusson incision is made respecting the nasal subunits, and allowance is made for a transverse medial extension along the glabella skin crease (Fig. 85.3a). The soft tissues are retracted laterally and superiorly to obtain exposure of the nasal bones, frontal process of the maxilla and the piriform rims. The soft tissue overlying the nasal bone is left undisturbed. Exposure of the contralateral nasal bones is achieved by undermining in a subperiosteal plane. A fine bur/saw is used to make the bone cuts along the frontal process of the maxilla and across the nasal bones (Fig. 85.3b). The contralateral nasal osteotomy is carried out with fine osteotomes, if necessary, through separate stab incisions. The osteotomy sites are prelocalised with low-profile bone plates, removed and replaced during the procedure. The underlying nasal mucosa and soft tissue along the piriform rim are released with a diathermy. The soft tissue incisions and the bone cuts are stepped or staggered.

The nasal septum restricts complete lateral retraction. The septal cartilage is transected with a cutting diathermy—the damp tonsil swab in the other nostril can prevent accidental injury to the contralateral lateral nasal wall mucosa and the facial skin. The 1 cm strut of nasal septal cartilage is preserved along the dorsum and columella to prevent collapse (Fig. 85.3c). The nasal bones and the soft tissues can now be retracted to the opposite side (Fig. 85.3d).

A soft tissue only and soft and hard tissue nasal swing can be combined with a larger midface/craniofacial resection for pathologies involving adjacent structures. The nasal swing can be linked with a frontal craniotomy for resection of tumours that also involve the central compartment of the anterior cranial fossa (Fig. 85.3e, f).

The plates are replaced, and the wound is closed in layers (Fig. 85.3g).

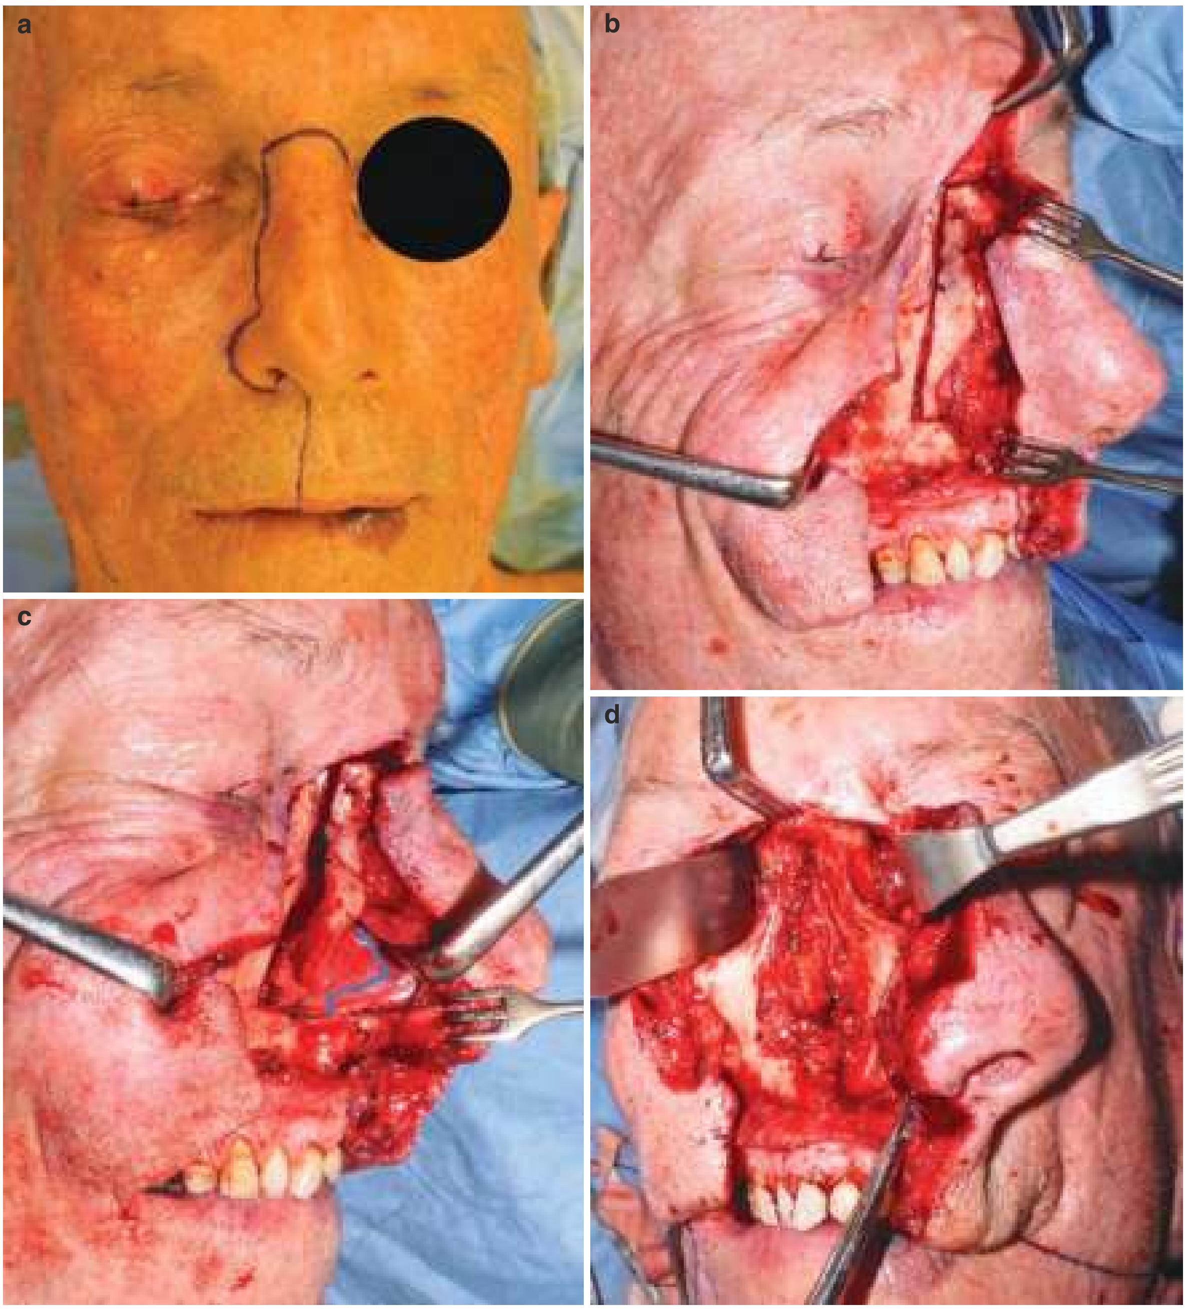

Fig. 85.3 Nasal swing. (**a**) Skin marking, respecting the nasal sub units. (**b**) Bone cuts along the frontal process of the maxilla and nasal bones. (**c**) Marking for septal incision preserving dorsal and caudal strut. (**d**) Exposure of the nasal cavity following retraction of the nose. (**e**) Bone cuts for "nasal/ethmoid clearance" as a part of a craniofacial resection. (**f**) Defect viewed from the cranial aspect following "nasal/ethmoid" clearance. (**g**) Wound closure following nasal swing

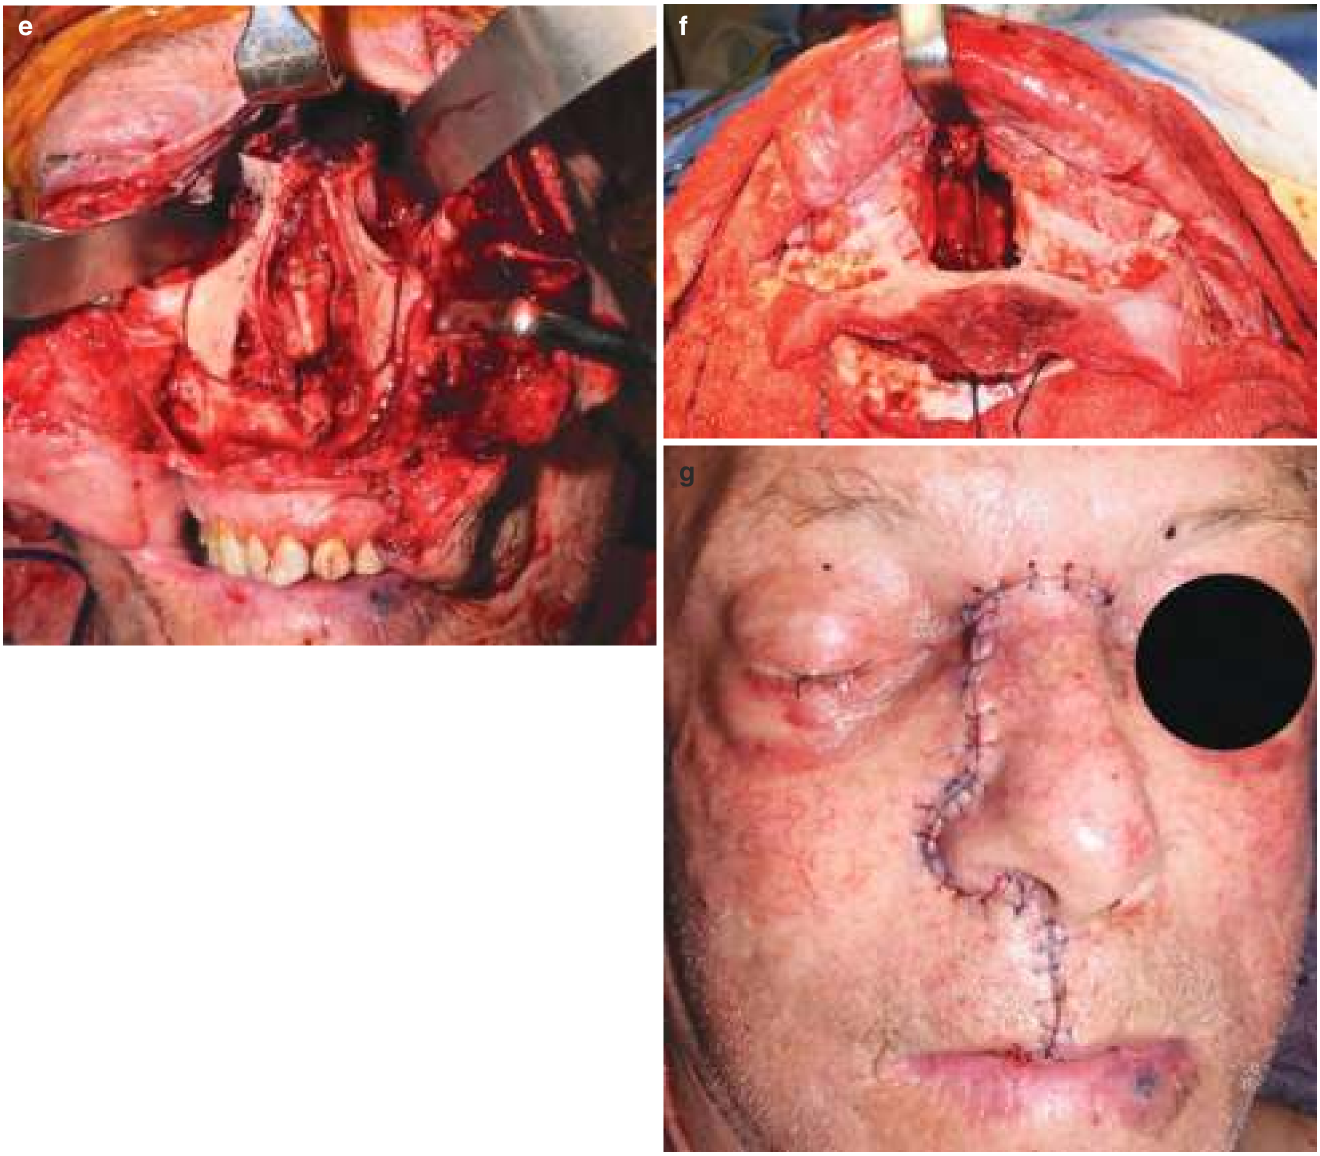

Fig. 85.3 (continued)

85.3.1 Potential Complications and Solutions (Clinical Pearls)

Unsightly scar: Use the modified incision along the philtrum, nasal subunits with “v” in the nasal floor and lip mucosa. Carry out meticulous closure in layers and acheive accurate approximation of the vermillion border.

Delayed bone healing (nasal osteotomy): Minimal soft tissue elevations along the osteotomy sites, pre-plating prior to completion of osteotomy, use fine saw blades, burs and osteotomes and copious irrigation.

Nasal collapse: Attempt to preserve caudal/dorsal septal strut.

Clinical Tips

- The soft tissue dissection is kept to the minimum, overlying the nasal bones.
- The osteotomy is planned along the frontal process of the maxilla, which is mobilised along with the nasal bones.
- Create a contralateral subperiosteal pocket and use “stab” incisions and fine osteotomes to complete the osteotomy.
- Pre-plate the osteotomies prior to completion.
- Preserve at least a 1 cm caudal and dorsal strut of septum to prevent nasal collapse.

85.4 Per Oral Access

A significant proportion of the oral lesions can be accessed and managed per orally. The use of a solely per oral access is dictated by the location and size of the lesion, the mouth opening and status of the dentition. An appropriately sized mouth prop/gag with cheek and tongue retractors and traction sutures can be utilised to provide the necessary access to safely carry out the procedure (Fig. 85.4).

Clinical Tips
- Utilise appropriate retraction to obtain the "best" access.
- "Orthodontic" cheek retractors can be very helpful for additional retraction and protecting the commissures.
- If teeth extractions are planned, these are best carried out prior to the resection to improve access.

85.5 Soft Tissue Lip Split

Lip split incisions to gain additional access to the oral cavity have been in practice for over 150 years. A midline chin incision was described by Roux [17] and subsequently popularised by Trotter [18] in the early 1900s. Further modifications by Macgregor [19] placed the chin component along the mentolabial fold, and Hayter [20] suggested incorporating a chevron in the vermillion and mentolabial area.

Fig. 85.4 Per oral access. Per oral access for excision of a tongue lesion

Soft tissue only lip split can provide excellent access to the posterior buccal mucosa and mandible, for lesions that cannot be safely excised through a per oral or cervical approach. The principle disadvantage of this approach is the need for lip split scar and likely sacrifice the mental nerve; this must be weighed against improved access. The latter is not a consideration if the inferior alveolar nerve has to be sacrificed in the subsequent resection. A lip split through the commissure would have to be considered for tumours located close to the commissure to avoid devascularising the segment between the midline lip split and commissure. This would also be a consideration for composite resections involving the adjacent skin.

A full-thickness vertical incision is made through the lower lip in the midline and extended inferiorly along the midline of the chin/upper neck (Fig. 85.5a). It continues with an appropriately placed low-neck skin crease incision. A "V" can be incorporated in the mucosal aspect of the lower lip to facilitate accurate approximation. The cosmetic outcome with a midline chin incision is excellent and reduces the risk of numbness and ischemia of the ipsilateral chin, associated with a curvilinear incision along the mental fold.

The neck skin flap is raised in a plane deep to the platysma, up to the lower border of the mandible, taking care to avoid injury to the marginal mandibular branch of the facial nerve. The cheek flap is elevated by detaching the platysma from the lower border of the mandible in the subperiosteal plane. More posteriorly, the dissection can be continued superficial or deep to the masseter muscle (Fig. 85.5b).

Intraoral soft tissue incisions are placed along the gingival crevice or the lower vestibule and are principally determined by the location of the tumour. The wound is meticulously closed in layers, taking care to accurately align the vermillion border.

85.5.1 Potential Complications and Solutions (Clinical Pearls)

Unsightly scar: Accurate alignment of the vermillion border and meticulous layered closure.

Mental and marginal mandibular nerve damage: Appropriate plane of dissection and identification and protection of the nerves.

Lip necrosis: Avoid "additional" midline incision for tumours in the commissure region or composite buccal mucosa resections.

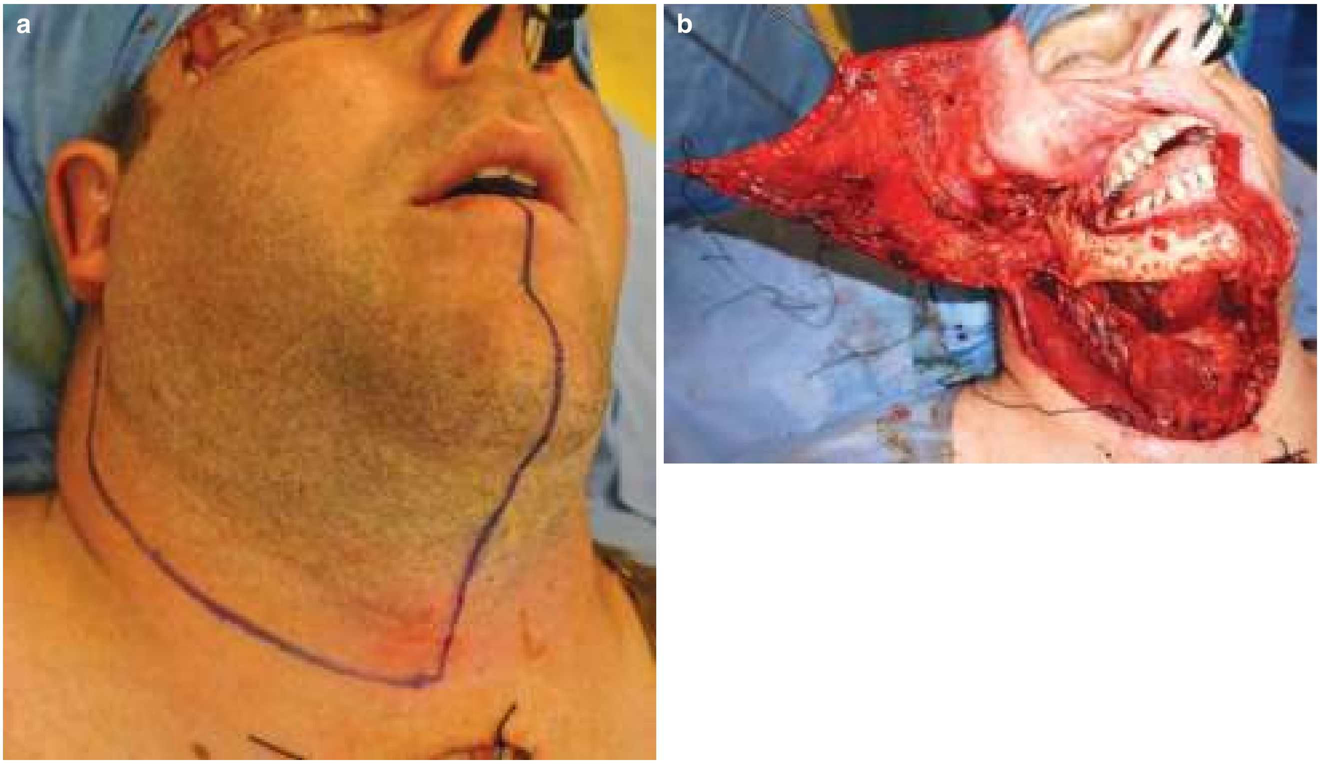

Fig. 85.5 Soft tissue lip split. (**a**) Skin markings for a soft tissue lip split. (**b**) Exposure following flap elevation

Clinical Tips

- Dissection of the anterior mandible is in the subperiosteal plane to minimise injury to the facial and mental nerves.
- Identify the mental nerve and decide if it can be preserved, prior to sacrificing it.
- More posteriorly, the dissection can be superficial or deep to the masseter muscle. If superficial dissection is planned, care must be exercised to prevent injury to the facial nerve branches and parotid duct.
- Avoid midline lip split for tumours adjacent to the commissure and composite resections.

85.6 Visor Flap

A visor flap can be utilised for lesions in the floor of mouth, tongue and mandible and can be combined with bilateral neck dissections. The incision is marked at an appropriate low-neck skin crease and extends from one mastoid tip process to the other (Fig. 85.6a). The skin flaps are raised in the sub-platysmal plane up to the lower border of the mandible, taking care to avoid injury to the marginal mandibular branch of the facial nerve. The periosteum is incised along the lower border of the mandible and a mucoperiosteal flap elevated, taking care to identify the mental nerves. Intraoral mucosal incisions are determined by the location of the lesion, and the mental nerves might have to be sacrificed to obtain further access or adequate margins. The skin flaps are retracted cephalad with “penrose” rubber drains (Fig. 85.6b).

When used as a part of lingual release/pull-through procedure to access a floor of mouth/tongue lesion, the mental nerves and labial/buccal soft tissue can be left undisturbed [21, 22]. Resection of the lesions in the anterior floor of mouth along with the mandible results in detachment of the tongue to the mandible. It is essential that the geniohyoid and genioglossus muscles are reattached to the reconstructed mandible to prevent the tongue from falling back. The wound is closed in layers. An advantage of the visor incision is the avoidance of a lip split facial scar, which needs to be weighed against the risk of bilateral injury to the marginal mandibular branch of the facial and mental nerves.

85.6.1 Potential Complications and Solutions (Clinical Pearls)

Mental and marginal mandibular nerve damage: Appropriate plane of dissection and identification and protection of the nerves.

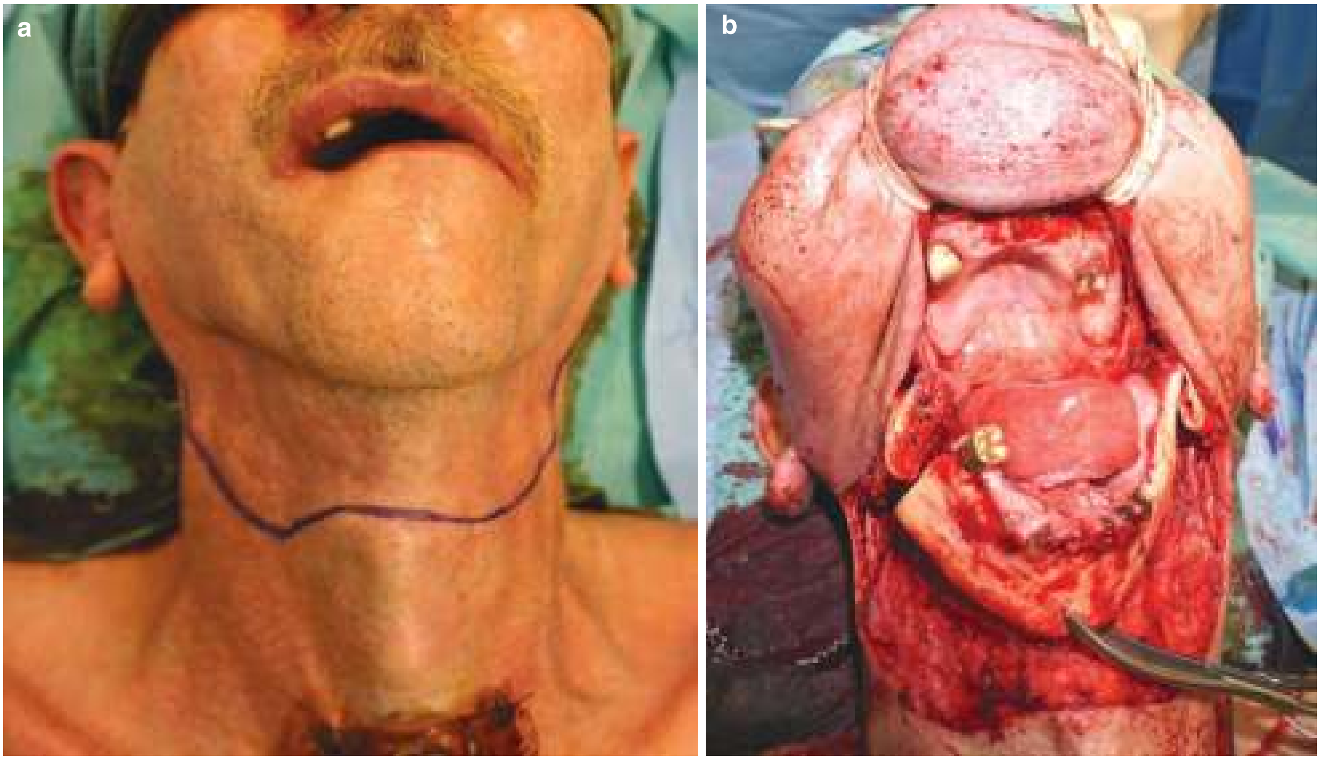

Fig. 85.6 Visor flap. (**a**) Skin markings for a visor flap. (**b**) Exposure following flap retraction with "penrose" rubber drains

Clinical Tips

- Expose the mandible in the subperiosteal plane to identify the mental foramen and minimise damage to the facial nerve.
- The intraoral labial/buccal vestibular incision is determined by the location of the tumour and can be placed along the vestibule or crevicular margins.
- If the tongue and the hyoid apparatus is detached from the anterior mandible, the remnant genioglossus and geniohyoid should be "formally" suspended to the (reconstructed) mandible with non-resorbable sutures.

85.7 Transmandibular Approaches

85.7.1 Mandibular Swing

85.7.1.1 Lip Split Paramedian Mandibulotomy

Mandibulotomy to access oral cavity, oropharynx and skull base has been in use for over 150 years, since its initial description by Roux [17] and Trotter [18]. It was popularised by Spiro [23], who suggested a median mandibulotomy, and McGregor [19] described a paramedian location, anterior to the mental foramen. Though various sites and design of the osteotomy have been described, a straight line paramedian mandibulotomy is currently the most widely used option, as it preserves the attachment of the anterior belly of the digastric, geniohyoid and genioglossus muscles and mental nerve. The availability of rigid fixation and fine saws negate the need for step osteotomies and tooth extractions in most cases.

The lip split with a mandibulotomy provides excellent access to the mid and posterior third of the tongue, floor of the mouth, soft palate, tonsillar fossa, oropharynx/posterior pharyngeal wall and supraglottic larynx. It can be extended posteriorly to provide additional access to the infratemporal fossa and the parapharyngeal space with safe vascular control. It can be considered in three discrete stages; lower lip/chin division, paramedian mandibulotomy and soft tissue elevation on the lingual aspect of the mandible.

A vertical full-thickness incision is made through the midline of the lower lip and extended inferiorly across the midline of the chin/upper neck and continues with an appropriately placed low-neck skin crease incision (Fig. 85.7a). A "V" can be incorporated in the mucosal aspect of the lower lip to facilitate accurate approximation.

The cosmetic outcome with a midline chin incision is excellent and reduces the risk of numbness and ischemia of the ipsilateral chin, associated with a curvilinear incision along the mental fold.

The neck skin flap is raised in a plane deep to the platysma, up to the lower border of the mandible, taking care to avoid injury to the marginal mandibular branch of the facial nerve. Intraorally, the incision through the labial mucosa and

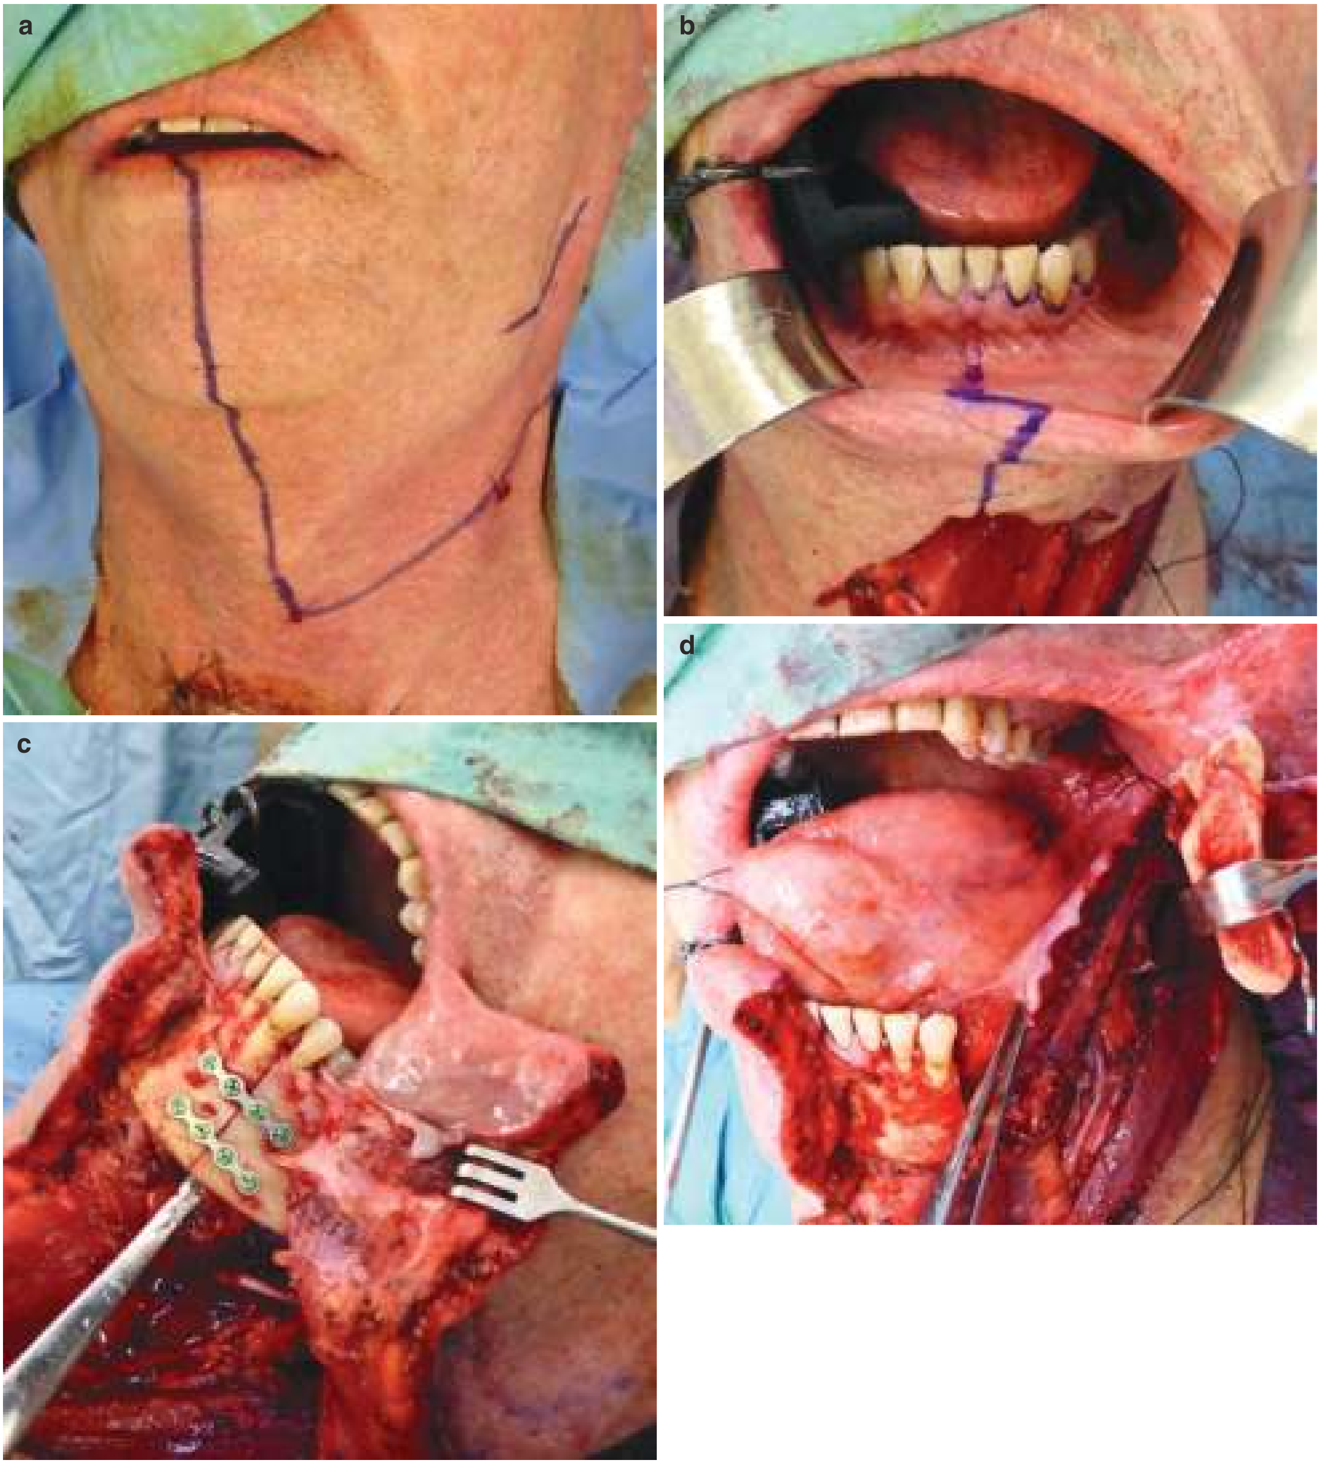

Fig. 85.7 Lip split paramedian mandibulotomy. (**a**) Skin marking for lip split mandibulotomy. (**b**) Mucosal marking for lip split mandibulotomy. (**c**) Lingual subperiosteal tunnel, bone cuts and pre-plating prior to completion of mandibulotomy. (**d**) Lingual crevicular incision and mandible retracted laterally following release of mylohyoid muscle. (**e**) Additional exposure of the infratemporal fossa by tracing the inferior dental and lingual nerves. Defect following maxillectomy and infratemporal fossa clearance (different patients)

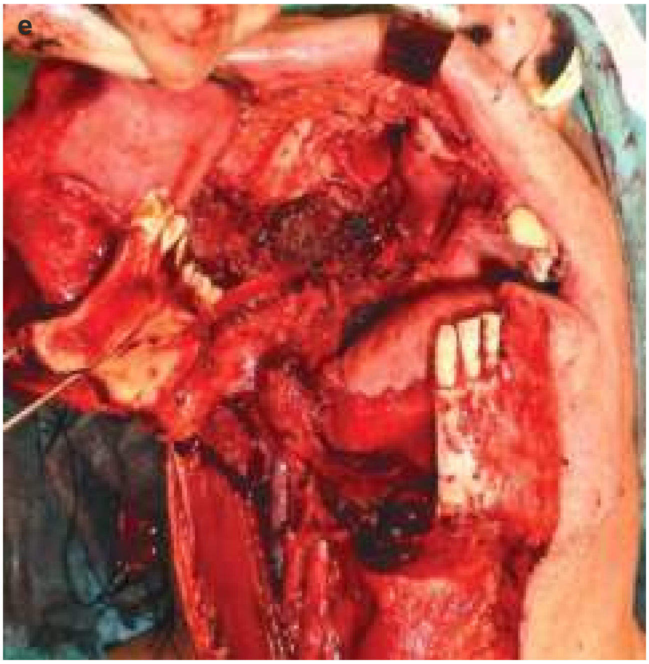

Fig. 85.7 (continued)

attached gingiva is designed (stepped), so that it does not directly overlie the planned osteotomy (Fig. 85.7b). The elevation of the periosteum and mentalis muscle should be restricted to allow identification and protection of the mental nerve and placement of the plates.

A soft tissue pocket is created by elevating the lingual mucosa off the mandible adjacent to the osteotomy. A periosteal elevator is placed in the pocket, and an osteotomy is carried out between the lower lateral incisor/canine or canine/first premolar region (Fig. 85.7c). The mandible is osteotomised with a fine saw, taking care to avoid injury to the tooth roots. Occasionally a tooth would have to be removed to facilitate the osteotomy. The mandible is pre-plated prior to completion of the bone cuts, and these are removed and replaced during the procedure. The osteotomy cuts are in a straight line, as a stepped osteotomy neither aids fixation or bone union and can increase the risk of injury to the teeth apices and mental nerve.

Once the mandible is divided, it is gently retracted laterally, and an incision made along the lingual gingival crevice and the mucoperiosteum elevated off the lingual mandible (Fig. 85.7d). The mylohyoid muscle is detached along its attachment to the mylohyoid ridge. Further soft tissue dissection is dictated by the location of the tumour.

If additional access is required to the infratemporal fossa/parapharyngeal space, it will be necessary to detach the medial pterygoid muscle from the medial ramus of the mandible. In addition, the stylomandibular ligament (at the angle of the mandible) and the sphenomandibular ligament (at the lingula) have to be detached to obtain the best possible access (Fig. 85.7e). The inferior dental and lingual nerve are identified early and protected and can be utilised as roadmaps to the foramen ovale and skull base. The maxillary artery can also be identified entering the infratemporal fossa, at the neck of the condyle by following the posterior border of the mandible. Early identification and ligation can help provide a relatively bloodless field for dissection of the infratemporal fossa.

The lingual gingival crevicular incision facilitates easy closure and avoids placement of the suture line at the depth (sump) of the wound. The mandible is held in occlusion, and the plates are replaced accurately to achieve the premorbid localisation. The wound is meticulously closed in layers.

85.7.2 Potential Complications and Solutions (Clinical Pearls)

Unsightly scar: Accurate alignment of the vermillion and meticulous layered closure.

Mental and marginal mandibular nerve damage: Appropriate plane of dissection and identification and protection of the nerves.

Delayed bone healing: Minimal soft tissue elevations along the osteotomy sites, pre-plating prior to completion of osteotomy, use fine saw blades, burs, osteotomes and copious irrigation. Osteotomy ideally in the canine region.

Damage to adjacent teeth: Design osteotomy where space allows, use fine instruments and consider extraction.

Clinical Tips

- A straight osteotomy in the canine region is ideal and the site pre-plated prior to completion of the bone cuts.
- The soft tissue incision and bone osteotomies are stepped, so that they do not lie on the same plane.
- The lingual soft tissues are retracted following a lingual crevicular incision.
- The medial pterygoid muscle and stylomandibular and sphenomandibular ligaments have to be detached to obtain addition access to the infratemporal fossa.
- The lingual and inferior dental nerves provide excellent landmarks and can be utilised as roadmaps to the skull base and foramen ovale.
- The maxillary artery should be identified at the neck of the condyle, as it enters the infratemporal fossa and ligated early in the procedure to minimise blood loss and improve visibility during infratemporal fossa clearance.

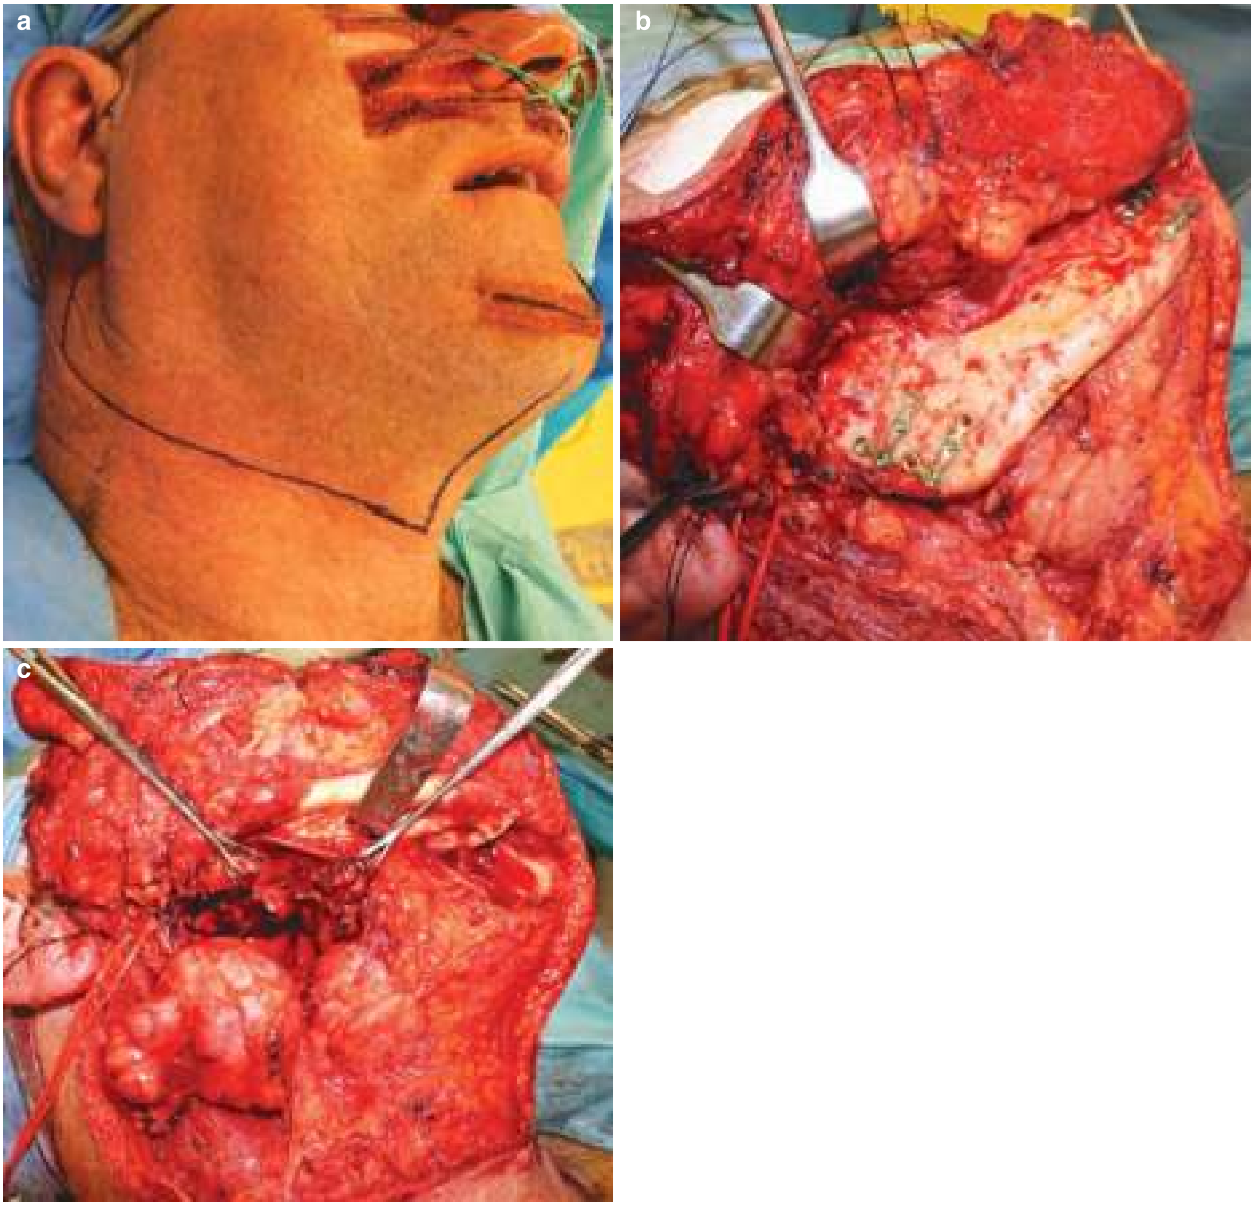

Fig. 85.8 Double mandibular osteotomy. (**a**) Skin markings for double mandibular osteotomy. (**b**) Bone cuts marked and mandible pre-plated. (**c**) Mandibular segment retracted laterally and superiorly to expose deep lobe parotid tumour

85.8 Double Mandibular Osteotomy

Mandibular osteotomies to access the parapharyngeal region can be broadly divided into those involving the oral cavity (lip split mandibulotomy) and those staying out with the oral cavity. Since it was initially popularised by Attia [24] to access parapharyngeal and pterygomaxillary region, several designs of osteotomies have been described, involving one, two and three osteotomies, variously placed in the paramedian and ramus/condylar region [25].

Double mandibular osteotomy provides excellent access to the infratemporal fossa, parapharyngeal space, deep lobe of the parotid and terminal extracranial internal carotid artery adjacent to the skull base, when the oral cavity does not have to be entered.

A low-neck skin crease incision with submental extension is made (Fig. 85.8a), and the neck flap is raised in the subplatysmal plane up to the lower border of the mandible, preserving the marginal mandibular branch of the facial nerve. The lateral mandible is exposed in a subperiosteal plane and the mental nerve identified and protected anteriorly. The masseter muscle is detached from the lateral ramus of the mandible up to the sigmoid notch. The anterior bone cuts are fashioned anterior to the mental foramen, between the canine/lateral incisor or canine/first premolar teeth roots. The posterior bone cut is made from the sigmoid notch to the lower border of the mandible, posterior to the lingula and inferior dental canal (similar to a vertical sub-sigmoid osteotomy). The mandible is pre-plated prior to completion of the bone cuts (Fig. 85.8b). The plates are removed and replaced during the procedure. Following completion of the osteotomy, the segment of the mandible containing the inferior dental nerve is retracted lateral and superiorly to provide wide access to the parapharyngeal and infra temporal areas (Fig. 85.8c).

Further soft tissue dissection is dictated by the necessity to access specific parts of the medial mandibular area.

The stylomandibular ligament can be detached from the posterior "condylar" segment to obtain further exposure of the stylomastoid area. The muscular and ligamentous attachments to the styloid process can be detached, and, if necessary, the styloid process is osteotomised to gain addition access to the "post-styloid" space, terminal extracranial internal carotid and the skull base close to the jugular foramen and lower cranial nerves.

This procedure avoids a lip split scar and helps preserve sensation to the lip while providing access to the more "difficult-to-reach" areas.

85.8.1 Potential Complications and Solutions (Clinical Pearls)

Mental and marginal mandibular nerve damage: Appropriate plane of dissection and identification and protection of the nerves. Osteotomies planned to avoid the course of the inferior dental nerve.

Delayed bone healing: Pre-plating prior to completion of osteotomy, use fine saw blades, burs, osteotomes and copious irrigation.

Damage to adjacent teeth: Design osteotomy where space allows, use fine instruments and consider extraction.

Clinical Tips

- This procedure is considered when intraoral access is "not" required.
- A lip split scar is avoided.
- The lateral mandible is exposed in the subperiosteal plane, and the mental and facial nerve branches are protected.
- The bone cuts are made anterior to the mental foramen and posterior to the mandibular foramen and inferior dental canal.
- The osteotomy site is pre-plated prior to completion of the bone cuts.
- Styloid process and its' attachments can be detached to gain addition access to the post styloid and "stylomastoid" spaces.

85.9 Zygomatic Osteotomy

Facial translocation techniques allow modular craniofacial disassembly of the facial skeleton to access "relatively" inaccessible regions of the skull base and nasopharynx. A variety of osteotomies have been described, but with the increased use of endoscopic approaches, the necessity for extensive procedures continues to diminish. Various modifications of zygomatic and orbital osteotomies in combination with craniotomies has been described since it was popularised by Lesoin [26], Hakuba [27] and Sindou [28] to access skull base lesions.

Zygomatic osteotomy, pedicled on the masseter muscle and its subsequent inferior displacement, provides simultaneous exposure of the temporal and infratemporal fossa and orbit. An additional frontotemporal craniotomy can link the middle and anterior cranial fossa and the middle cranial fossa with the infratemporal fossa. The extent of the "zygomatic" osteotomy and the direction of retraction of the temporalis is determined by the location of the pathology. For subcranial lesions, (temporal/infratemporal fossa/orbit), the temporalis is retracted superiorly following a coronoidectomy. For simultaneous exposure of the anterior/middle cranial fossa and temporal/infratemporal fossa/orbit, the temporalis is reflected inferiorly. The vascularity of the temporalis muscle can be at risk with both superior and inferior retraction.

The zygomatic body, arch and lateral and inferior orbital rims are exposed via a coronal flap (Fig. 85.1e, g). Meticulous subperiosteal orbital dissection is carried out to protect the orbital contents, which are retracted with thin malleable retractors. The temporalis is detached from the lateral orbit in the temporal fossa. The lateral end of the inferior orbital fissure is identified in the temporal fossa and orbit with a blunt hook. The bone cuts are made with a fine saw: superiorly at the frontozygomatic suture, infero-laterally from the lateral infraorbital rim through the body of the zygoma towards the inferior orbital fissure and posteriorly just anterior to the articular eminence. A sagittal bone cut is then made in the lateral orbital wall from the temporal fossa aspect, extending from the frontozygomatic suture osteotomy to the inferior orbital fissure (Fig. 85.9a). A more limited zygomatic arch osteotomy can be utilised, when orbital access is not required (Fig. 85.9b). The osteotomy is preplated, and plates are removed and replaced during the procedure (Fig. 85.9b). The cuts are completed, and the zygoma is mobilised and pedicled inferiorly on the masseter muscle.

Exposure to the infratemporal fossa is limited with a zygomatic osteotomy, which restricts its use to benign pathology, when utilised as a sole means of access. It can however be combined with frontotemporal craniotomy to widely access the anterior and middle cranial fossa, optic canal, superior orbital fissure and for combined middle cranial/infratemporal fossa resections (Figs. 85.1h and 85.9c).

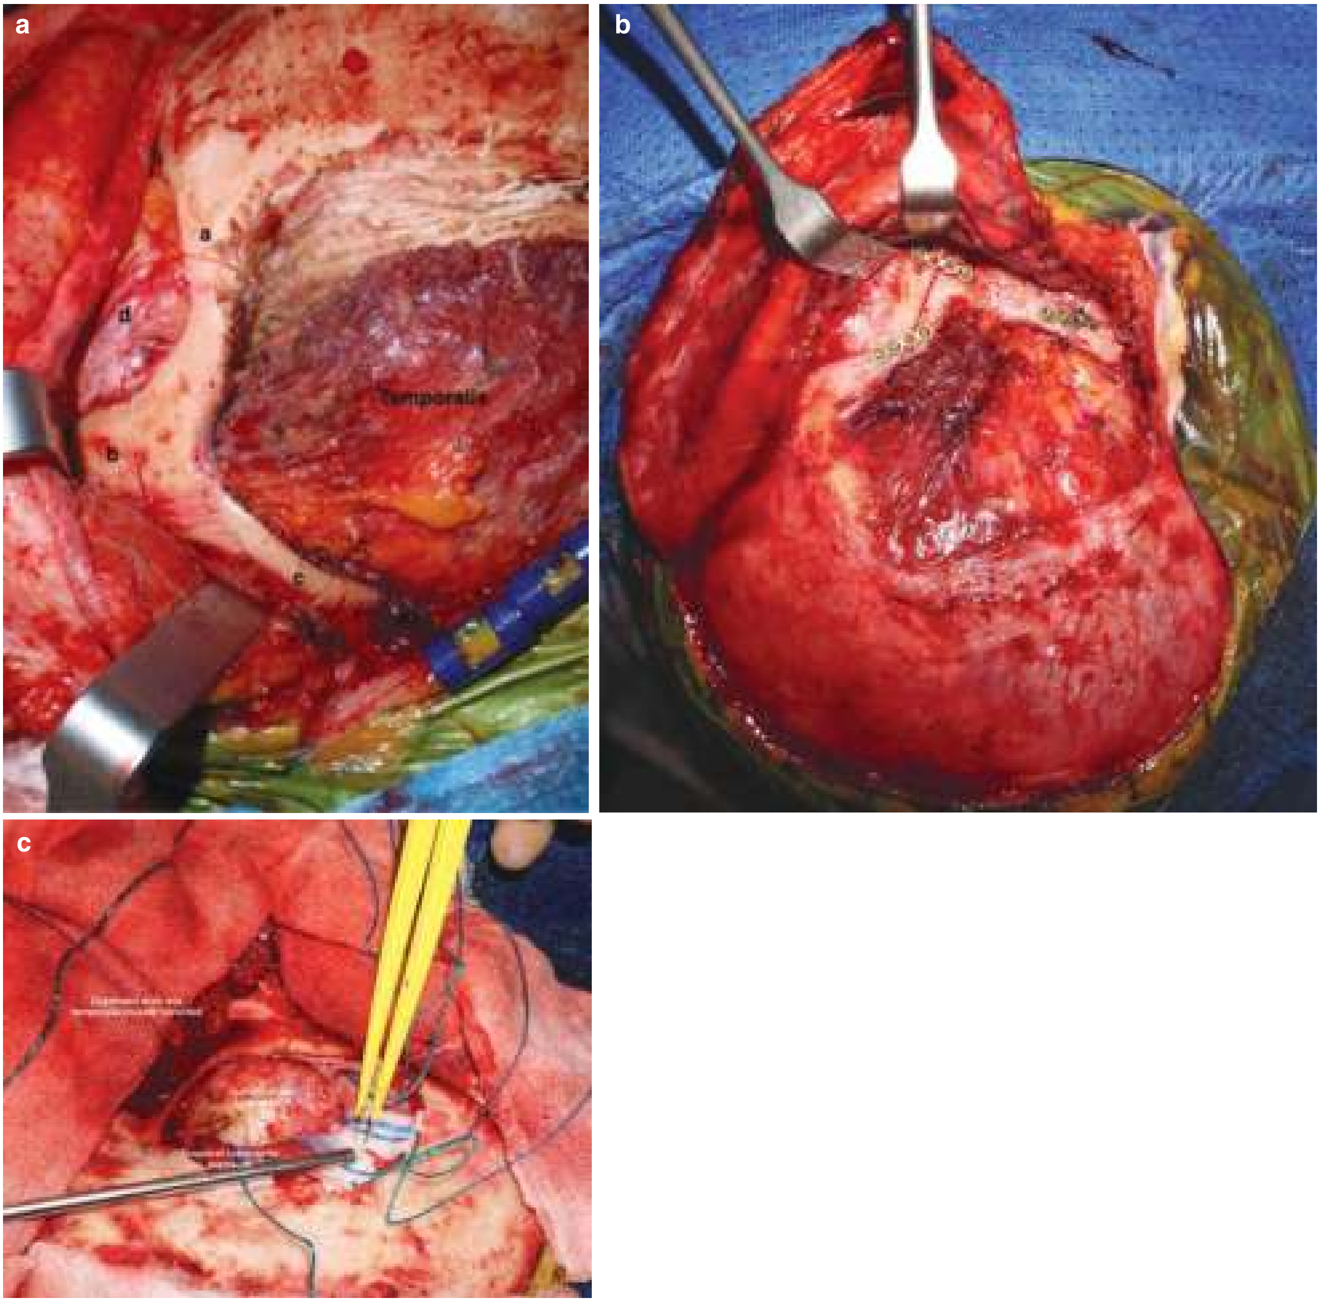

Fig. 85.9 Zygomatic osteotomy. (**a**) Bone cuts marked for a zygomatic osteotomy. (**a**) Osteotomy above frontozygomatic suture, (**b**) osteotomy across body of zygoma, (**c**) osteotomy across zygomatic arch and (**d**) orbital contents. (**b**) Bone cuts marked and pre-plated for zygomatic arch osteotomy (extended to lateral orbital rim due to increased width of orbital rim). (**c**) Tumour exposed in the floor of the middle cranial fossa following temporal craniotomy and retraction of the zygomatic arch and temporalis

85.9.1 Potential Complications and Solutions (Clinical Pearls)

Delayed bone healing: Preserve masseter attachment, pre-plating prior to completion of osteotomy, use fine saw blades, burs, osteotomes and copious irrigation.

Damage to orbital contents: Meticulous intra-orbital subperiosteal dissection and haemostasis, fine malleable retractors for orbital retraction and bone cuts under "direct" vision.

Malposition of lateral canthus: Accurate bone re-approximation with pre-plating. Consider tagging lateral canthus prior to detachment and subsequent reattachment.

Clinical Tips

- The lateral limit of the inferior orbital fissure in the orbit and temporal fossa is an important landmark for orbital and zygomatic osteotomies. A "blunt hook" can help with its safe identification.
- The extent of the osteotomy is determined by the location of the lesion and the need to enter the orbit.
- The attachment of the masseter muscle to the osteotomised zygomatic complex should be preserved.
- The osteotomy along the zygomatic arch should be made anterior to the articular eminence, to avoid disturbing the temporomandibular joint.
- The osteotomy sites are pre-plated, prior to completion of the bone cuts.
- Trismus is often expected and can be minimised by jaw opening exercises.

85.10 Lateral and Superior Orbitotomies

Lateral orbitotomy was initially popularised by Kronlein [29] but with a reverse "C"-shaped incision overlying the temple. A variety of modifications, principally in the design of the skin incisions, have been described subsequently: lateral canthotomy [30, 31] "S"-shaped incision over the orbital rim, upper eyelid skin crease incision and coronal flap.

Superior/lateral orbitotomies, combined with frontal [32] and pterional [33] craniotomies have been extensively used since their original descriptions in the 1980s.

This approach is useful for lacrimal and lateral/superior/inferior extra and intraconal orbital lesions and provides additional access for "lookup" approaches to the anterior and middle cranial fossa and for reconstruction with a temporalis flap following orbital exenteration.

A coronal flap is raised, and the zygomatic complex is exposed as described above for the zygomatic osteotomy (Fig. 85.10a). For isolated lesions, a Stallard-Wright [31] "S"-shaped incision extending from the eyebrow, inferolaterally over the lateral orbital rim to the crow's feet skin crease or an upper eyelid skin crease, can be utilised (Fig. 85.10b). The temporalis muscle is reflected posteriorly to expose the temporal aspect of the lateral orbit, and the orbital periosteum (periorbita) is elevated from lateral orbital wall (Fig. 85.10c). The lateral end of inferior orbital fissure is identified with a blunt hook, both within the orbit and the temporal fossa. Perforating blood vessels are identified and coagulated prior to division.

The orbital contents are protected with a malleable retractor, and the bone cuts are made with a thin saw. Superiorly, just above the frontozygomatic suture; inferiorly, inferior lateral orbital rim along the superior border of the zygomatic arch (the superior border of the zygomatic arch is at the same level as the orbital floor) up to the lateral limit of inferior orbital fissure.

The posterior cut is made with a fine bur/piezo saw in the lateral orbital wall, joining the superior bone cut to the lateral limit of the inferior orbital fissure. This is more easily made from the temporal aspect. The bone cuts are pre-plated prior to removal of the osteotomised segment and plates replaced following completion of the procedure.

The lateral orbitotomy can be combined with a superior orbitotomy and is usually performed in conjunction with a frontotemporal craniotomy. The craniotomy is best performed initially, and the superior orbital wall is delineated from the cranial aspect. With malleable retractors in situ, the superior and lateral orbitotomy can be carried out under direct vision (Fig. 85.10d). This provides excellent exposure of the contents of the superior orbit, superior orbital fissure and optic nerve/canal (Fig. 85.10e). This can also be used for "lookup" approaches to the superior anterior and middle cranial fossa lesions. The bone flaps are replaced (Fig. 85.10f), and the wounds are closed in layers. The medial extent of the superior orbitomy can be limited by the extent of the frontal sinus. The supraorbital neurovascular bundle will have to be protected/retracted.

85.10.1 Potential Complications and Solutions (Clinical Pearls)

Delayed bone healing: Pre-plating prior to completion of osteotomy, use fine saw blades, burs, osteotomes and copious irrigation.

Damage to orbital contents: Meticulous intra-orbital subperiosteal dissection and haemostasis, fine malleable retractors for orbital retraction and bone cuts under "direct" vision.

Malposition of lateral canthus: Accurate bone re-approximation with pre-plating. Consider tagging lateral canthus prior to detachment and subsequent reattachment.

Clinical Tips

- The lateral limit of the inferior orbital fissure in the orbit and temporal fossa is an important landmark for orbital and zygomatic osteotomies. A "blunt hook" can help with its safe identification.
- The extent of the osteotomy is determined by the location of the lesion.
- The superior surface of the zygomatic arch is in line with the orbital floor and is a useful landmark for bone cuts in the lateral orbital rim.
- The osteotomy sites are pre-plated prior to completion of the bone cuts.

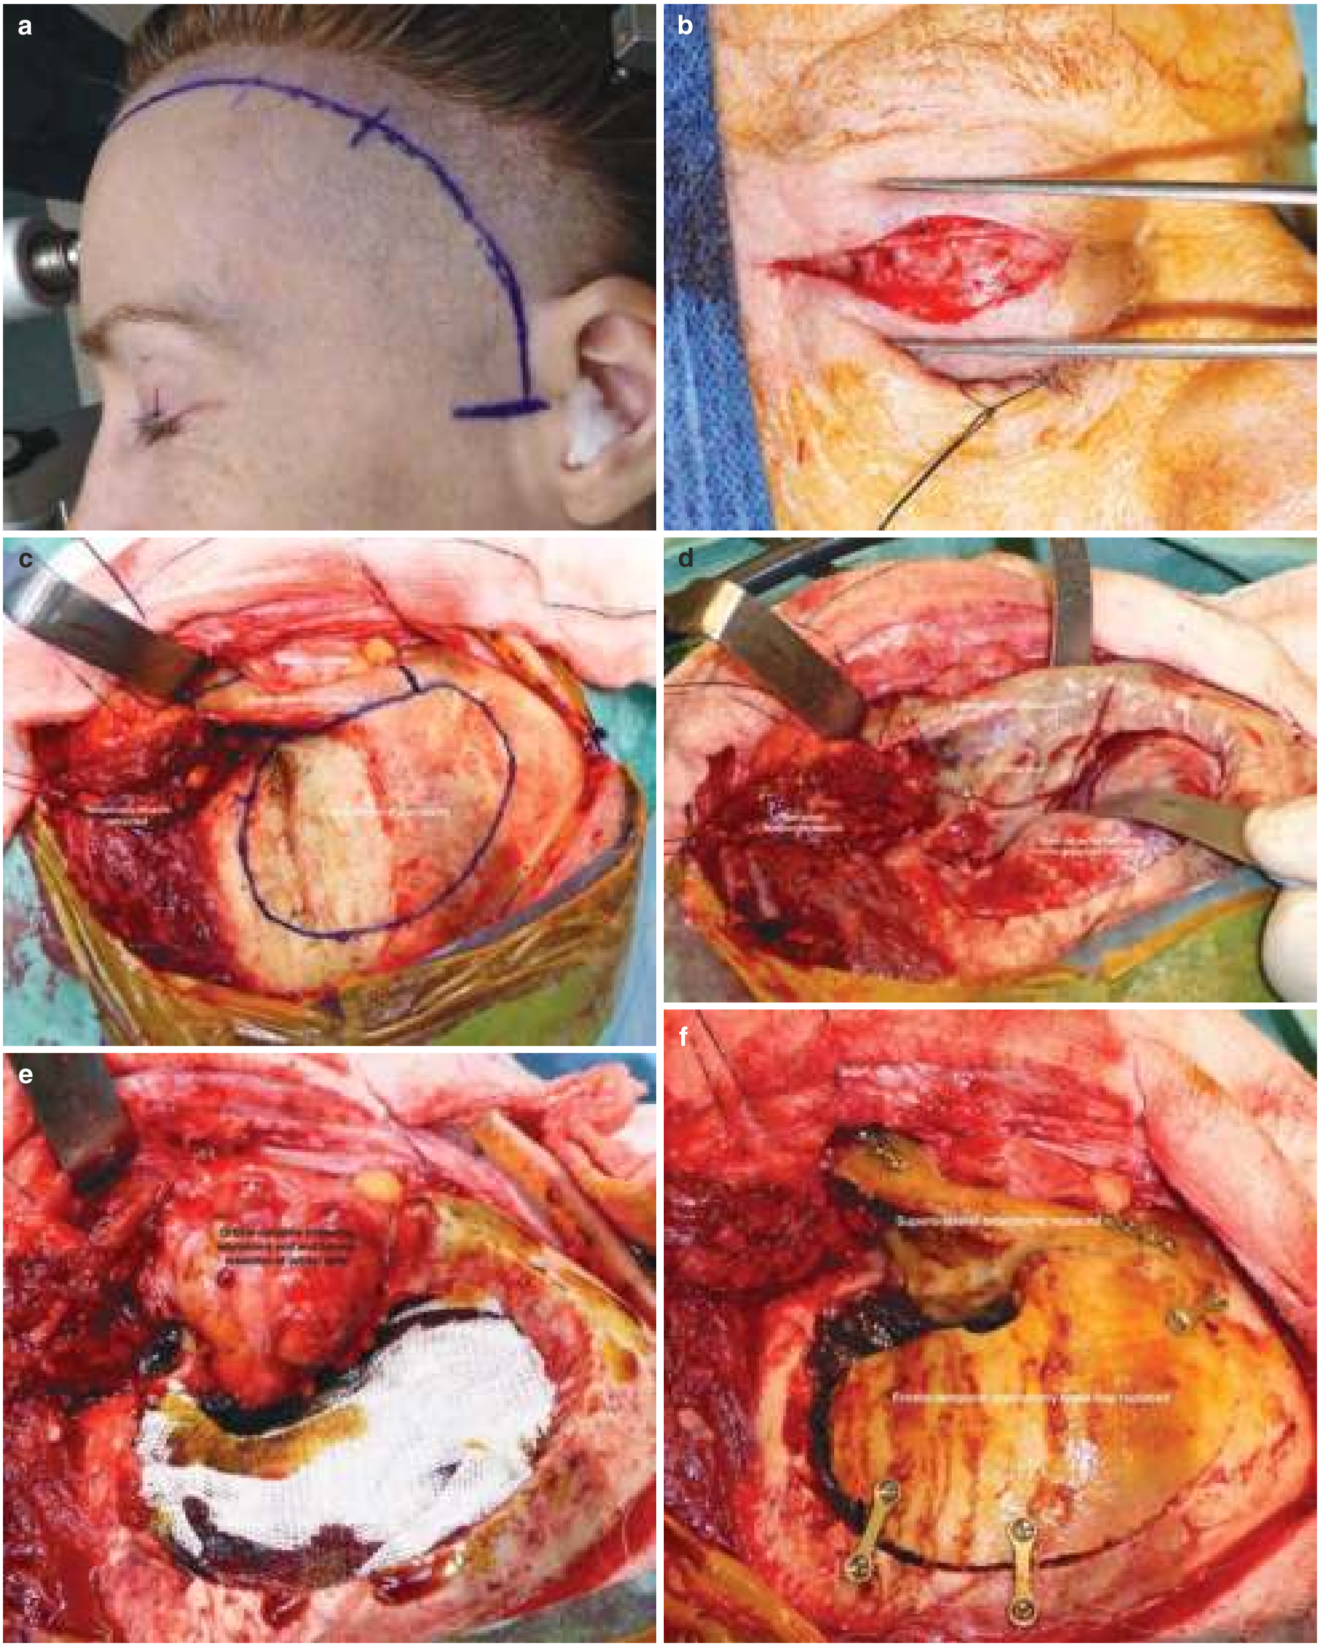

Fig. 85.10 Lateral and superior orbitotomies. (**a**) Skin marking for a hemicoronal flap. (**b**) Upper eyelid skin crease incision for lateral orbitotomy. (**c**) Bone marking for superolateral orbitotomy and frontotemporal craniotomy. (**d**) Superolateral orbitotomy bone cuts following craniotomy. (**e**) Exposure of the orbital contents following orbitotomy. (**f**) Craniotomy and orbitotomy bone flaps replaced

85.11 Conclusion

Multiple routes are available to the clinician to access the pathology in the craniomaxillofacial region. The technical aspects of the individual procedures are described in detail, along with the potential alternatives and a progressive algorithm. An understanding of the relevant anatomy, a critical analysis of the extent of the lesion, exposure required and potential reconstruction helps in determining the most appropriate choice of procedure. There is no substitute to working within well-functioning teams to obtain the relevant clinical experience.

85.12 Algorithms

The following algorithms provide a potential sequence that can be considered for progressive access for pathologies in the head and neck region. The algorithms "exclude" endoscopic approaches that can be used in isolation or in combination with open access for lesions especially in the nose, orbit, anterior skull base and retromaxilla.

1. *Access to Buccal mucosa*

Per oral access

↓

Soft tissue lip split
(Mid line / commisure lip split)

↓

Composite resection (skin / mucosa involvement)

↓

Compartment resection (skin / mucosa/ bone involvement)

2. *Access to Tongue*

Per oral access (anterior / lateral tongue)

↓

Lip split mandibulotomy (lateral / posterior tongue / extensive floor of mouth involvement)

↓

Visor / lingual release (extensive bilateral tongue / floor of mouth involvement)

3. *Access to Mandible*

Per oral access (limited crestal involvement / marginal mandibulectomy)

↓

Transcervical / submental extension (lateral mandible, +/- floor of mouth involvement / segmental mandibulectomy)

↓

Soft tissue lip split (lateral / posterior mandible/ extensive floor of mouth / parapharyngeal involvement / segmental mandibulectomy)

↓

Visor flap (bilateral mandible / floor of mouth involvement)

4. *Access to Maxilla**

Per oral access (crestal / infra structure involvement)

↓

Modified Weber-Fergusson (More extensive maxillary involvement, but no significant orbital/ ethmoid or posterior extension)

↓

Modified Weber- Fergusson with Diffenbach extension (Maxillary with significant orbital involvement)

↓

Modified Weber-Fergusson with Lynch extension (Maxillary with significant ethmoid involvement)

↓

Lip split mandibulotomy +/- Modified Weber-Fergusson (posterior maxillary, maxillary with significant posterior extension)

↓

Maxillary swing (posterior maxillary/ postero- medial extension to
Nasopharynx: anterior maxilla can be preserved)

↓

Facial degloving approach (anterior / bilateral maxillary lesion that cannot be accessed with per oral approach and need to avoid facial scar)

*Consider early coronoidectomy to improve access

5. *Access to Nasal cavity**

Per nasal (small anterior lesion)

↓

Lateral rhinotomy (ipsilateral nasal lesion)

↓

Nasal swing (soft tissue) – Bilateral lesion, able to preserve nasal skin

↓

Nasal swing (soft tissue / nasal bone) – Bilateral lesion, able to preserve skin and nasal bone)

↓

Facial degloving approach (Bilateral / inferior lesions, able to preserve nasal Skin

↓

Lefort 1 osteotomy (bilateral / inferior lesions)

↓

*With the wide spread use of endoscopic techniques, the need for open approaches as the "sole" access modality continues to diminish.

6. *Access to Orbitotomies*

(a) *Lateral orbitotomy (lateral lesions / temporalis reconstruction)*

Lateral canthotomy

↓

Upper eyelid skin crease

↓

Hemicoronal

(b) *Lateral / superior orbitotomy (supero-lateral lesions / combined cranio- orbital lesions)*

Hemi coronal / Bicoronal flap with fronto-temporal craniotomy

(c) *Inferior orbitotomy (inferior lesions)*

Lower eyelid skin crease incision

7. *Access to Parapharyngeal space (deep lobe parotid / post styloid compartment pathology)*

Transcervical

↓

Transcervical transparotid

↓

Double mandibular osteotomy (no oropharyngeal mucosal involvement)

↓

Lip split mandibulotomy (oropharyngeal mucosal involvement)

Common access procedures to the various sites[a]

Access	Procedure
Oral cavity	Per oral
	Soft tissue lip split
	Lip split with access mandibulotomy
	Visor flap
Maxilla	Per oral
	Modified Weber-Fergusson
	Modified Weber-Fergusson with Lynch and eyelid extensions
	Lip split mandibulotomy
	Facial degloving
	Combinations
Infratemporal fossa	Modified Weber-Fergusson with eyelid extension and early coronoidectomy (with maxillectomy)
	Lip split mandibulotomy
	Coronal flap with zygomatic osteotomy
	Maxillary swing
	Combinations
Nasal cavity	Per nasal
	Lateral rhinotomy
	Nasal swing
	Le fort 1 osteotomy
	Facial degloving
Pterygopalatine fossa/ nasopharynx	Maxillary swing
	Transpalatal approaches
	Le fort 1 down fracture ± midline split
Orbit	Various soft tissue incisions
	Lateral orbitotomy
	Superior orbitotomy
	Inferior orbitotomy
	Combinations

[a]Excludes endoscopic approaches, which can be utilised alone or in combination with the open approaches

Reconstructive Procedures of the Oral and Maxillofacial Region

86 Soft Tissue Reconstruction of the Maxillofacial Region

Benjamin Turner, John Collin, and Rui Fernandes

86.1 General Considerations

The general precept of reconstructive surgery is to assess what tissue and structures are missing and what is available to replace them, ensuring that where possible 'like should replace like'. Hard tissue defects are best restored with hard tissue and soft, soft tissue. Usually skin closest to the defect will give the best cosmetic match. Hard tissue reconstruction falls outwith the remit of this chapter, but where required it should be performed first to provide the foundation for successful soft tissue reconstruction. Next, muscle and fasciocutaneous tissue should be resuspended from the maxillofacial skeleton to restore muscle function and prevent ptosis of the soft tissues. The aerodigestive tract needs to be isolated from the cranial cavity, deep neck spaces and external skin to reduce the risk of spreading infection, fistula and sinus formation. Finally, the aphorism that form follows function is germane and careful reconstruction of normal anatomy will often meet the dual goals of cosmesis and restoration of function. Anatomical subunits should be respected, and generally if the defect is greater than 50% of a subunit, better results are obtained with removal and reconstruction of the entire subunit such that scars are camouflaged within their boundary lines (Table 86.1).

For any particular defect, the choice of reconstruction can range from simple to complex, along a continuum commonly described as the 'reconstructive ladder'(Table 86.2) [1]. The 'reconstructive matrix' has also been described as a development of this linear concept to take into account technical requirements and potential risks to the patient on additional axes (Fig. 86.1) [2].

Table 86.1 Key concepts of reconstructive surgery

Replace like with like
Hard tissue reconstruction first
Respect anatomical units/subunits
Local skin usually best cosmetic option
Consider options within reconstructive ladder/matrix

86.1.1 Healing by Secondary Intention

Where there has been soft tissue loss and/or the skin is not re-approximated, healing occurs via secondary intention with deposition of granulation tissue (Fig. 86.2). Typically this results in a broader area of scar tissue and is therefore inadvisable at most sites in the maxillofacial region. Superficial defects of concave subsites (e.g. medial canthus, conchal bowl) or mucosa are the exception and may be left to heal by secondary intention with good cosmetic results.

86.1.2 Primary Closure

Primary closure describes the apposition of skin edges to permit healing without granulation tissue formation and minimal scaring (Fig. 86.2). Ideally lines of primary closure should coincide with the boundaries of the anatomical subunits (Fig. 86.3), such that the scar is hidden in a natural skin crease or hairline or mimics the natural highlight of the white roll of the lip, for example. Similarly, for ablative procedures involving 50% or more of an anatomical subunit, it is preferred to remove the entire subunit for these reasons. Obviously reconstruction would then entail some kind of tissue transfer. A further consideration is orientation of closure

Secondary Intention		+/ - negative pressure dressings	

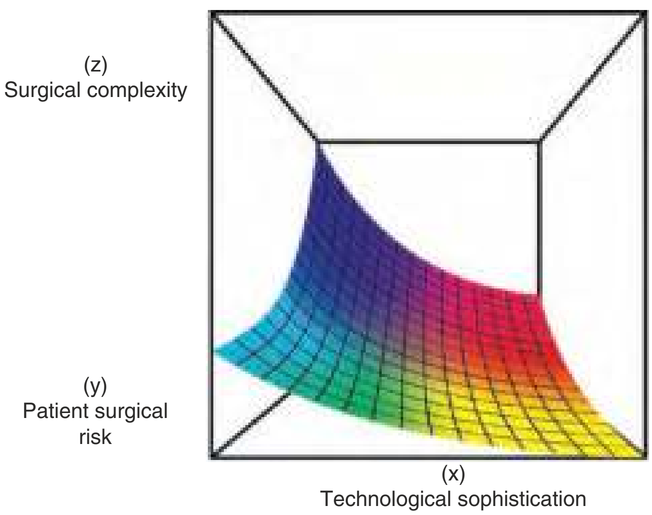

Fig. 86.1 The reconstructive matrix

with respect to the lines of relaxed skin tension that typically run perpendicular to underlying muscle fibres where possible. These two factors may dictate the decision to excise further tissue in a traumatic injury. The temptation to excise and close primarily out with these orientations should be avoided; however, as unless tissue is grossly contaminated or frankly necrotic, a straight surgical scar is usually more prominent than random pattern scars. The generous vascular supply of the face means that it is always best to err on the side of caution and perform minimal debridement such that a maximum of soft tissue is preserved.

Primary closure is appropriate for small defects that can be closed without significant tension or distortion of key areas such as the apertures of the mouth, nares and orbit. The latter is particularly sensitive to these effects and can result in ectropion and ocular sequelae if appropriate care is not taken. Techniques such as a creating a superior lateral canthal curve to the Mustarde flap, canthopexy and Frost sutures can be employed to reduce the risk of ectropion.

86.1.3 Grafts

The third rung of the reconstructive ladder is occupied by grafts, which may be further categorized as simple if composed of a single tissue type—commonly split or full-thickness skin but also mucosal grafts, or composite when containing more than one tissue type. Generally they are autografts, although xenografts and bioengineered material such as porcine collagen (Permacol), Polytetrafluoroethylene, fish skin and dermal matrix (e.g. Integra) have certain utility in maxillofacial reconstruction (Table 86.2).

86.1.4 Flaps

Flaps may be local, pedicled (regional or distant) or free. Local flaps transfer tissue to a defect by advancement and/or rotation and are typically supplied by a random vascular pattern. Axial flaps based on a named vessel can potentially pro-

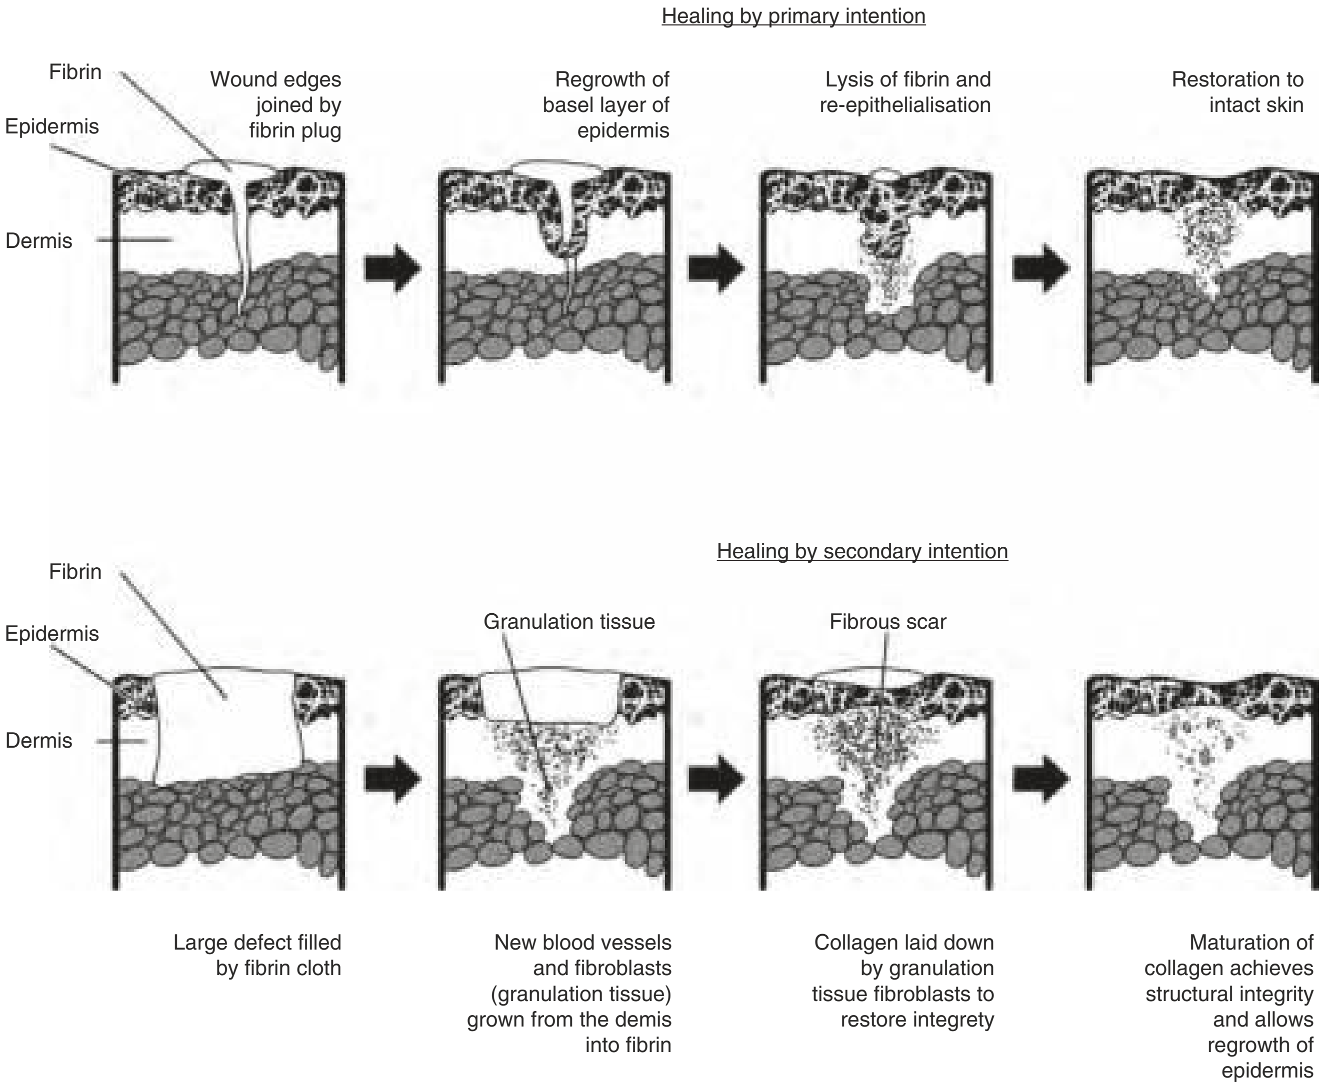

Fig. 86.2 Wound healing by primary and secondary intention

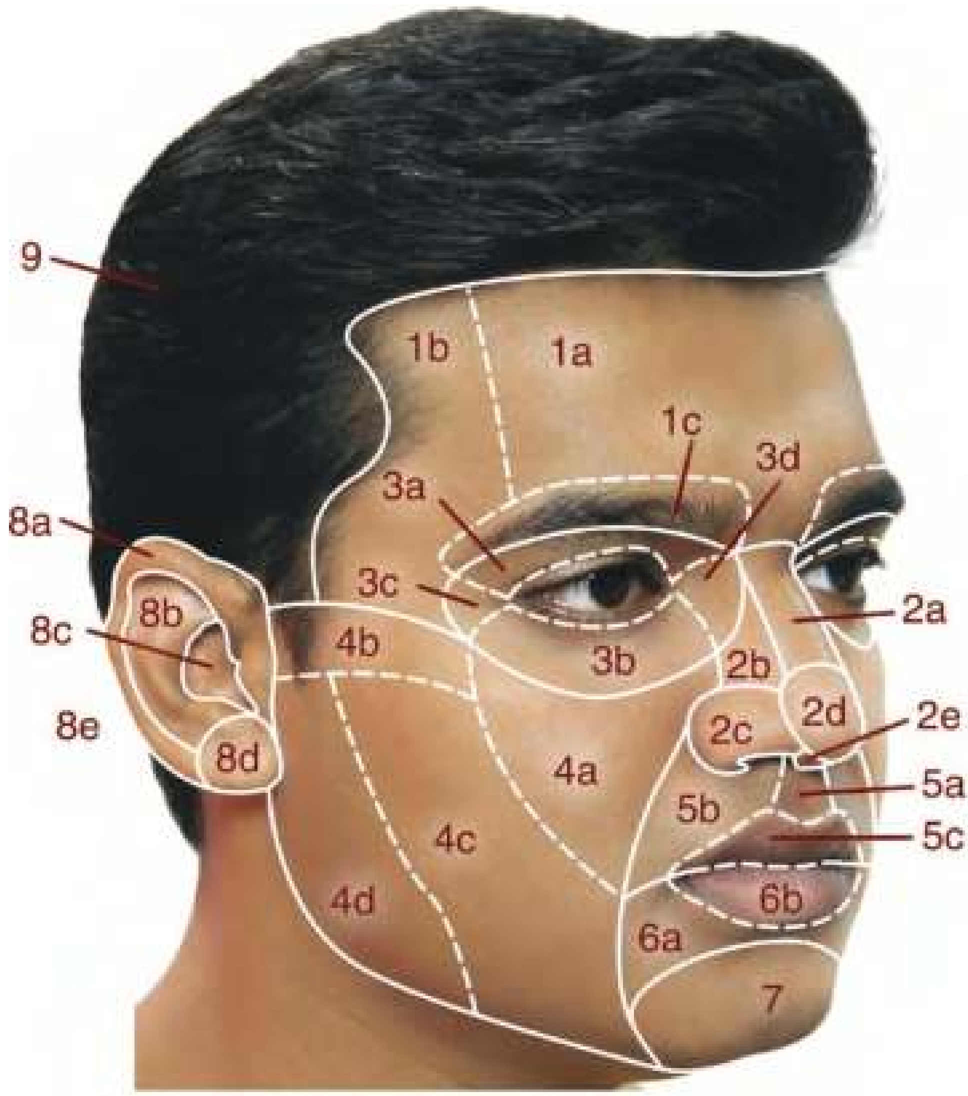
vide a flap of longer length to width ratio. Examples in the head and neck region include the paramedian forehead flap, nasolabial flap and facial artery myomucosal flap.

Regional pedicled flaps are able to provide a far greater area of soft tissue coverage than is possible with local flaps in the maxillofacial region, without requiring the facilities and expertise for microvascular reconstruction. They are generally less technique sensitive and susceptible to failure than microvascular free flaps; however, partial failure can still be problematic. For example, the pectoralis major myocutaneous flap has been reported to have a partial necrosis rate of up to 29% [3, 4]. Furthermore, while pedicled flaps are versatile and can usually provide a good skin match, free tissue transfer can often be a better option.

Free flaps offer many reconstructive options and can provide good cosmetic and functional outcomes. They may be sub-classified according to the tissue they contain and whether the pedicle is a named vessel or from a perforator system. Free flaps are available to reconstruct practically any size of defect in the maxillofacial region. Freedom from a pedicle allows them to be placed in any location, native vessels permitting.

Fig. 86.3 Facial aesthetic units (Also refer Fig. 49.2)



Facial Cosmetic Units

1. Forehead:
   1a. Central
   1b. Lateral
   1c. Brow

2. Nose:
   2a. Dorsum
   2b. Lateral wall
   2c. Ala
   2d. Tip
   2e. Columella

3. Eyelid:
   3a. Superior
   3b. Inferior
   3c. Lateral canthus
   3d. Medial canthus

4. Cheek:
   4a. Infraorbital
   4b. Zygomatic

4. Cheek:
   4a. Infraorbital
   4b. Zygomatic
   4c. Buccal
   4d. Parotid-masseteric

5. Upper lip:
   5a. Philtrum
   5b. Lateral
   5c. Vermilion

6. Lower lip:
   6a. Central

   8d. Earlobe
   8e. Retroauricular

9. Scalp

Disadvantages of flaps include:

- Their cost in resources and expertise.
- Increased operative time.
- Donor site morbidity.
- The risk of partial or complete failure.

86.1.5 Transplantation

Over recent years a number of partial and total facial transplants have been performed successfully. These cases are rare, requiring extremely careful selection and require a huge amount of resources. When indicated, however, this may be the only option to provide a cosmetic and to some extent functional outcome. Additional factors not associated with other reconstructive techniques, including donor selection, psychology, ethics and long-term immunosuppression require thorough consideration.

86.2 Reconstruction of the Oral Cavity

The functional roles of the oral cavity are among the most important in the body and are extremely sensitive to alteration resulting from even an apparently small defect. The coordinated action of structures within a relatively small anatomical region are critical for both nutrition (mastication and deglutition) and social interaction (speech and facial expression), two of the most vital activities that determine a patient's quality of life.

86.2.1 Reconstruction of the Lips

The aim of lip reconstruction should be to restore both function and aesthetics. Careful reconstitution of lip anatomy, such as the white roll, vermilion border and Cupid's bow, are required for a satisfactory cosmetic outcome. Continuity of the orbicularis oris muscle and adequate perioral sensation are needed to maintain lip competence. This is important during mastication and the oral stage of deglutition, particularly with fluids, and to prevent drooling in repose. The size of the reconstructed oral aperture will affect function too. All of these factors will contribute to the aesthetics of the lower third of the face.

The lips are unique in that they represent the transition from cutaneous tissue to keratinized dry and non-keratinized wet mucosa. As a result reconstruction of lip defects is best achieved by using remaining lip tissue when possible. This also often preserves contiguous, innervated orbicularis oris muscle and hence function as explained above.

Table 86.3 Time line of lip reconstruction techniques

Year	Author	Technique
1000 BC	Shushruta	First mention of lip repair
1597 AD	Tagliacozzi	Upper and lower lip repair using forearm flap
1768	Louie	Wedge excision described
1838	Sabattini	Full-thickness switch from lower to upper
1845	Dieffenbach	Cheek advancement for upper lip repair
1857	Von Bruns	Cheek advancement for lower lip repair
1872	Estlander	Upper to lower switch at commissure
1898	Abbe	Lip switch for bilateral cleft lip
1909	Lexer	Tongue flaps for lip repair
1954	Schuchardt	Sliding inferiorly based cheek flaps
1969	Bakamjian	Deltopectoral flap to lower lip defect
1974	Karapandzic	Advancement along nasolabial fold for lower lip defects

Therefore, local rotational, advancement and cross-lip flaps have become mainstays of reconstruction for larger deformities not amenable to direct or sliding lip closure (Table 86.3).

86.2.2 Reconstruction of the Vermillion

Deformity of the vermillion and the white roll of the lips is readily apparent to most observers; therefore careful reconstruction is vital for cosmesis. Small superficial defects that do not involve the underlying orbicularis muscle may be left to heal satisfactorily by secondary intention, although the process is slow (25 days on average) and can result in contracture [5, 6]. For these reasons, primary closure of a small vertically oriented fusiform excision is the preferred option, especially as often the defect will extend just beyond the vermillion, so control of the vermillion border re-approximation is required. Where redundant 'dog ear' mucosal tissue is likely to occur with primary closure of a mucosa only defect, a V-Y island of mucosa can be advanced from the labial mucosa or laterally from adjacent vermillion [7].

Large superficial defects of the upper or lower vermillion are best managed by resection of the entire vermillion subunit (lip shave) and advancement of a flap of labial mucosa. This provides a close cosmetic match, particularly in older patients. Sensation often returns with this approach; however, atrophy and contracture can be apparent particularly if the depth of the flap is not matched carefully to the depth of the defect. Alternatively, transfer of the vermillion of the opposing lip has been described, either as a single or bi-pedicled mucosal flap. Underlying muscle can be included as a myomucosal flap pedicled on the labial vessels [8]. These approaches require division and inset as a second procedure, arguably for minimal benefit compared with mucosal advancement from the labial mucosa. Reconstruction with tongue [9], buccal mucosal or myomucosal flaps can give acceptable results. Finally, anal verge mucosa grafts to the lips has also been described [10].

86.2.3 Reconstruction of the Lower Lip

86.2.3.1 Defects Up to one Half of Lower Lip Width

Depending on the laxity of the lower lip, which is mainly related to the age of the patient, most defects of less than one third to half the width of the lower lip can be closed primarily with excellent cosmetic and functional outcomes. The defect is extended inferiorly along a 'v' or shield shape incision. The point of the 'v' can be curved laterally to follow the labiomental groove to camouflage the scar in wider defects. In even larger defects, this groove can be followed on one or both sides of the base of the resection to aid in tissue mobilization. Some surgeons utilize a 'w'-shaped incision at the base of the defect, but this may result in a less cosmetic scar. Defects that involve the commissure can be more challenging as blunting that results may require a further commissuroplasty procedure.

86.2.3.2 Defects Greater Than One Half Lower Lip Width

Lower lip defects of this proportion are unlikely to be able to be closed primarily without causing unacceptable microstomia.

Lip Switch Flaps

A reverse Abbe flap (see *upper lip reconstruction* below) can be used to reconstruct larger lower lip defects, whereby a segment of upper lip with the same vertical dimension, but around 50% of the width of the lower lip defect is pedicled laterally on the labial artery. To prevent deformity of the upper lip, harvest should only be from lateral to the philtrum. In theory bilateral reverse Abbe flaps can be used, although the two pedicles that result make oral intake difficult until the flaps are inset.

Karapandzic Flap

The Karapandzic flap allows reconstruction of lower lip defects up to 80% of the lower lip width [11], with good preservation of function and aesthetics (Fig. 86.4). Some degree of microstomia and blunting of the commissures is caused, however. Unilateral or bilateral transdermal curvilinear incisions that follow the nasolabial creases allow mobilization and re-approximation of the remaining lower lip [12]. The incision extends through dermis only, preserving the neurovascular supply to the remaining lower lip either side of the defect. This is the main advantage compared with the older advancement flaps such as the Gillie's fan flap (Fig. 86.5), which disrupt underlying neurovasculature due to full-thickness incisions.

86.2.3.3 Subtotal Defects

Cheek Advancement Flaps

Bilateral horizontal cheek advancement flaps where described by Bernard (1852) and von Burow (1853) for reconstruction of large lip defects [13]. Tissue is advanced from the cheek by extending incisions laterally from the commissure and excising three triangles – two lateral Burow's triangles and one triangle around the defect of the lower lip itself. Webster refined this technique for reconstruction of lower lip defects using only partial-thickness incisions along the nasolabial and labiomental creases [14] (Figs. 86.6, 86.7 and 86.8). This concept was further refined

Bernard von burrow flap

by Pirgousis and Fernandes for lower lip reconstruction [15] (Figs. 86.9 and 86.10).

Nasolabial Flaps

Fujimori described 'gate' flaps that are effectively nasolabial flaps, which can be combined with a lower labial mucosa advancement flap to reconstruct the entire lower lip [16]. A similar technique allows reconstruct of the upper lip [17] (Fig. 86.11).

86.2.3.4 Reconstruction of the Upper Lip

Primary Closure

Defects of the upper lip are less amenable to primary closure than those of the lower lip. There is relatively less laxity, and asymmetry is more apparent because of deviation or distortion of the philtrum and nasal base. Defects up to around one quarter to one third of upper lip width can still be re-approximated satisfactorily, particularly if laterally situated. The philtrum is less forgiving though and while defects up to around half the width can be closed primarily, there is a tendency for flattening and upwards retraction of the vermillion in this subsite.

Lip Switch Flaps

The first report of a two-stage pedicled 'lip switch' flap was by Sabattini in 1838 [18]. The labial artery-based flap was popularized by Abbe in 1898, however, for use in cases of bilateral cleft lip [19]. The lower lip donor site is designed to be half the width of the upper lip defect (to equalized the horizontal discrepancy between upper and lower lips), equal to the height of the defect, and with a laterally based pedicle.

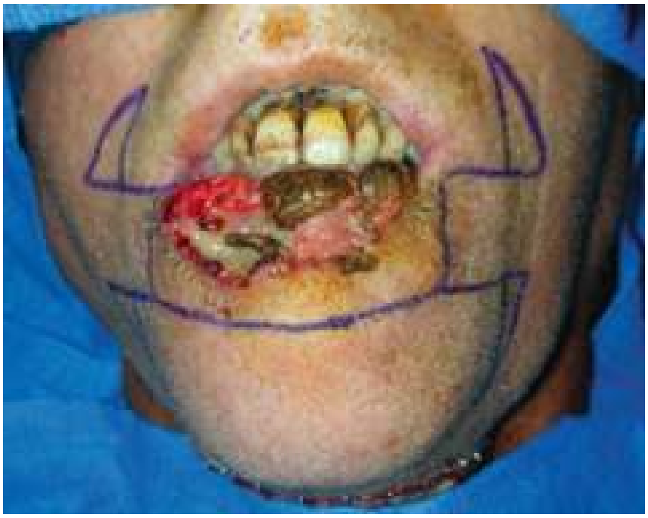

Fig. 86.7 Webster-Bernard-Burrow flap markings prior to lower lip resection

Fig. 86.8 Webster-Bernard-von Burow flap following closure

Fig. 86.9 Fernandes flap incisions following lower lip resection

Fig. 86.10 Fernandes flap following closure

The central lower lip is the preferred donor site, as it is hair-bearing in males and leaves the least prominent scar. The white roll should be marked prior to incision and potential obscuration due to bleeding, oedema and pallor. The flap is raised including skin, muscle and mucosa but with preservation of the lateral vermilion incorporating the labial vessels. The flap is rotated and inset, taking care to re-approximate the orbicularis oris muscle and align the white roll (Fig. 86.12). After 2–3 weeks, the pedicle is divided and the flap inset. For defects of the commissure, Estlander described a similar flap where the commissure is the rotation point, and therefore no secondary insetting is required (Fig. 86.13).

Perialar Crescentic Advancement

Initially described by Webster [20], a perialar incision can be made unilaterally or bilaterally to recruit lateral tissue for closure of upper lip defects (Figs. 86.14 and 86.15). This technique can also be combined with an Abbe flap to recon-

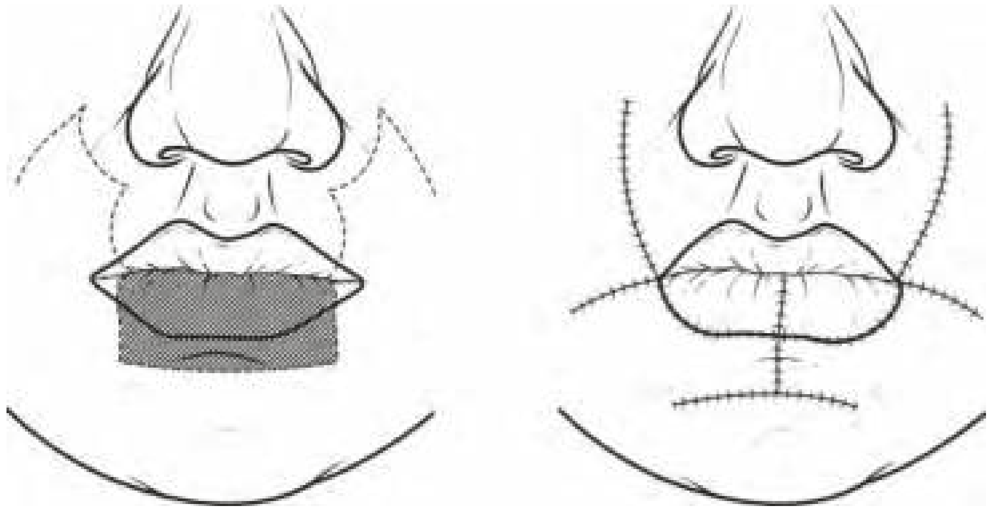

Fig. 86.11 Bilateral nasolabial flaps for lower lip reconstruction

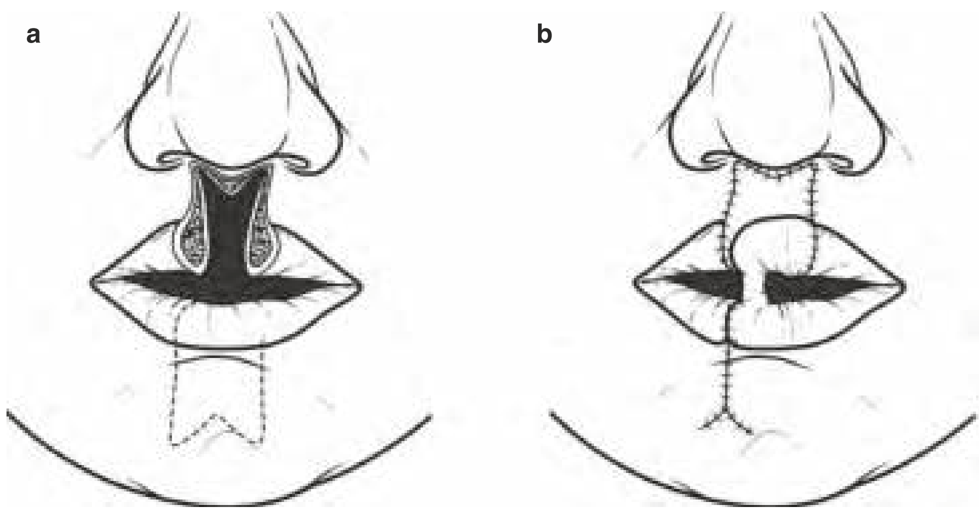

Fig. 86.12 Abbe flap for upper lip reconstruction. (**a**) Defect and flap markings. (**b**) Flap inset prior to division of pedicle

struct the philtrum when defects involve the midline of the upper lip.

Reverse Karapandzic

Incisions following the melolabial groove upwards to join the superior margin of an upper lip defect can be used to advance lateral tissue in a similar fashion as the Karapandzic flap does for closure of lower lip defects.

86.2.3.5 Commissuroplasty

Most of the reconstructive techniques described above result in blunting and rounding of the oral aperture. The simplest way to correct this is to make a horizontal full-thickness incision through the blunted commissure, extending laterally to correspond with the position of the contralateral normal commissure. Epithelium superior and inferior to the incision is excised and labial mucosa advanced from intraorally to recreate the vermilion (Fig. 86.16). An alternative method was described by Gillies and entails excision of a triangular segment of skin lateral to the rounded commissure, to a point comparable with the normal side. A vermilion flap from the opposite lip is then raised and rotated into this and a mucosal flap advanced to reconstruct the vermilion of the donor site (Fig. 86.17).

86.2.3.6 Total Lip Defects

A combination of the techniques presented above can be employed to reconstruct total defects of one or other lip. Increasingly, free tissue transfer is used instead, however. The most commonly used flap for this purpose is the radial free flap (Figs. 86.18 and 86.19). This is mainly due to the thin, soft, pliable tissue offered and reliable, long pedicle.

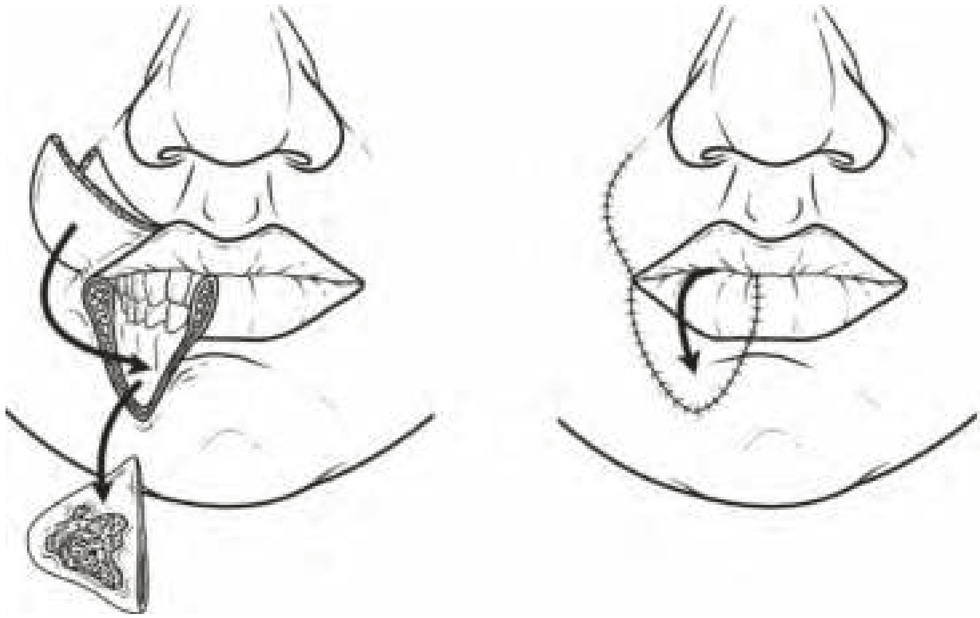

Fig. 86.13 Estlander flap for reconstruction of defect involving commissure. A medially pedicled full-thickness flap half the width of the defect is raised from the upper lip and inset into the lower lip defect

Fig. 86.14 Perialar crescentic flap to reconstruct upper lip defect

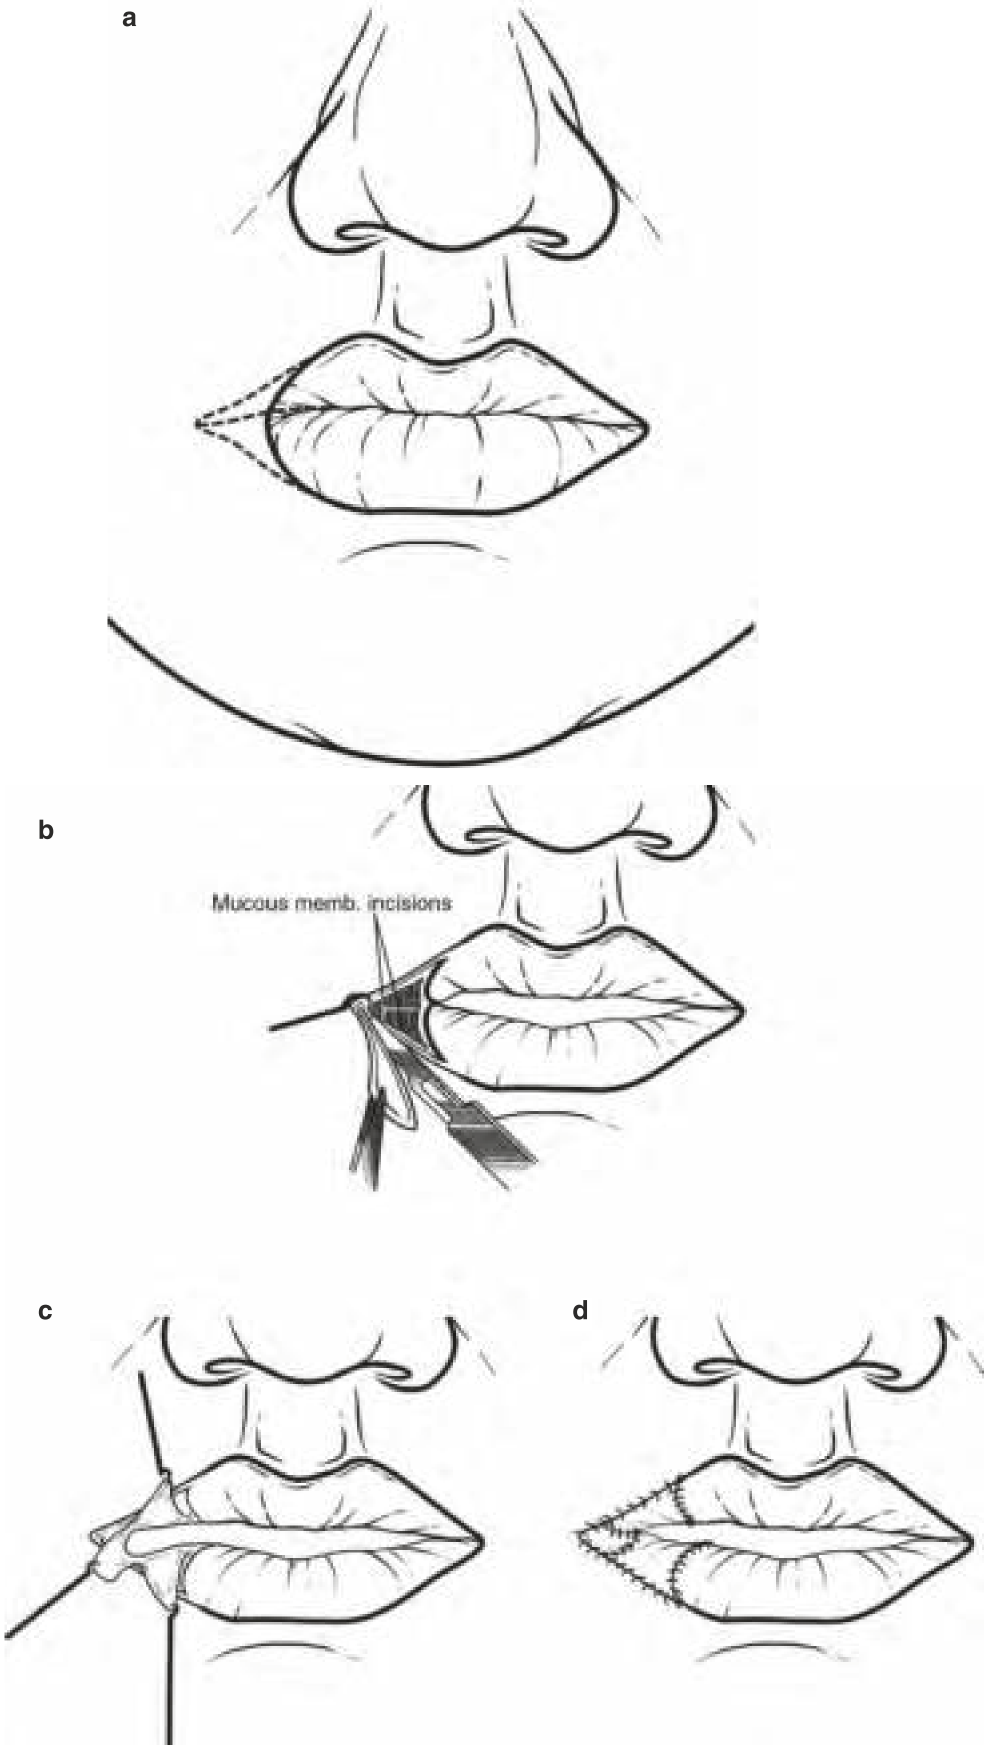

Fig. 86.16 (**a–d**) Commissuroplasty. A full thickness incision is made through the blunted commissure and an area de-epithelialised to mirror the normal side (dashed lines, **a**). This is then re-surfaced with mucosal flaps raised from intraorally (**b–d**)

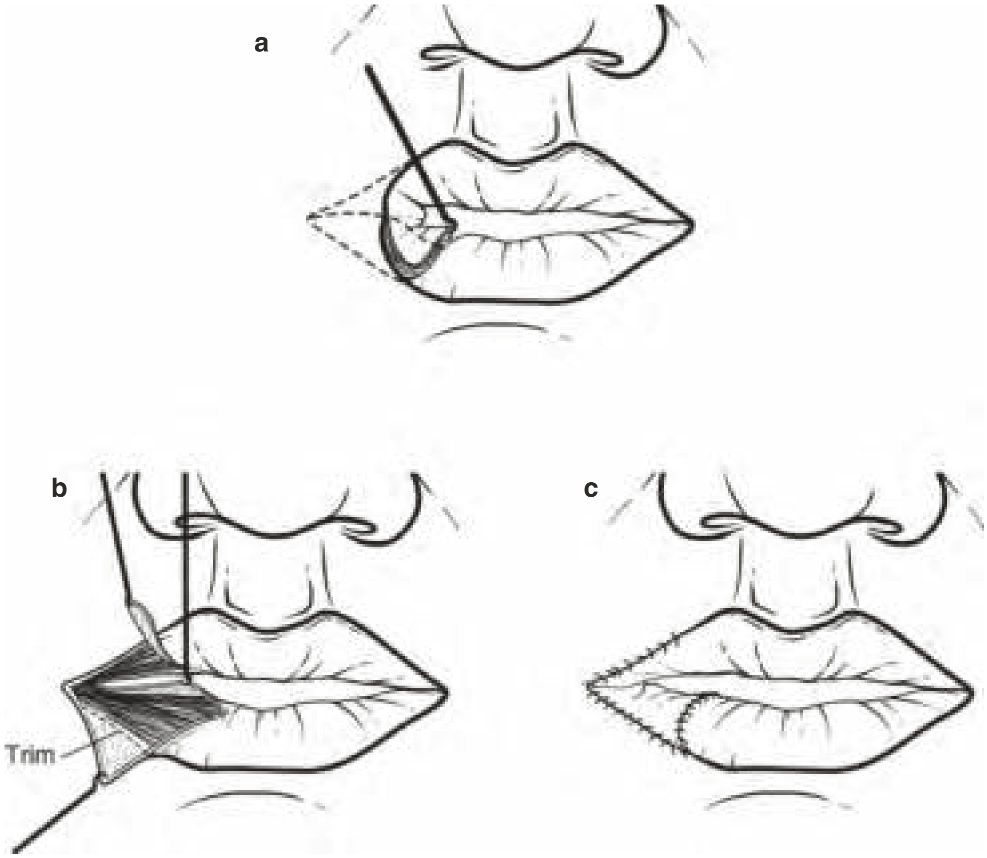

Fig. 86.17 (**a**–**c**) Gillies commissuroplasty. An area mirroring the normal commissure is de-epithelialised (dashed lines, **a**). Vermillion is raised from the lower lip and inset into the de-epithelialised upper lip (**a**, **b**). The lower vermillion is reconstructed with a mucosal flap raised from the labial mucosa (**b**, **c**)

There is also the option to include palmaris longus tendon harvest [21]. This can be used as a sling between the commissures, or to the malar periosteum to improve lip form and oral competence. Alternatively, the flexor carpi radialis tendon or a nonvascularized fascia lata graft can be utilized for the same purpose. Coaptation of the lateral antebrachial cutaneous nerve to the mental nerve has been described to restore sensation to radial flap reconstruction of the lower lip [22]. Other free flaps that have been employed for total lip reconstruction include the gracilis for the lower lip [23–25] and temporal scalp for upper lip defects [26, 27].

86.3 Buccal Mucosa and Cheek

The main function of the cheek is to hold food between the occlusal surfaces of the teeth during mastication. Inadequate reconstruction can lead to excess tissue that interferes with mastication or insufficient tissue and scarring that results in trismus. Where possible the parotid duct should be repaired and/or re-sited in the buccal mucosa if involved in the defect or reconstruction to prevent obstructive parotitis. Small buccal mucosa defects can be closed primarily, but larger mucosal defects often benefit from reconstruction with a split-thickness skin graft or ipsilateral buccal fat pad [28]. As size and depth of the defect increases, the use of regional flaps described in the part of this chapter that addresses floor of the mouth defects should also be considered. The radial forearm flap is the most commonly used flap for reconstruction of intraoral buccal defects due to its pliability and lack of bulk (Figs. 86.20 and 86.21). Thicker and more extensive defects may benefit from an anterolateral thigh flap, depending on the patient's body habitus. Full-thickness cheek defects often require reconstruction of both the intraoral and extraoral surfaces. A combination of techniques may be employed, for example, a regional or free flap for the skin and a split-thickness skin graft for mucosa, but often it is best to consider reconstructing with a folded or dual paddled flap. Both radial forearm [29] and anterolateral thigh [30] free flaps are well suited for bi-paddled designs. The first is more pliable and thinner; the second can be made larger and confers less donor site morbidity, as it can generally be closed primarily. The portion between the paddles is de-epithelialized where it will lie within the substance of the cheek. Alternatively, if the lip is involved in the defect, the intervening tissue can instead be used to reconstruct the lip. Obviously this will be a static repair and will therefore have an effect on oral competence.

Full-thickness cheek defects often involve the buccal or marginal mandibular branches of the facial nerve, with con-

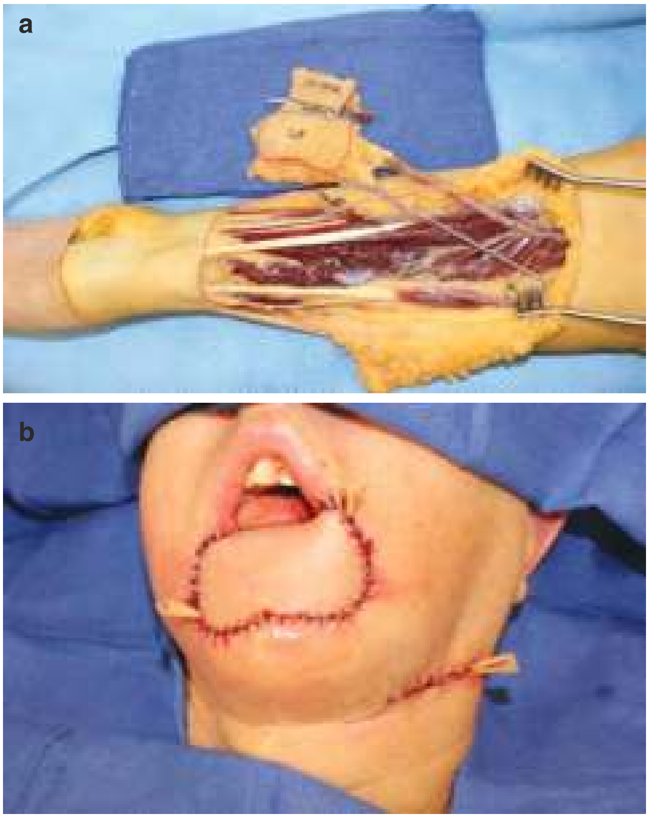

Fig. 86.18 (**a**) Design of RFFF for lower lip reconstruction. (**b**) RFFF after inset to subtotal lower lip defect

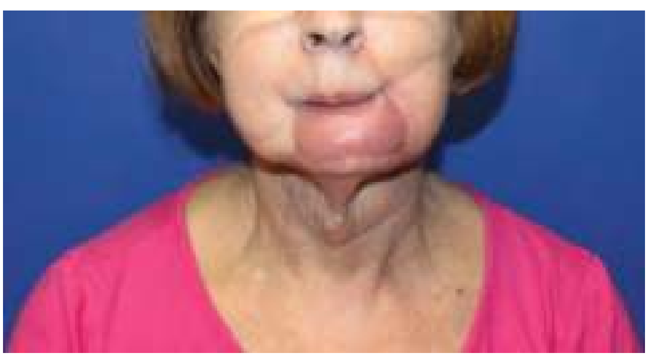

Fig. 86.19 Late postoperative appearance of RFFF reconstruction of subtotal lower lip defect

sequent paralysis of the lower face. A detailed description of facial reanimation is outwith the scope of this chapter; however the methods can broadly be categorized as either static or dynamic. Static reanimation includes gold or platinum weights or springs to aid upper eyelid closure and resuspension of the oral commissure to deep temporal fascia with palmaris longus, fascia lata, acellular dermal matrix, PTFE or polypropylene [31]. Dynamic reanimation involves either

Fig. 86.20 Buccal mucosa defect

Fig. 86.21 RFFF inset to reconstruct buccal mucosa defect

the reinnervation, usually with nerve grafts or the interposition of innervated muscle, commonly temporalis transposition or a gracilis neuromuscular free flap [32].

86.4 Floor of Mouth

The floor of the mouth comprises the myomucosal diaphragm that extends from the ventral surface of the tongue, bounded anteriorly and laterally by the lingual aspect of the mandibular gingiva and posteriorly by the retromolar trigone. This inferior limit of the oral cavity provides a reservoir for food during mastication, while the muscles are also active during deglutition. The mylohyoid, geniohyoid and anterior digastric muscles raise the aerodigestive tract anterosuperiorly during swallowing, anchoring the tongue and increasing the diameter of the fauces. At rest the same muscles, particularly genioglossus, prevent upper airway compromise by posterior displacement of the tongue: an important consideration when reconstructing this region. Finally, mobility of the tongue during speech, mastication and swallowing depends on adequate anterolateral separation from the mandible, and therefore reconstruction should also aim to recreate the lingual sulcus and prevent ankyloglossia.

One commonly employed method to reconstruct floor of mouth defects is the submental artery island flap, first described by Martin et al. in 1993 [33]. It is easily raised with minimal donor site morbidity to provide a large and reliable paddle. The pedicle is up to 8 cm in length, and cutaneous dimensions up to 7 × 18 cm can be harvested, sufficient to reconstruct most pure floor of mouth defects. It confers less donor site morbidity than the main alternative of a radial forearm flap; often there is even a cosmetic improvement in the patient's soft tissue profile. The main concern with the use of this flap is in the oncological setting is due to potential compromise of nodal dissection in level 1. In one small series, four of nine patients undergoing SIF suffered local or regional recurrence thought to be attributable to incomplete nodal harvest [34]. On the other hand, Howard et al. found that in 50 patients undergoing SIF, all with clinically negative level 1 nodes, none experienced recurrence attributable to the flap [35]. It is generally accepted that the flap is contraindicated in necks with clinically positive nodes, particularly in level I. A history of radiation is a relative contraindication, though good outcomes have been described despite this [36, 37]. Finally, since the submental vessels arise from the facial vessels, the flap cannot be performed in patients who have undergone a neck dissection with sacrifice of the facial vessels. In such patients or where tissue is required outside previous radiation fields, the infrahyoid island flap [38] is an alternative of similar size and character to the SIF. Supraclavicular island (Fig. 86.22) and pectoralis major flaps are also well-proven options that generally lie outside any previously operated or radiated field. They have broad pedicles, which unless skeletonized can introduce excess tissue into the defect or the tunnel from donor site. A radial forearm free flap may therefore be preferred, providing a thin, supple reconstruction with negligible pedicle bulk (Figs. 86.23 and 86.24).

Fig. 86.24 RFFF reconstruction of floor of mouth defect demonstrating good tongue mobility

86.5 Tongue Reconstruction

Adequate tongue function requires interaction between sensory and motor components of both voluntary and involuntary nervous systems to achieve intelligible speech, mastication and swallowing. Therefore tongue defects have a significant effect on quality of life compared with other oropharyngeal structures, proportional to their volume. Tongue reconstruction that recreates the biomechanics of the healthy tongue leads to better function and even cortical adaptation to the neotongue [39]. In terms of speech, the ability for the anterior tongue to contact the palate is particularly important. Speech therapy following tongue reconstruction should be considered as it can improve proprioception of the reconstructed tongue and facilitate cortical plasticity.

86.5.1 Primary Closure

Small volume defects of the free oral tongue can often be closed primarily with satisfactory outcomes (Figs. 86.25 and 86.26). As the area of the defect increases, the option of healing by secondary intention should be considered as this can result in a more natural tongue morphology, while dehiscence is often the natural course for primary closure in any case.

86.5.2 Pedicled Flap Reconstruction

Tongue defects can be reconstructed with a variety of pedicled flaps, often utilized when free tissue transfer is precluded. Prior to development of free tissue transfer, the pectoralis major and deltopectoral flap were common options, with the facial artery myomucosal flap an alternative for smaller volume defects. There has been a renaissance in the use of other regional flaps over recent years, such as the submental (Figs. 86.27 and 86.28), supraclavicular, trapezius and infrahyoid island flaps.

Fig. 86.27 Submental flap prior to reconstruction of lateral tongue defect

Fig. 86.28 Late postoperative appearance of submental flap reconstruction of left lateral tongue

Fig. 86.29 RFFF to reconstruct right hemiglossectomy

86.5.3 Free Flap Reconstruction

Tongue reconstruction with a microvascular free flap is usually recommended to restore form, resist contractures and tethering in defects greater than a quarter of the original tongue size [40]. The flap should be designed to recreate premorbid morphology in all three dimensions as far as possible.

The radial forearm free flap is the workhorse of tongue reconstruction for good reason (Fig. 86.29). It provides thin, pliable, soft tissue and large-calibre vessels of consistent anatomy and excellent length for microvascular anastomosis. Harvest can be simultaneous with resection and presents limited morbidity. The lateral antebrachial cutaneous nerve can be coapted to the lingual nerve to provide a sensate flap with some evidence of improved function and resistance to atrophy [41]. Defects greater than three quarters of the tongue may benefit from reconstruction with tissue of greater substance such as an anterolateral thigh (ALT) or rectus abdominis free flap. ALT harvest results in a more easily hidden scar and potential sensory loss is less troublesome. Total glossectomy reconstruction is particularly challenging. Recreation of three-dimensional morphology is critical, with emphasis on height and a tip protuberance, to facilitate speech and swallowing [42] (Figs. 86.30 and 86.31). A flap that is around one third greater than the defect is recommended to achieve this aim due to inevitable atrophy. Hyolaryngeal suspension should also be considered as an adjunct, to reduce the risk of persistent laryngeal aspiration [43].

Fig. 86.30 Folded ALT flap for glossectomy reconstruction prior to pedicle division

86.6 Palatal Soft Tissue Defects

Simple mucosal defects overlying the hard palate can be left to close by secondary intention. Although the process is sometimes prolonged, pain and remucosalization can be aided by an acrylic cover plate retained by bone screws or dental cribs. Buccal mucosa with or without buccal fat pad can be advanced to repair palatal mucosa if the adjacent alveolus is edentulous. Palatal mucosal flaps, facial artery myomucosal flaps, temporalis or temporoparietal flaps and tongue flaps are alternatives. Functional reconstruction of the soft palate is difficult, but uvula, posterior pharyngeal wall or folded radial free flaps are options to consider.

Fig. 86.31 (**a**) ALT flap inset for glossectomy reconstruction. (**b**) Late postoperative appearance

86.7 Facial Reconstruction

The aims of facial reconstruction differ from those of oral reconstruction. While the emphasis in the latter case is on function, without neglecting cosmesis, the priority here is reversed. Besides the disfigurement itself, patients will often suffer significant and irremediable social detriment due to inadequate facial reconstruction. Cosmetically acceptable results require a detailed understanding of facial anatomy. This is best considered in terms of the facial aesthetic units [44] (Fig. 86.3). This approach was first described by Gonzales-Ulloa [45–48], who demonstrated that scars can be hidden in the natural lines dividing units from one another. Menick later discussed the importance of human perception in reconstruction [49].

86.7.1 Forehead Reconstruction

The forehead comprises midline and paired median, lateral, temporal and brow subunits (Fig. 86.32). Small defects can be closed primarily parallel to horizontal RSTLs that run perpendicular to the underlying frontalis muscle fibres. The defect can be extended to an ellipse or with terminal M-plasties to achieve this. Midline defects may be closed vertically with acceptable results, particularly in the aged face. Undermining and careful closure of the galeal layer is important when closing larger defects primarily.

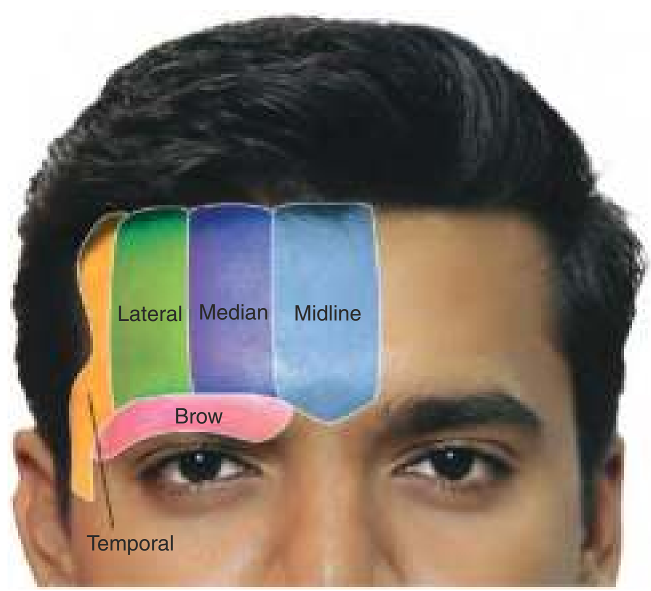

Fig. 86.32 Aesthetic subunits of the forehead

Split or full-thickness skin grafts can be used for large defects, although there will be a mismatch with the native skin particularly if split thickness. An alternative is tissue expansion either to provide full-thickness skin from a site such as the supraclavicular fossa or locally to provide tissue for a local flap.

Reconstruction of the forehead with local flaps usually has a better cosmetic outcome than skin grafts. Unilateral or bilateral horizontal 'H' advancement flaps work well, as does an 'A' to 'T' flap at the hairline. Finally, large forehead and scalp defects can be reconstructed with free tissue transfer. With this option, often the best cosmetic results are achieved with a radial flap or latissimus dorsi muscle flap combined with a skin graft.

86.7.2 Eyelid Reconstruction

The eyelids are of critical importance in protecting the globes and preventing loss of vision through exposure keratitis. The main goals of reconstruction are therefore to recreate a lid that lies passively against the globe without ectropion or entropion and permits full eye closure (Table 86.4). Both the upper and lower eyelids have a bilaminar structure, which has relevance to reconstructive options. The anterior lamella is composed of the thinnest skin in the body and underlying preseptal orbicularis oculi muscle. The posterior lamella is comprised of the tarsal plate and conjunctiva. The tarsal plates impart some rigidity to the eyelids and contain meibomian glands to produce the lipid component of tears. They are around 25 mm in width and 1 mm thick, with the upper plate 7–12 mm and the lower plate 3–4 mm in height. The upper tarsal plate is attached to the levator palpebrae superioris (oculomotor innervation) muscle via the levator aponeurosis and sympathetically innervated Muller's muscle. The lower plate is attached to orbital septum rather than an aponeurosis.

The orbicularis oculi muscle has three parts. The preseptal and pretarsal components are active in blinking, promoting lachrymal flow from gland to canaliculi and insert into the canthal tendons. The outermost orbital component is involved in voluntary eyelid closure and does not insert into the canthal tendons. There are two preaponeurotic fat pads present in the upper lid and three post septal fat pads in the lower lid (nasal, central and lateral). They are separated by fibrous septa, plus the inferior oblique muscle between nasal and central lower fat pads.

Table 86.4 Aims of eyelid reconstruction

Reconstruction of anterior and posterior lamellae
Adequate supple skin that permits normal eyelid movements
Avoidance of entropion or ectropion
Non-keratinized mucosa adjacent to globe
Degree of rigidity such that lid is applied to the globe in all areas

86.7.2.1 Healing by Secondary Intention

Small superficial defects limited to the anterior lamella may be left to heal by secondary intention particularly in the medial canthal region where the nasal bones resist scar contracture and therefore ectropion. This approach should generally be avoided in central or lateral lower eyelid defects due to the high risk of cicatricial ectropion.

86.7.2.2 Primary Closure and Grafts

Small defects not involving the ciliary margin can be closed parallel to relaxed skin tension lines if lagophthalmos does not result. For larger defects confined to the anterior lamella, full-thickness skin grafts from the opposing lid are ideal, providing a good match with minimal hair and resistance to the contraction associated with split-thickness grafts.

If the defect involves the ciliary margin, primary closure is possible up to one third of the lid width. Typically a 7/0 resorbable vertical mattress suture though meibomian gland orifices is used to align the ciliary margin, the tarsal plate is closed with 6/0 resorbable sutures and finally skin with 6/0 fast resorbing sutures (Fig. 86.33). Conversion to a pentagonal defect with squaring of the tarsal defect and a slight temporal slant to the anterior lamella portion can be helpful to prevent notching of the ciliary margin. A lateral canthotomy and superior or inferior cantholysis can help recruit lateral tissue. Care must be taken to appose both the tarsus and skin to avoid notching of the ciliary margin.

86.7.2.3 Local Flaps

Full-thickness defects up to 60% of the lower lid width can be repaired with a Tenzel flap [50] (Fig. 86.34), which rotates and advances tissue from the lateral canthus. Alternatively defects of this size can be repaired with a tarsoconjunctival graft and musculocutaneous advancement flap or a Hughes flap [51] (Fig. 86.35). The latter method is a two-stage procedure that involves a pedicled tarsoconjunctival flap from the upper lid covered with skin grafted from one of the upper lids. The pedicle is divided after 4–6 weeks. To prevent entropion of the upper lid, 3–4 mm of tarsus should be preserved. This method in reverse has also been described to repair defects of the upper eyelid [52]. A cervicofacial (Mustarde) flap can also be combined with a Hughes flap, free tarsoconjunctival or palatal mucosa or nasal septal graft to reconstruct lower lid defects.

Defects one third to one half the upper lid width can be repaired with a reverse Tenzel flap or sliding tarsoconjunctival flap (Fig. 86.36) and skin graft. Larger defects can be repaired with a Cutler-Beard flap [53] that transfers an infratarsal full-thickness lower lid flap underneath a bridge of preserved lower ciliary margin (Fig. 86.37). The pedicle is divided after 6–8 weeks. Interposition of a cartilage or dermal matrix graft between the lamellae of the flap can improve the form of the reconstructed upper lid [54] (Table 86.5).

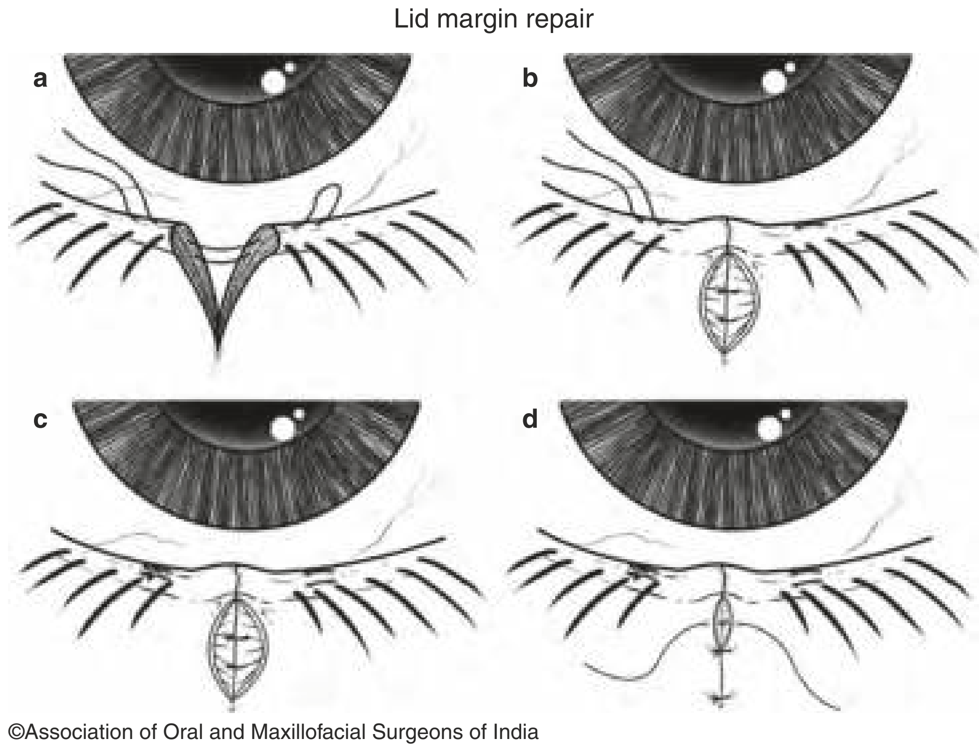

Fig. 86.33 (**a**–**d**) Primary closure for small defects involving the ciliary margin. A vertical mattress resorbable suture is placed through the meiobian duct orifice region (**a**), to oppose the ciliary margin (**b**). The muscle (**c**) and skin (**d**) are then closed in layers

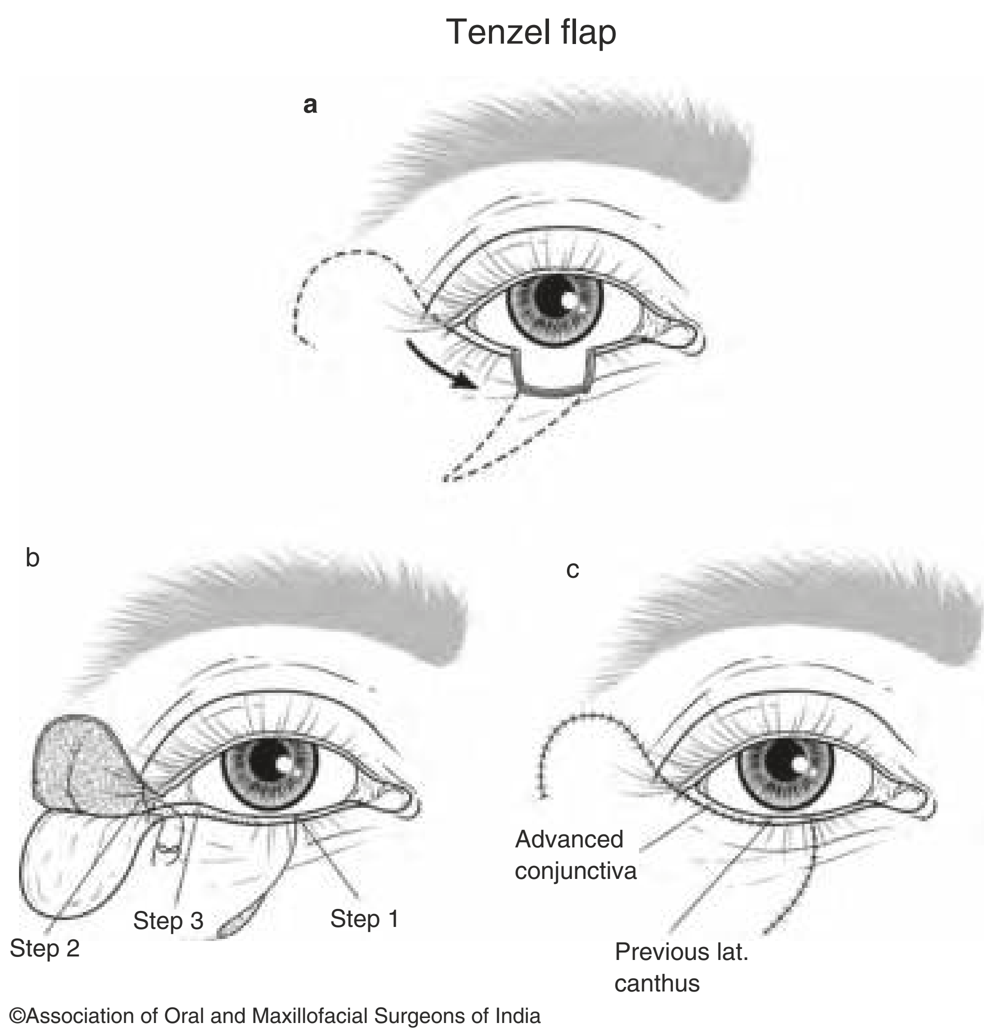

Fig. 86.34 (**a**–**c**) Tenzel flap to advance lateral tissue into lower lid defect. A superiorly curved incision is extended laterally through the lateral canthus (**a**) to allow advancement of a partial thickness flap and remaining lateral lid to close a lower lid defect (**b**). Excess skin inferior to the defect is excised in the manner of a Burow's triangle

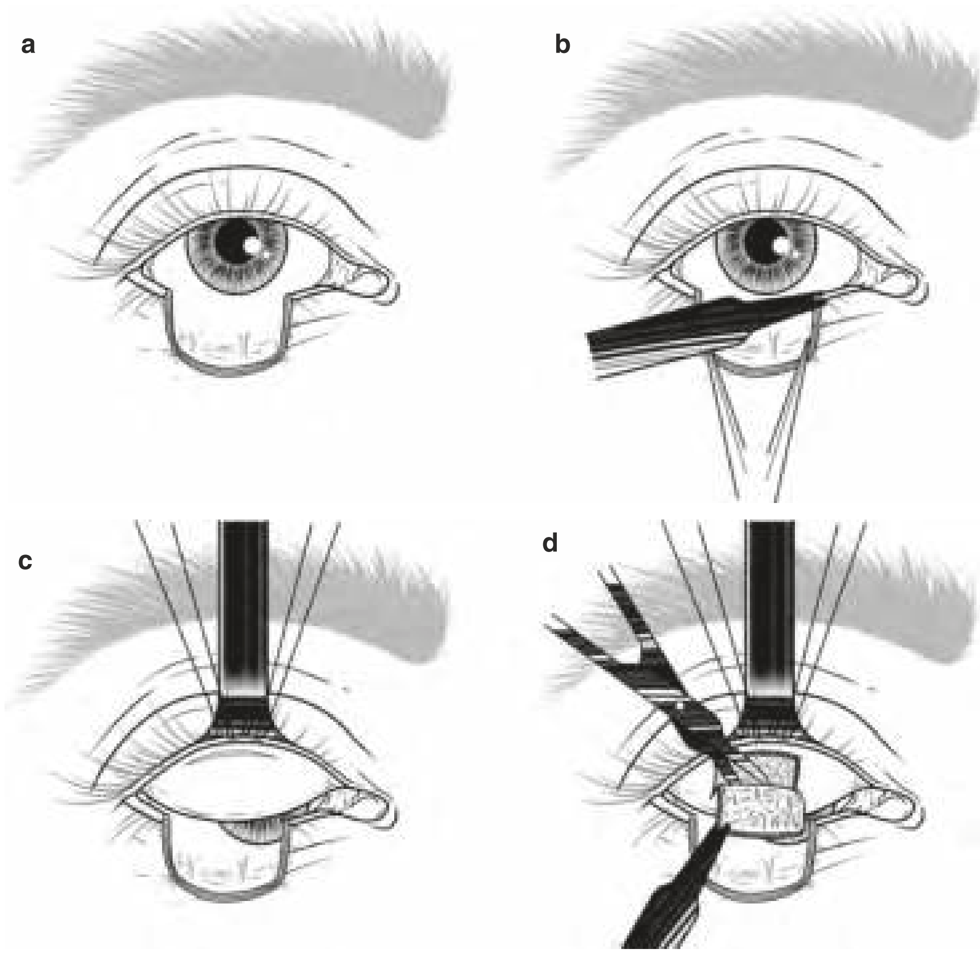

Fig. 86.35 (**a–d**) Hughes tarsoconjunctival flap from upper lid to reconstruct lower lid defect. A lower lid defect (**a**) is reconstructed with a superiorly based tarsoconjuctival flap raised from the deep aspect of the upper lid (**b–d**). The flap is covered with a skin graft from one of the upper lids and the pedicle divided after 4-6 weeks

86.7.3 Ear Reconstruction (Also refer Chap. 35)

The external ear is a relatively isolated aesthetic unit with its own complex subunit anatomy (Fig. 86.38). Reconstruction requires attention to shape, angular orientation with respect to the adjacent skull, and symmetry with the contralateral ear [55]. Of these three points, the last is the most important. Finally, the reconstructed ear should serve as support for spectacles or hearing aids (Table 86.6).

The major constitutive subunits, working from peripheral to central, are the helix, scapha, antihelix and concha (subdivided into cymba and cavum). The tragus, antitragus and lobule are less critical to overall auricular aesthetics, as a defect involving these subunits has minimal effect on the shape of the remainder of the external ear.

Orientation with respect to the skull follows these general guidelines [55]:

1. Auricular height = distance between lateral orbital rim and root of helix at the level of the brow.
2. Approximately 15° deviation from the skull in the vertical axis.
3. Approximately 25–30° deviation from the skull in the horizontal axis.
4. Highest point of helix level with lateral brow.
5. Helical rim protrudes 1–2.5 cm from skull.

The following will concentrate on helical defects, since the helix is the most common site, and many lesions centred in other regions will extend to involve it as well [56]. The classical reconstructive ladder is somewhat modified for defects of the ear. For defects overlying intact perichondrium, a full-thickness skin graft is the optimal technique, rather than primary closure [55]. Alternative approaches must be used when perichondrium has been resected, as denuded cartilage will not support a skin graft. If the defect exposes cartilage in an area where it can be resected without altering the shape of the ear, it should be resected down to the opposing perichondrium, which should be covered with a skin graft [55]. The retroauricular skin is the best colour match, and the scar at the donor site is well hidden by the ear.

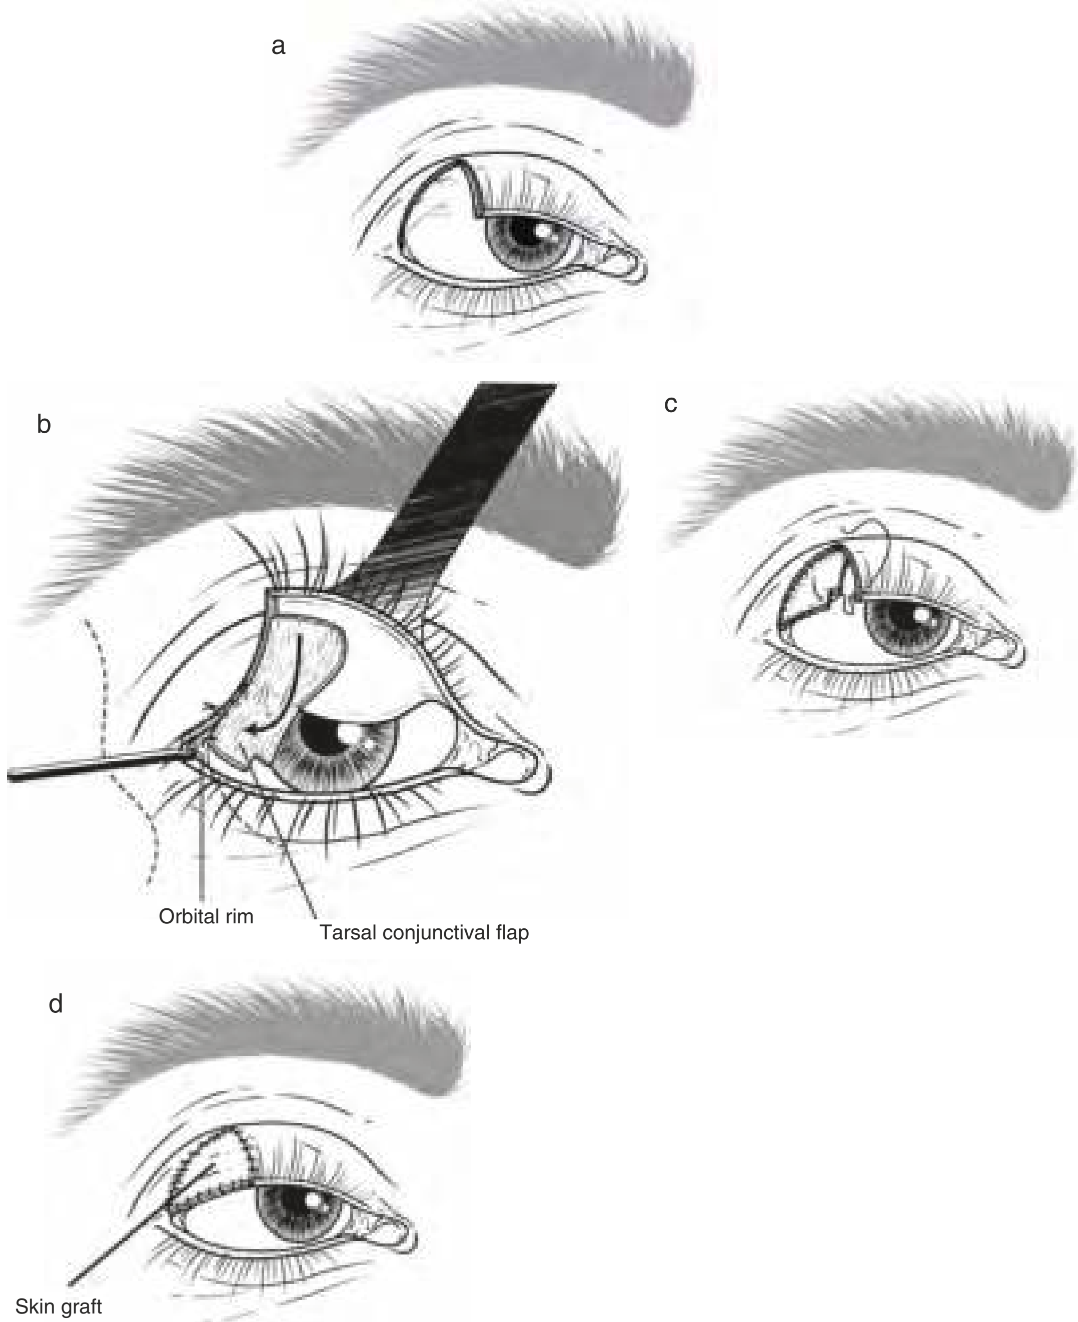

Fig. 86.36 (**a**–**d**) Sliding tarsoconjunctival flap for upper lid defect repair. An upper lid defect (**a**) is repaired with a superiorly based tarsoconjunctival flap raised from the adjacent remaining lid (**b**). The flap is transposed and inset into the defect (**c**), prior to coverage with a skin graft harvested from another eyelid (**d**)

Resection of shape-determining cartilage requires further subdivision. Small helical defects, ideally less than 1.5 cm, can be closed primarily [57]. Primary closure can be facilitated by the extension of the defect into a wedge excision.

For larger defects, the resulting distortion exaggerates the ear's lateral depth and makes it stand out too far from the skull. Defects between 1.5 and 2.5 cm, or roughly one third of the ear's height, can be closed by means of the helical advancement flap first described by Antia and Buch [57–59] (Fig. 86.39). In this repair, the helical sulcus is incised superiorly and inferiorly through the cartilage, but sparing the posterior perichondrium and skin, which then serves as the vascular supply for the flap. A crescent of skin and cartilage can be resected from the scapha anterior to this incision, in order to decrease the size discrepancy between the helix and antihelix and thereby the degree of cupping in the final repair [57].

Fig. 86.37 (**a**–**d**) Cutler-Beard full-thickness lower lid flap to upper lid defect

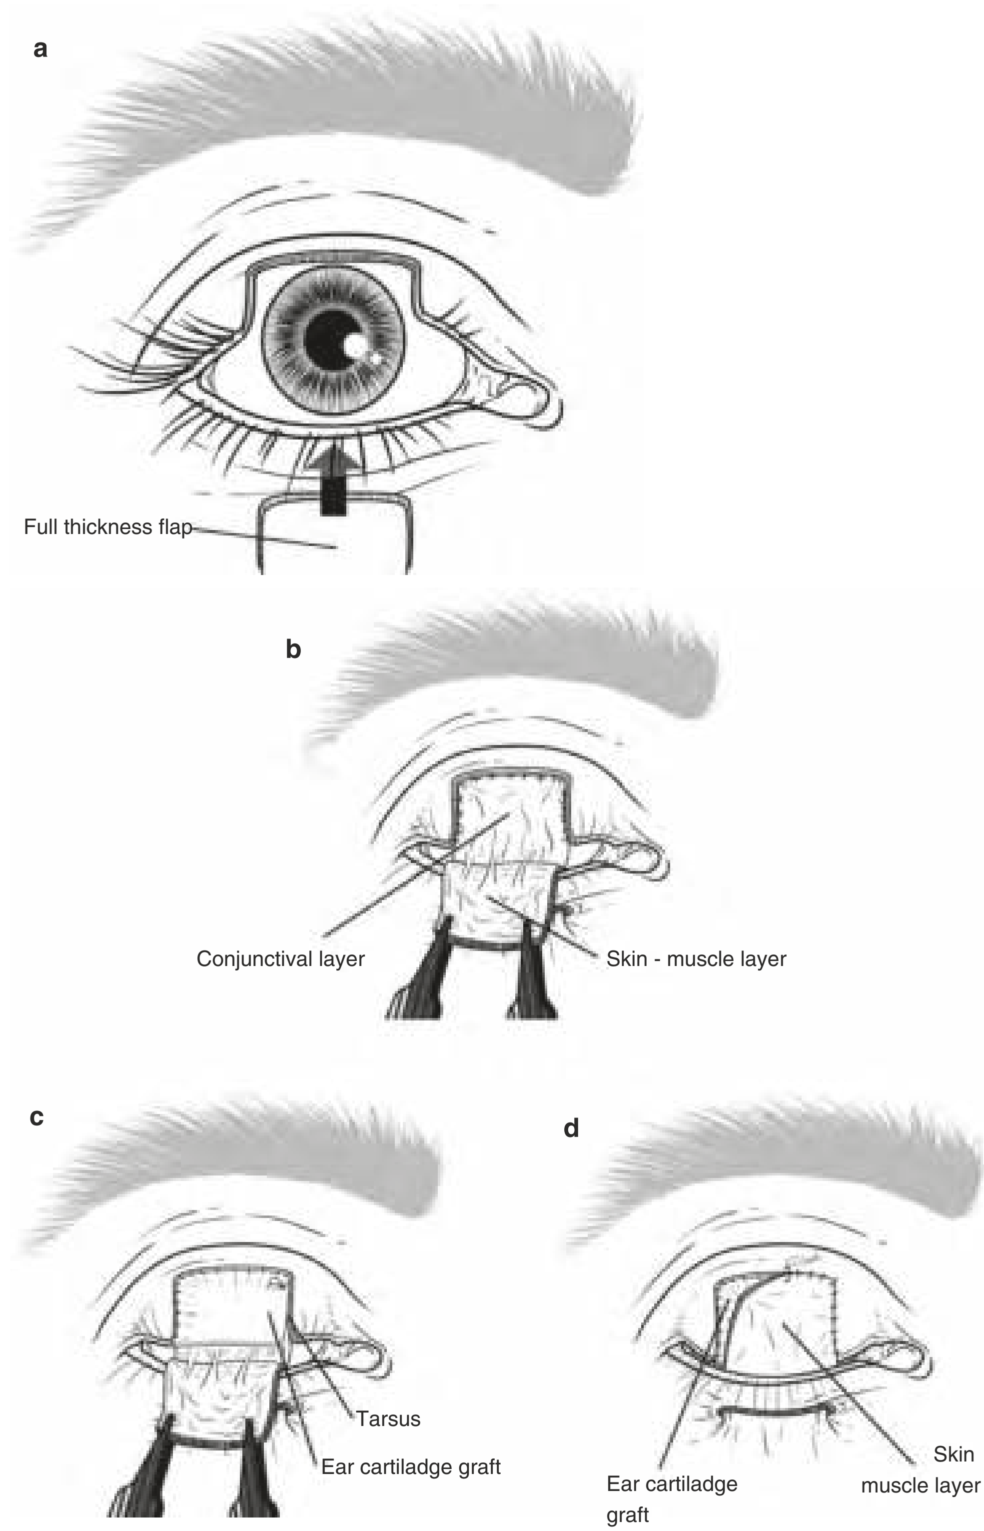

Table 86.5 Options for eyelid reconstruction

Lower eyelid reconstruction
Direct closure (<30–45% defects)
Lateral canthotomy and inferior cantholysis (gains 5 mm)
Tenzel flap (<60% defects)
Tarsoconjunctival graft and musculocutaneous advancement
Hughes flap
Mustarde flap + graft for posterior lamella
Upper eyelid reconstruction
Direct closure
Lateral canthotomy and superior cantholysis
Sliding tarsoconjunctival flap
Cutler-Beard flap (60%–100% defects)

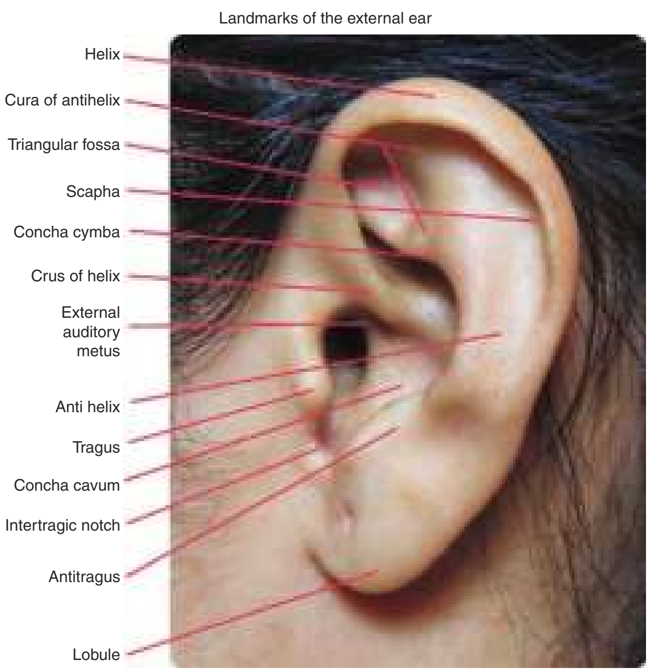

Fig. 86.38 Anatomy of the pinna

Table 86.6 Aims of ear reconstruction

Recreation of natural morphology	
Symmetry with contralateral ear	Height

	Size
Support for spectacles/hearing aids	

Some authors suggest that the Antia-Buch approach is not appropriate for larger marginal defects, since it induces excessive microtia [55]. Others advocate a more aggressive Antia-Buch repair [57], arguing that the microtia will only be noticeable in those exceptional viewing situations when both ears are visible at once. Alternate strategies for a larger defect include adjacent tissue transfer such as a staged tubular pedicled graft [60] or retroauricular flap [61].

For near or complete loss of the external ear, the three options are:

1. No reconstruction.
2. Staged autogenous reconstruction.
3. Prosthetic reconstruction.

A patient wishing to avoid repeated surgery, or a poor surgical candidate, might be best served by the first option. Staged autogenous reconstruction was pioneered by Tanzer [62], who described a six-stage approach. This has since been simplified to a three or two-stage approach by the work of Brent [63] and then Nagata [64]. In summary, a cartilaginous framework is fashioned from costal cartilage, sutured to the remainder of the native ear and reposed beneath the skin as stage one. Stage two refashions the posterior aspect of the ear and establishes the correct angulation away from the skull. Exogenous cartilage substitutes can be used for this approach as well.

Finally, the entire external ear can be reconstructed with a prosthesis attached via adhesive or osseointegrated implants [65–67]. This solution is often best for patients in who the surrounding skin is compromised, for example by radiation or burns [55]. Typically implants require a minimum of 4 mm thickness of temporal bone and connect to the prosthesis via magnets.

86.7.4 Nasal Reconstruction

Nasal reconstruction must be considered with respect to aesthetic subunits (Fig. 86.40). The nine nasal subunits are the dorsum, lateral walls, tip, ala, soft triangles and columella. A detailed discussion of nasal aesthetics is beyond the scope of this text, but we will describe the approaches most pertinent to trauma and oncologic reconstruction. Only the smallest nasal defects can be closed primarily. However, the available regional flap options are versatile and highly cosmetically acceptable. Lateral defects can often be closed with a nasolabial flap, providing a good colour match and hiding the donor scar in the nasolabial fold [68]. Some blunting of the nasofacial angle can occur particularly if not resisted with deep sutures. Larger defects (>2 cm.) cannot be closed with the limited volume of tissue available, and the dorsum and tip are not accessible with this flap [69]. Other options are the bilobed rotation flap for sidewall defects or sliding Rintala flap for dorsal and tip defects.

Larger defects, and those centred near the midline, are generally best repaired with a paramedian forehead flap. This approach was first described by Sushruta in the sixth-century BC [70] and has undergone very little change since.

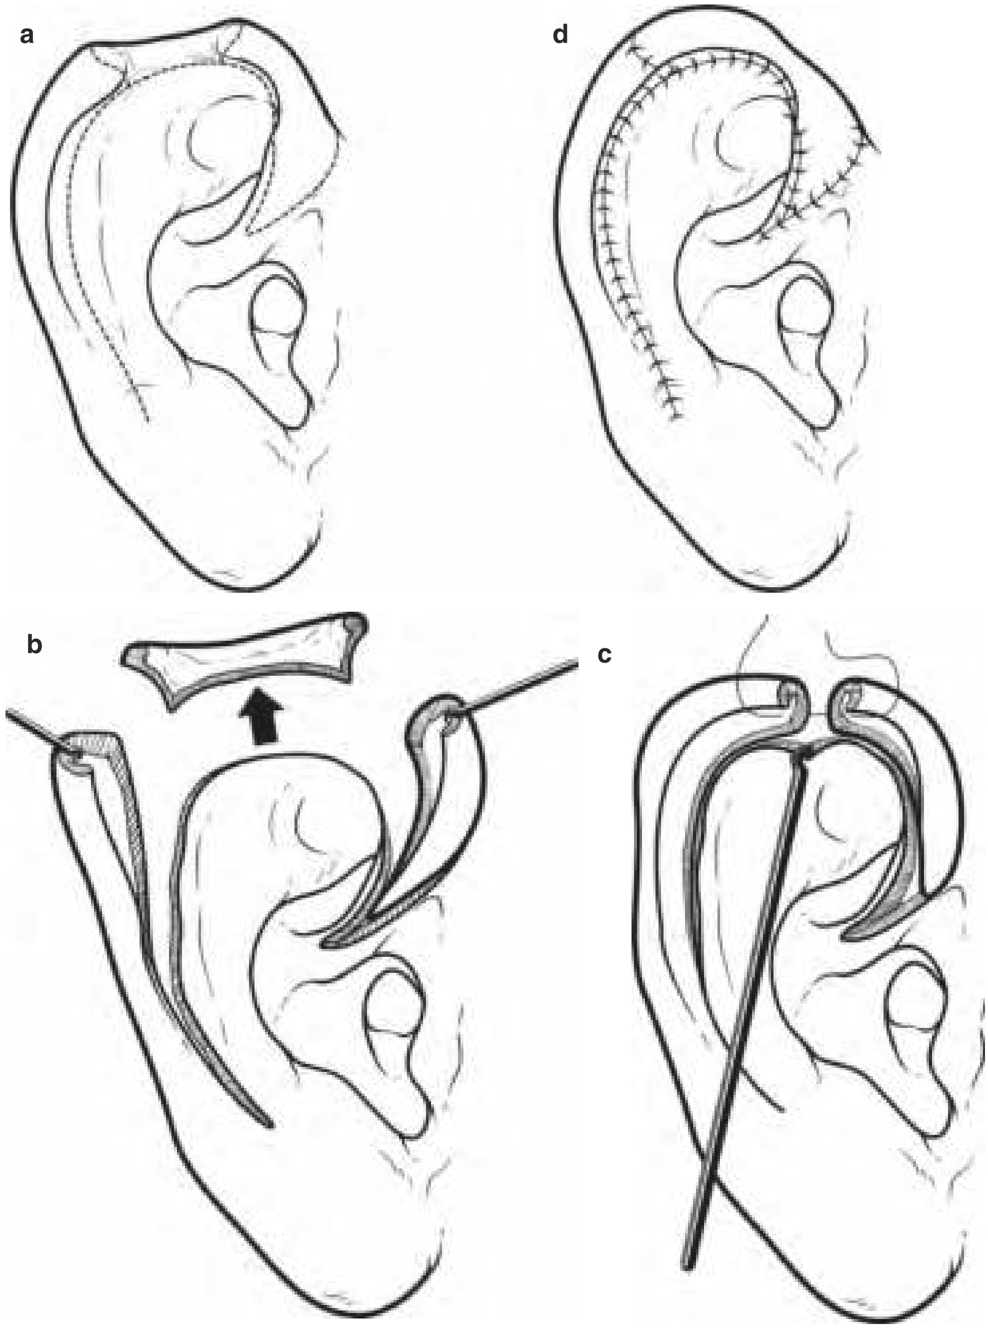

Fig. 86.39 (**a**–**d**) Antia-Buch helical rim advancement flap. A defect of the helix is repaired by advancement of adjacent helix. Full thickness incisions are made along the inside of the helix +/– a partial thickness incision anterior to the root of the helix (dotted lines, (**a**). A crescent or wedge of scaphal cartilage is excised (**b**) to reduce its circumference and permit approximation of the remaining helix (**c**). Finally, excess skin overlying the scaphal cartilage can be trimmed and the incisions closed (**d**)

The flap provides skin of similar character and sufficient size to replace an entire nasal subunit and also a portion of nasal vestibule for alar defects, potentially improving aesthetic outcome [68, 69]. The first stage involves rotation of a paramedian skin paddle about a narrow pedicle based on the supratrochlear vessels. The flap is generally based on the contralateral vessels, as this produces less torsion of the vessels. The dissection is carried out in the subcutaneous plane at the distal aspect, to provide pliable skin for the repair, but transfers to the subgaleal and ultimately subperiosteal planes as it proceeds proximally towards the pedicle. The paddle is sutured in place, with stents for the nares if necessary. The second stage is carried out approximately 3 weeks after the first, in order to provide for neovascularization. At this stage, the pedicle is divided and the superior edge of the flap inset. A third stage can be carried out to debulk the flap and is often required for ideal aesthetic outcome [69]. In patients with vascular disease, a greater proportion of the flap can be carried out in the subgaleal plane, and a debulking stage performed before division and inset, in order to decrease the chance of flap necrosis [70]. Reconstruction of alar nasal mucosa in full-thickness defects can be achieved with a

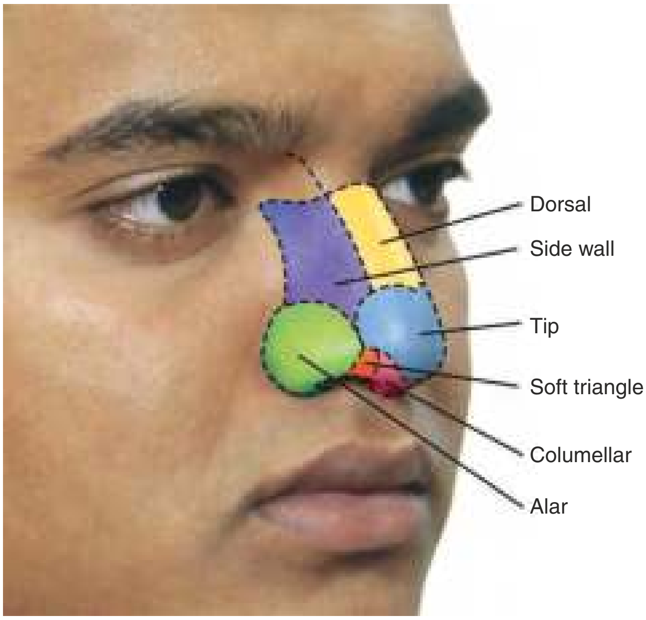

Fig. 86.40 Aesthetic subunits of the nose

hinged nasal septum mucoperichondrial flap. Alar rim defects can also benefit from reconstruction with composite grafts harvested from the lobule or helical rim of the pinna.

Defects involving significant bony or cartilaginous destruction require repair with similar tissue. Small cartilaginous defects can be reconstructed with nasal septal cartilage [68], but only a limited volume can be harvested without impairing septal integrity and tip support. Grafts may also be taken from the ear or rib; the first confers less morbidity and has a favourable contour for alar reconstruction, while the second provides a larger volume of cartilage stock [55]. Many potential donor sites are available for bony defects, including calvarium, mandible, iliac crest and long bones (tibia or radius). The dorsal contour is the most important to reconstruct; this can be accomplished with an osseous strut graft [69].

In total or subtotal nasal defects, reconstruction of the internal and external soft tissue and hard tissue requires consideration. Most commonly a radial forearm free flap is employed and can be harvested with a portion of radial bone for use as a dorsal strut [71]. The best cosmetic outcome is generally achieved with this flap when combined with paramedian forehead flap to reconstruct the external skin. Finally, nasal prostheses require less surgery and can provide an excellent match in appearance to the premorbid nose. They can be retained with adhesive, spectacles or osseointegrated implants. Their chief disadvantage is cost, as they must be replaced every 1 to 2 years [68].

86.7.5 Reconstruction of the Extraoral Cheek

The greater laxity and simpler architecture of the skin of the cheek allows primary closure of most defects, usually by conversion to an ellipse. However, even moderate tension can result in a wide scar or distort adjacent aesthetic units, and ectropion of the lower eyelid is a particular concern here. If primary closure can be achieved to lie along the nasolabial or preauricular creases, this can give an excellent cosmetic outcome. For larger defects, these natural lines can be utilized with cervicofacial rotation flap reconstruction.

87 Distraction Osteogenesis of the Maxillofacial Region

R. S. Neelakandan

87.1 Introduction

Reconstruction of the facial skeleton is a technique sensitive process for the reconstructive surgeon as the resulting outcome should improve the form and function of the patient. Distraction osteogenesis (DO) can be defined as the biologic process consisting of new bone formation between the bone segment surfaces that are gradually separated by incremental applied traction. It is a technique to which precludes donor site morbidity which is commonly performed to correct long bone deformities but gaining popularity in the maxillofacial reconstructive procedures in the recent times. The recent advancement of DO procedure is the transport distraction osteogenesis (TDO) which involves osteogenesis and histogenesis from the residual host tissues.

Following gradual movement of the transport segment, new bone regenerate formation occurs behind it filling the defect.

Ilizarov and his colleague's classified bone transport techniques as:
Monofocal.
Bifocal.
Trifocal.

The bifocal and trifocal techniques play a major role in regenerating new bone across the continuity defects. TDO involves creating a new bone and soft tissue to cover the defect by moving a segment of bone and new soft tissue formation behind it until the segment docks the receiving host bone. TDO can be achieved by movement of bone segments across the defect (Fig. 87.1a, b, and c).

TDO is of three types:
Bifocal.
Trifocal.
Quadrifocal.

Bifocal distraction is the incremental movement of one viable bone segment, trifocal distraction is the incremental movement of two viable bone segments and quadrifocal distraction is the incremental movement of three viable bone segments.

87.2 History of DO

Distraction osteogenesis (DO), a well-established technique used for several decades by orthopedic surgeons to repair long bone defects has over the past 15 years gained acceptance for correction of various craniofacial deformities. Bone distraction is not a new concept. Distraction was introduced first by Codvilla nearly a 100 years ago and was subsequently popularized during the 1940s by Ilizarov, who developed a single-stage procedure to lengthen long bones without the use of grafting material. The feasibility of applying Ilizarov's principles to different craniofacial deformities was not considered until several decades after his pioneering work in the peripheral skeleton. In the purest sense, the first reports of craniofacial DO were in the early 1960s, when rapid expansion of the palate was carried out in growing patients. This practice, however, involved distraction of a naturally occurring physis. Finally, in 1973, Snyder first described the Ilizarov technique to lengthen a surgical osteotomy of the

canine mandible. Interest in craniofacial distraction at first grew slowly, with sporadic experimental reports appearing over the ensuing two decades. However, in the early 1990s, experimental investigation intensified following reports from New York University on lengthening of dog mandibles and from Constantino and Friedman et al., who used DO to successfully close canine segmental lower jaw defects. Thereafter, several studies on various animal models demonstrated the application of osteodistraction at a number of different sites, including the mandible, midface, and cranial vault. It was Michieli and Miotti who first suggested the protocol for mandibular distraction in humans which included a latency period of 1 week after osteotomy followed by activation rate of 1 mm on alternate days and a minimum of 45 days consolidation period of every 15 mm distraction. In 1992, the first clinical results of craniofacial DO were reported by McCarthy et al. in a small series of patients with congenital mandible deformities. Since then, several larger series with longer follow-up periods have appeared. More recently, the technique has been successfully used for midfacial and upper craniofacial skeletal defects (Table 87.1) [1].

87.3 Biology of Transport Distraction

The adaptive function of bone to mechanical stimuli causing resorption of existing bone and formation of new bone is the continuous remodeling process of the bone tissue and was recognized as the Wolff's law. The principle behind DO is the application of defined mechanical strains to the reparative callus that is formed in the osteotomy gap. It is based on the law of tension stress by which states that gradual traction on living tissues creates stresses that can stimulate and maintain regeneration and active growth of these tissues.

Table 87.1 The history of DO is long and various researchers has contributed to its development, as summarized below

1728	Fauchard	Arch Expansion for accommodation of crowd teeth
1828	Wescott	Palatal arch expansion device
1893	Angel and Goddard	Modified Wescott's device
1905	Codivilla	Femur distraction
1927	Rosenthal	Intraoral tooth borne osteodistraction device for mandible
1937	Kazangian	Over the face appliance and distracted mandible using elastic traction
1948	Crawford	Demonstrated distraction force on a fracture callus
1959	Kole	Used traction to correct anterior open bite
Mid-twentieth century	Ilizarov	Long bone distraction
1973	Synder et al.	Distraction of membranous bone of facial skeleton
1976	Michieli and Miotti	Developed mandibular distraction. First suggested operative protocol for human mandibular distraction protocol
1989, 1992	McCarthy et al.	Used miniature orthopedic device for small bone lengthening. Reported first clinical case of mandibular DO in humans
1990	Constantino et al.	Reported the first bifocal distraction (TDO) of the mandible by using an external custom made distraction device
1997	Fedotov	Designed a semi-circular external distractor, very similar to the present day external distractors. Designed monofocal, bifocal, and trifocal distraction based on the size of the defect to be reconstructed
1987	Wolfson	Designed the first intra oral distractor—Considered as a landmark in TDO But was never used in patients

The sequence of DO is, osteotomy first, followed by latency period, which is the duration from bone division to the onset of traction. The third phase is the distraction phase which is the time when gradual traction is applied and distraction regenerate is formed, followed by the consolidation period which allows maturation and corticalization of the regenerate after traction forces are discontinued. The last stage is the remodeling phase where there is completion of the regenerated bone remodeling [1] (Fig. 87.2a, b).

Sequence of DO

Osteotomy.
Latency period.
Distraction phase.
Consolidation period.
Remodeling phase.

The entire healing process of TDO is similar to that of a fracture healing process. The osteotomy causes discontinuity of the skeletal segment which triggers an evolutionary process of bone repair. It involves recruitment of osteoprogenitor cells, followed by cellular modulation or osteoinduction, and establishment of an environmental template or osteoconduction resulting in a reparative callus. The latency period is the period from bone division to the onset of traction. It represents the time allowed for reparative callus formation. On the fifth day after osteotomy, a mini-cellular network of growing capillary loops is formed in the medullary canal of both proximal and distal segments in the areas adjacent to the fracture line. This is a stage represented by soft callus where granulation tissue is converted to fibrous tissue by fibroblasts starting in the periphery.

During distraction phase traction force is applied to the bone segments and is slowly pulled apart, resulting in formation of new bony tissues which progressively increases the intersegmental gap. The cartilaginous callus is replaced by new bone formation due to various cellular activities, and this stage of hard callus remains for approximately 3–4 months. However, the normal fracture healing process is interrupted by the application of gradual traction to the soft callus. As distraction begins, the fibrous tissue of the soft callus becomes longitudinally oriented along the axis of distraction. In the second week of distraction, primary trabeculae

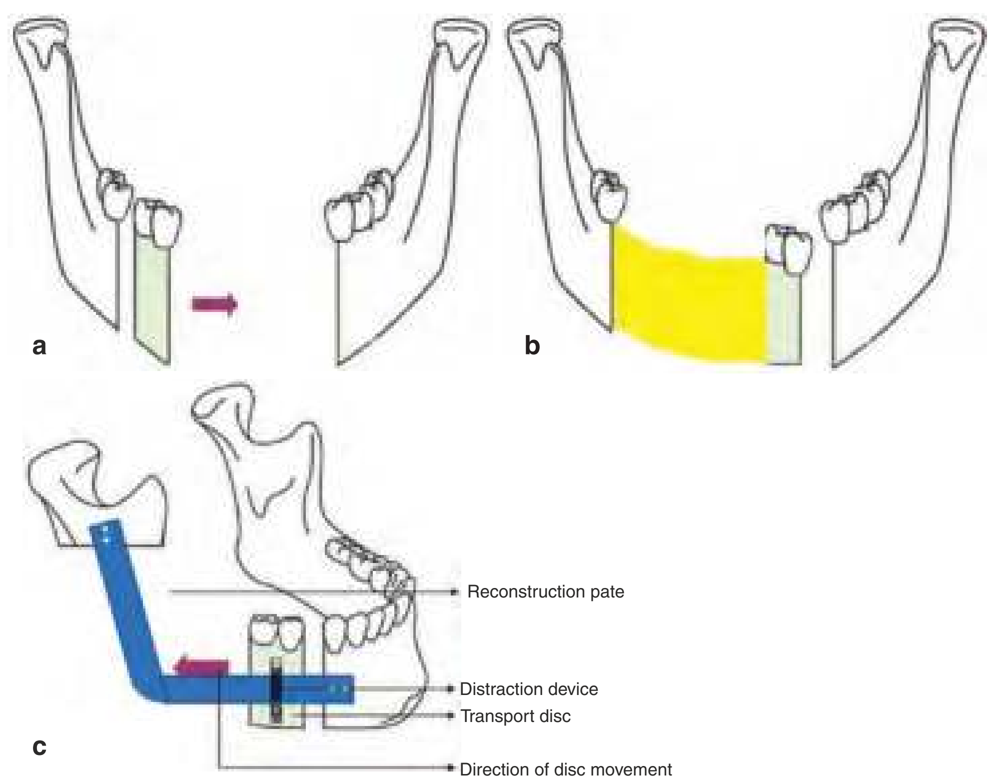

Fig. 87.2 (**a**, **b**) Traction force applied to the bone segments, slowly pulling them apart, resulting in formation of new bone. (**c**) Line diagram depicting process of TDO in a mandible requiring reconstruction for a segmental defect

begin to form and the osteoid begins to mineralize. In TDO both membranous and endochondral processes play an important role in the process of new bone formation.

The consolidation period is defined as the time between cessation of traction forces to the removal of distraction device. It represents the time required for complete mineralization of the distraction regenerate. The remodeling period is the period from the application of full functional loading to the complete remodeling of the newly formed bone. The distraction regenerate is remodeled to mature bone during remodeling at a later stage.

87.4 Biology of Bone Transport

Biologically, bone transport techniques are based on two distinct processes, *distraction osteogenesis* and *transformational osteogenesis*. DO as previously described, is a biologic process of new bone formation between the surfaces of bone segments that are gradually separated by incremental traction. Transformational osteogenesis is a mechanically induced biologic process of pathologic bony tissue transformation into normal bone. Importantly, these two processes occur simultaneously during bifocal bone transport. Distraction osteogenesis occurs between the surfaces of the residual host bone segment and the trailing edge of the transport disc, while transformational osteogenesis occurs between the leading edge of the transport disc and the residual target bone segment (Figs. 87.3 and 87.4a, b).

In TDO the transport segments undergo stress due to compressive forces as well as distraction force. For instance, in bifocal transport, the leading edge realizes compression force, while the trailing edge realizes distraction force, and with trifocal transport, the leading edge of both segments realizes one common compressive force, and the trailing edge realizes two distraction forces one on either side.

87.5 Device Design

The concept of TDO has been increasingly applied to the craniofacial skeleton in the recent years. Initially used in experimental animal models, then gradually it gained popularity in the clinical setup. After encountering failures with avascularized and vascularized grafts in our patients with mandibular continuity defects, this modality of reconstruction was contemplated in our clinical practice. After treating 22 cases with earlier generation distraction devices, there were certain biological and mechanical problems resulting due to lack of vector control and inadequate tension stress effect. For these reasons various modifications were made in the initial design with an aim to improve the vector control and stability of the device.

> The transport distraction device may be divided into three components:
> - The reconstruction plate for stability.
> - The distractor component for mobilizing the transport segment on activation.
> - The screws for anchorage.

A proper surgical plan and device design should be followed in each case to achieve the desired results. Few factors that are to be considered are the cross-sectional dimension of the transport disc and the length of the defect along with number of teeth in the disc which can be used for prosthetic rehabilitation as well as to monitor the movement of transport disc during the distraction. It is essential to decide if the condyle should be retained or disarticulated to incorporate the condylar component in the device. It is advisable to retain the condyle when possible so as to maintain the natural joint architecture (Table 87.2 and Figs. 87.5, 87.6, 87.7, 87.8, 87.9 and 87.10).

87.6 Biomechanical and Vector Consideration in Mandible and Selection of Device

The success of distraction osteogenesis is based on biological and biomechanical factors. The biological factors are the length and geometric shape of the defect (straight unilateral posterior/curved across midline), cross-sectional area, and

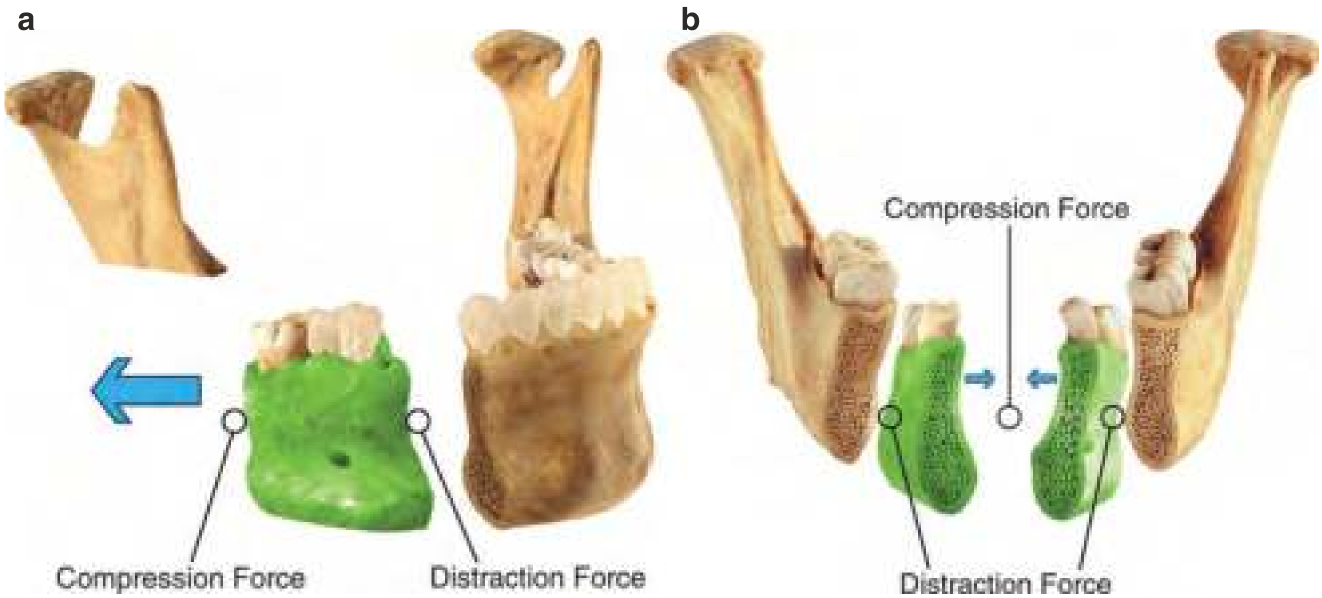

Fig. 87.4 (**a**, **b**) Stress realized by transport segment in bifocal and trifocal distraction

Table 87.2 Generations of transport distraction devices, its merits, and demerits

DO device	Design	Merits	Demerits
1st generation extraoral device (Fig. 87.5a, b, c, d, e)	A single guidance rod with a single anchorage fixator on either side of the cut ends of residual host bone without a reconstruction plate to stabilize the cut ends of the mandible		Unstable residual host bone with inadequate control of the transport segment producing sagittal deviations Pin tract scarring
2nd generation (Fig. 87.6a, b, c)	Reinforced with an additional guidance rod, and the device is anchored to the residual host bone of either side with double anchorage fixators The cut ends of the bone are stabilized with a reconstruction plate	Better control of the transport disc and improved anchorage Reduced incidence of sagittal deviation	
3rd generation cantilever distractor (Fig. 87.7a, b)	Used when there is no proximal bone available for fixing the anchorage fixator All the anchorage fixators are anchored to the available bone, proximal to the transport segment	Used when there is no proximal bone available	
4th generation internal distractor (Fig. 87.8a, b, c)	A straight device- and plate-guided internal distractor with 1 mm calibrated guidance rod with a transport device, attached directly to the reconstruction plate	Better vector control owing Better patient compliance No pin tract scar	Can be used only for straight regeneration
5th generation (Fig. 87.9a, b, c)	An arched device consisting of a reconstruction plate bent according to the contours of the defect and is tissue buried to which a 1 mm calibrated arched guidance rod is attached with a connecting vertical arm	Completely placed intraorally Can be used to regenerate bone across the midline for central defects	
6th generation push ball device (Fig. 87.10a, b)	Push ball device consists of a C-shaped cross-sectional hollow guidance rod with the transport device transfixed to the underlying transport segment that is moved through a series of metal balls within the guidance rod activated through a portal at the free end of the rod	It can be used for both straight and curved defect	Over-riding and clogging of the metal balls can happen

density of the transport disc and tension of the soft tissue envelope. The biomechanical factors are dependent on the length and geometric shape of the defect that dictates the selection of straight or curved device.

Every vector is a one-dimensional entity, whereas the desired movements are in most cases two- or three-dimensional. The base of the mandible is constituted by five linear vectors (Fig. 87.11). Two A-P linear vector running

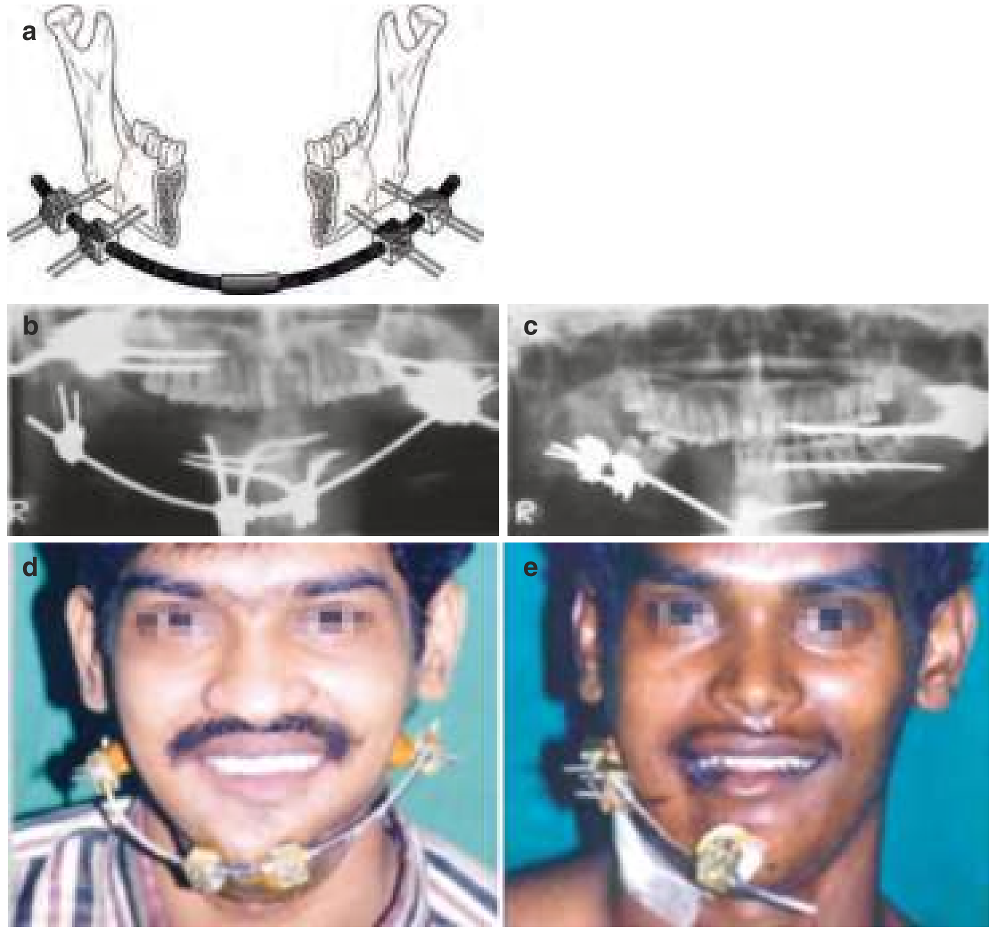

Fig. 87.5 (**a**) first generation extraoral device. (**b**, **c**) Panoramic radiographs showing the placed first generation distractor device. (**d**, **e**) Clinical pictures with the first generation device

parallel to the base of the mandible one on either side in the body region, two A-P linear vector running parallel to the base of the mandible in the parasymphysis region, and one horizontal linear vector running again parallel to the base of the mandible in the mid symphysial region. If the defect is along a single vector, it is best reconstructed with straight regeneration, and if the defect is along more than single vector, it is best reconstructed with arched regeneration.

With the advent of various generations of devices for distraction osteogenesis, it is the author's contention that the straight tissue buried distraction device is preferred for unilateral defects, whereas, for bilateral defects crossing the midline, extraoral transcutaneous pin fixation device, either bifocal or trifocal is preferred, as it provides better vector control.

87.7 Classification of Mandibular Defects in TDO

Mandibular defects for reconstruction purpose are classified as central and lateral defects. Central defects can be either symmetrical or asymmetrical, and lateral defects can be either straight, when the defect is posterior to the second premolar and arched when the defect is from anterior to second premolar (Fig. 87.12a, b).

For reconstruction of central defects, when there is a symmetrical central defect, arched regeneration could be contemplated trifocally with identical transport segment from either side and when there is an asymmetrical central defect arched regeneration could be contemplated quadrifocally with nonidentical transport segments (Fig. 87.13).

Fig. 87.6 (**a**) second generation transport distraction device. (**b**) Panoramic radiograph showing placement of second generation device with a reconstruction plate. (**c**) Clinical picture showing second generation device

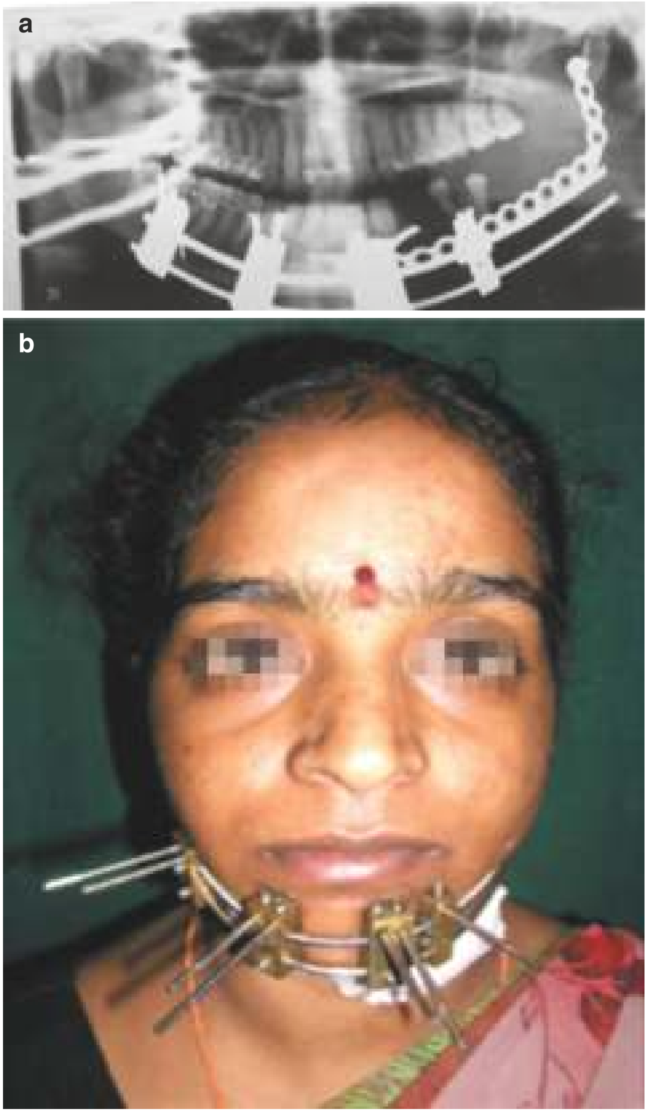

Fig. 87.7 (**a**) Frontal profile view of patient with placement of third generation distractor device. (**b**) Panoramic radiograph showing the presence of third generation distractor device

When it comes to reconstruction of lateral defects, a single-vector defect posterior to the second premolar could be regenerated bifocally, and a two-vector defect anterior to canine could be regenerated either bifocally or trifocally depending upon the availability of horizontal ramus to create transport disc (Fig. 87.14a, b).

The choice of the transport distraction device is dependent upon the site of defect. For defects posterior to second premolar, a straight bar device with or without condylar prosthesis could be used and for defects anterior to first premolar an arched bar device across the midline could be used. However, a curvilinear push ball device could be used for both the types of defects.

87.8 Indications of TDO

Transport regeneration is indicated when there is a continuity defect of mandible due to any cause. It is indicated not only as a primary modality of reconstruction following tumor ablative surgery or bone loss due to trauma but also as a secondary modality of reconstruction whenever there is failure with previous reconstruction. It can also be carried out on pediatric patients and even on irradiated patients.

However, it has a limitation when there are no horizontal rami available on either side to create transport segment. Even in such situation, bone grafting and subsequent transportation can be contemplated.

87.9 Presurgical Investigations

When it comes to investigations, panoramic radiograph and CT will help us to know the exact extension of the lesion and thereby to assume the type of defect we are dealing with. This helps in selection of device.

Stereolithographic 3D models help us in contouring the device exactly along the defect presurgically. This helps in minimizing the working time on the table (Fig. 87.15a, b, c, d).

87.10 Surgical Procedure

Transport distraction involves creating a transport disc in the residual host bone stump, adjacent to a discontinuity defect or a resection site. The transport disk is then advanced 1.0 mm per day to span the discontinuity defect. As this transport disc advances toward the target host bone segment, callus forms at its trailing edge, which gradually matures and calcifies. Once the transport disc reaches the docking site, the segment is held in neutral fixation until a cortical outline is seen in the regenerate. At the time of distractor removal, a small bone graft may need to be positioned between the transport disc and the docking site because the transport disc becomes rounded and encased with a fibrocartilaginous cap on the advancing front. Osseous union between the disc and docking site necessitates removal of this intervening fibrocartilaginous cap.

87.11 Biological Consideration While Designing Transport Disc

Periosteal preservation is the single most important biologic consideration while designing bone transport, for the transport segment solely depends on periosteal blood supply for its viability. Hence extreme care at every stage—right from making a small incision to minimal periosteal reflection to abundant irrigation and water tight mucosal closure over the transport segment—should be ensured.

While designing the transport segment, parallelism of the cut edges of the residual host bone segment, transport segment, and target bone segment should be ensured to achieve even docking of the transport disc to the cut edges of residual target bone segment. This is carried out by taking the vertical osteotomy cut perpendicular to an imaginary baseline that runs between gonion and menton and parallel to maxillary occlusal plane (Fig. 87.16a–e) followed by implant rehabilitation (Figs. 87.17 and 87.18).

87.12 Vascular, Clinical, Radiological, and Histological Features of the Regenerated Bone

The process of TDO induces tensile stretching of the osteoblast-like cells that alters the local regulation of bone formation and increases the expression of the growth factors. This entire process is vascular-dependent and requires the maintenance of an adequate blood supply. DeCoster et al. in their animal experimental model on transport distraction osteogenesis used injection angiography to study the arterial response of the bone undergoing transport distraction. The angiographic techniques revealed that the transport segment had an intact arterial supply after the osteotomy cut was completed (adhering to surgical principles of TDO) and, also, after transport distraction was activated. They also showed an extensive increase in vessels in distracted limbs of the experimental animals with proximal stretching and distal kinking of the major artery in that limb. Such studies involving major facial vessels during TDO are awaited to be added to maxillofacial literature [2]. Formation of callus can be detected earliest with ultrasonography where it appears as a mixed to hyper echoic area depending upon the degree of maturation. The color Doppler study of the callus demonstrates the quantum of vascularity in the regenerate before maturation [1, 2] (Fig. 87.19).

For radiological examination (Figs. 87.20 and 87.21) regular plain film radiographs remain the mainstay for screening the TDO during active distraction and consolidation period. Panoramic radiograph, submento-vertex view, lateral oblique mandibular projections, and posteroanterior and lateral skull views may all aid in planning and screening the

TDO. These radiographs have their limitation of 2D view of the mutivectorial 3D procedure.

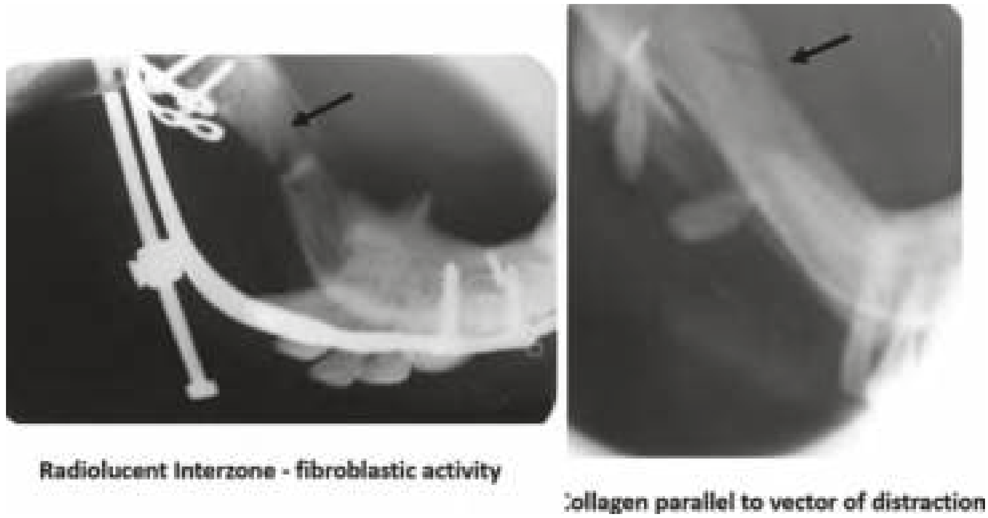
Multi-slice-computed tomographic scans provide a better preview but have the limitation of excessive radiation exposure and scatter due to the distraction device when it is in situ. Elsalanty et al. have extensively experimented on cone-beam CT densitometry and three-dimensional histomorphometry in mandibular bone defects reconstructed with bone transport and found that the physical dimensions and architectural parameters of the new bone regenerated remain comparable to the contralateral normal bone in TDO [3]. In their study, the radiographic density comparison was done

Fig. 87.19 Ultrasound appearance of regenerate

by studying the radiographic attenuation of the regenerate measuring in Hounsfield units (HU) and comparing it to the outer, inner, and inferior cortices of the bone on opposite side of the mandible (normal bone). Their results showed that the density of the distraction regenerate was comparable to the inner and outer cortices of the control bone, whereas the lower border of the control side of the mandible showed higher density than the regenerate at 1 month of consolidation. The Hounsfield unit value of the regenerate by TDO was toward the 2000 mark (2000 HU) after a month of consolidation. Microcomputed tomography-based three-dimensional histomorphometry used to assess percentage of bone volume, bone mineral density, degree of anisotropy, trabecular thickness, trabecular number, trabecular pattern factor, and trabecular separation showed no significant differences between the regenerate and the normal bone after a month of consolidation in all parameters except percent bone volume and the trabecular separation. Percentage bone volume is reported to be significantly less, while trabecular separation is significantly higher in the regenerate (Fig. 87.22a, b).

Garcia et al. studied the histology of the regenerate and docking site in bone transport in the tibial-diaphyseal defect of adult sheep model and concluded that there is a marked difference between the ossification of the docking site and of the regenerate. Intramembranous ossification plays a major role in the regenerate, with bone forming from the host bone segment to the target segment. The ossification of the docking site shows endochondral and intramembranous ossification simultaneously, but the intramembranous ossification is limited to rare and small foci [4].

Fig. 87.20 Radiological appearance of regenerate during active distraction



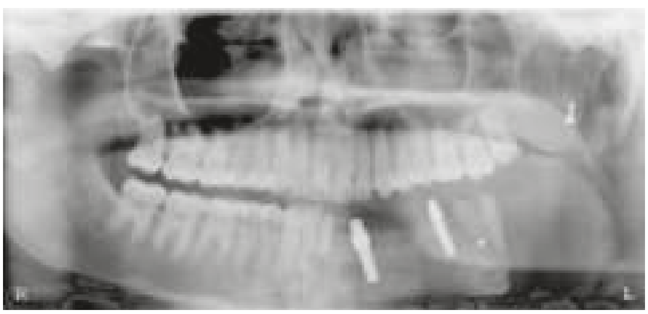


Fig. 87.21 Osseointegrated dental implants in the regenerated bone

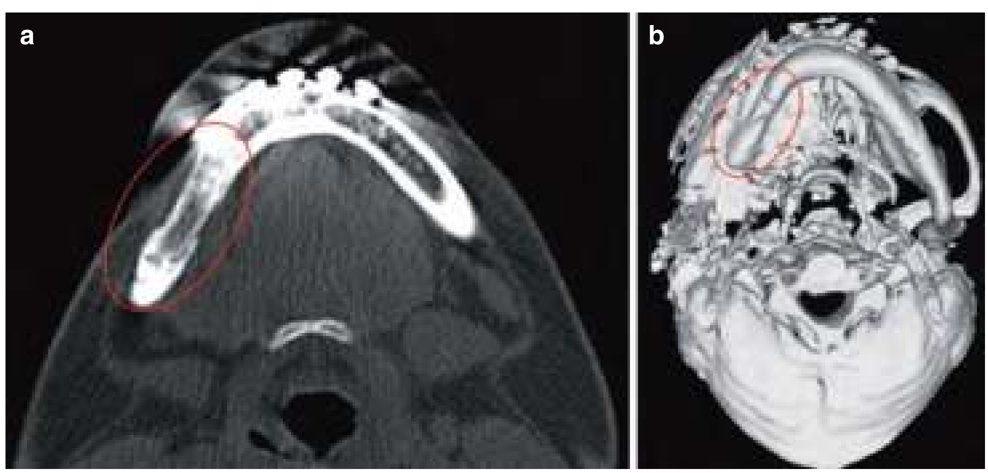
Fig. 87.22 (**a**, **b**) CT appearance of regenerate



Studies done on the architecture and microstructure of cortical bone regenerated with TDO, it has been found that at 12 weeks of consolidation, bone created during bone transport distraction osteogenesis was comparable to native bone in microstructure, architecture, and mechanical properties, and when appropriate time has lapsed, the properties of the regenerate bone were identical to the host bone.

Çakır-Özkan et al. in their study on immunohistochemical analysis of reconstructed sheep mandibles by transport distraction osteogenesis reported strong positive staining for BMP-2, -4, and TGF-β in the cells, and matrix components. These growth factors are believed to enhance the osteogenesis in TDO [5].

87.13 Transport Distraction Osteogenesis in Maxilla

Ever since the concept of transport distraction on long bone was initiated by Ilizarov and then after it was subsequently introduced on the facial skeleton by Constantino, Fodotov, Wolford, and many others, a lot of articles got published in the world literature affirming the possibility of regenerating quality bone for any length of mandibular defects [6]. It has even become a gold standard in comparison to other modalities of reconstruction. So, the question arises whether transport distraction has a role in maxillary reconstruction. [7, 8]

Cheung et al. were the first to publish their work on reconstruction of a maxillectomy defect using transport DO in animal experimental model [9]. Our contention is that when transport distraction has become an accepted norm in the reconstruction of mandibular continuity defects, maxilla with its multiple vascular perfusion, rich periosteal supply, and increased cancellous bone is expected to biologically respond even better to the distraction force [10].

Here are a few cases showing our evolution in transport distraction osteogenesis for reconstruction of maxillary defects.

In our maiden clinical attempt at reconstructing a maxillary defect using TDO a straight distraction device was used. The limitation we had with straight bar device was that they were all buccally directed and not conforming to the posterior maxillary arch (Fig. 87.23a, b, c, d, e, f). Subsequently we have successfully employed bifocal transport distraction (Fig. 87.24a, b, c, d, e, f, g, h, i) and trifocal transport distraction (Fig. 87.25a, b, c, d, e, f, g, h) for reconstruction of maxillary defects. Maxillary TDO has also been successful to treat alveolar clefts of maxilla (Fig. 87.26a, b, c, d, e, f, g).

87.14 Advantages of TDO

Though bone transport may not be possible in all situations, when indicated, it has an edge over other modalities for it doesn't require any specialized hands or equipment, it doesn't prolong the duration of surgery and hence is cost-effective. Since no bone grafting is required, there is no donor site morbidity, and there is recreation of alveolar ridge with attached mucosa, buccal, and lingual sulci, all in near normal anatomy. TDO not only regenerates new bone but also every element of soft tissue around it as well. These are summarized in Table 87.2.

87.15 Complications of Bone Transport

The complications with bone transport in regenerating new bone formation can be discussed under biological and mechanical factors.

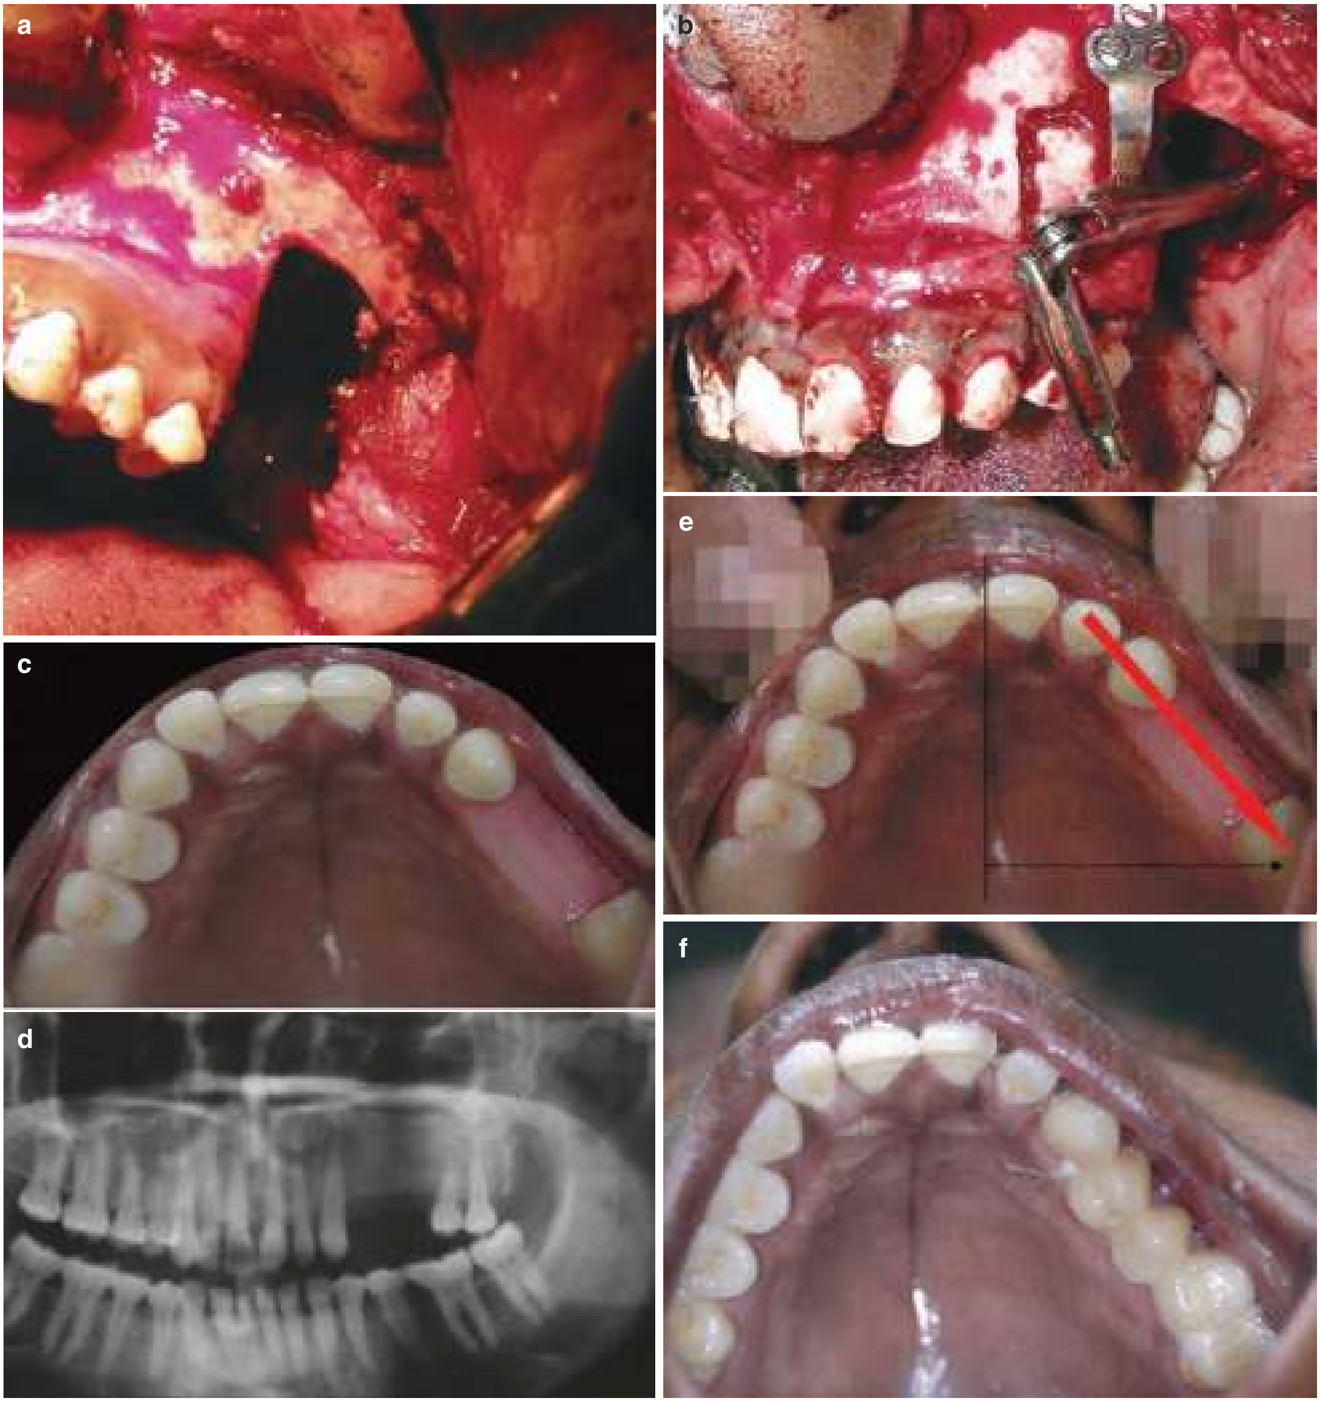


Fig. 87.23 (**a**) Straight transport distraction device post-resection defect. (**b**) Transport disc with device. (**c**, **d**) Evidence of histogenesis and osteogenesis in the clinical picture and OPG respectively, after consolidation phase. (**e**) Buccal deviation of the regenerate. (**e**) Transport distraction in progress across midline. (**f**, **g**) Transport disc on docking and consolidation. (**h**, **i**) Post-consolidation and rehabilitation with complete denture

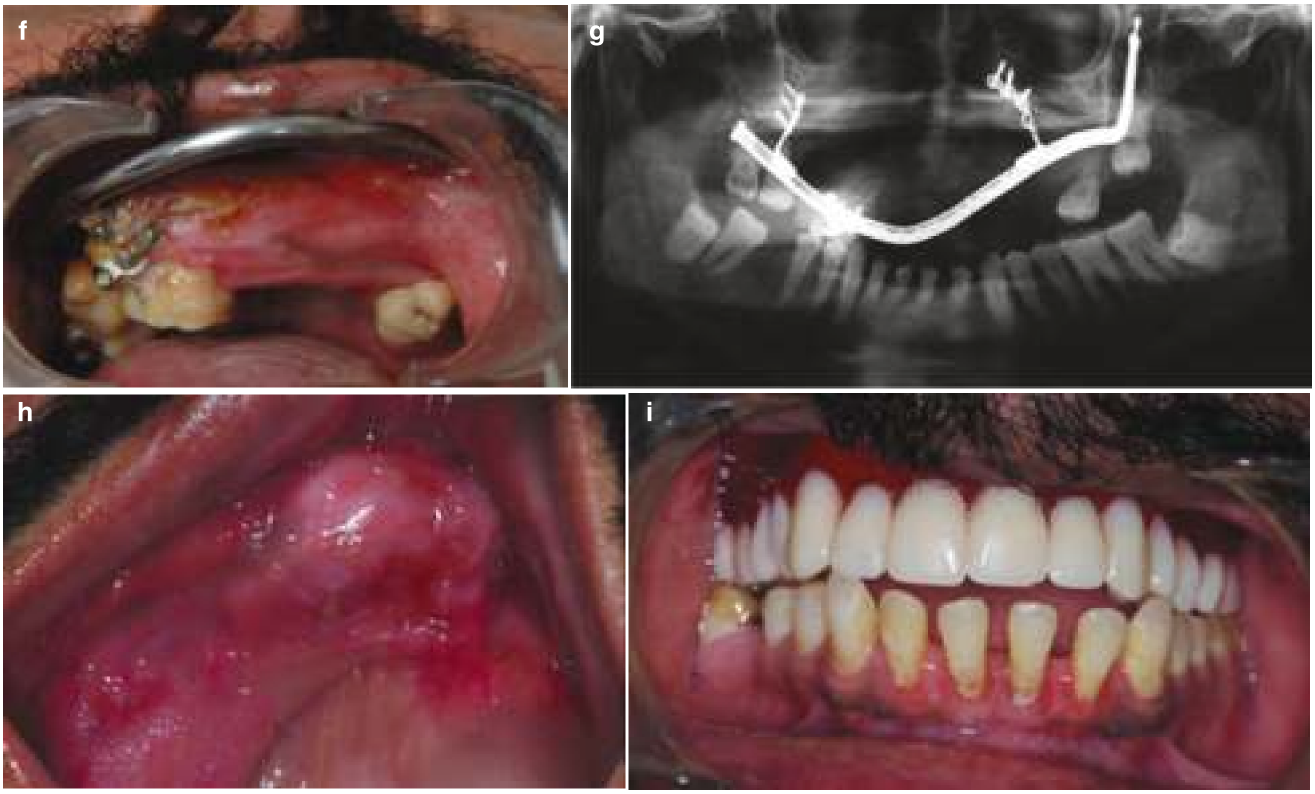

Fig. 87.24 (continued)

The biological factors are the ones which we have very little control over, whereas the mechanical factors of vector control and bodily movement of transport segment across the midline can be successfully carried out by modifying the device (Table 87.3) [11, 12].

87.15.1 Hypertrophic Regenerate

This occurs when a single transport segment is designed to regenerate a lengthy defect, when the collagen fibers are overstretched with the central portion of the callus narrowing representing an hourglass appearance in the radiograph (Fig. 87.27). This phenomenon can also occur when the cross-sectional thickness of the transport segment is not adequate to recreate good volume of bone.

87.15.2 Drifting of Teeth

The teeth in the transport segment and RHBS tend to drift as distraction proceeds due to pull of transseptal fibers across the line of osteotomy. This problem could be overcome by applying a figure of eight wire to stabilize the teeth in each segment (Fig. 87.28a, b, c).

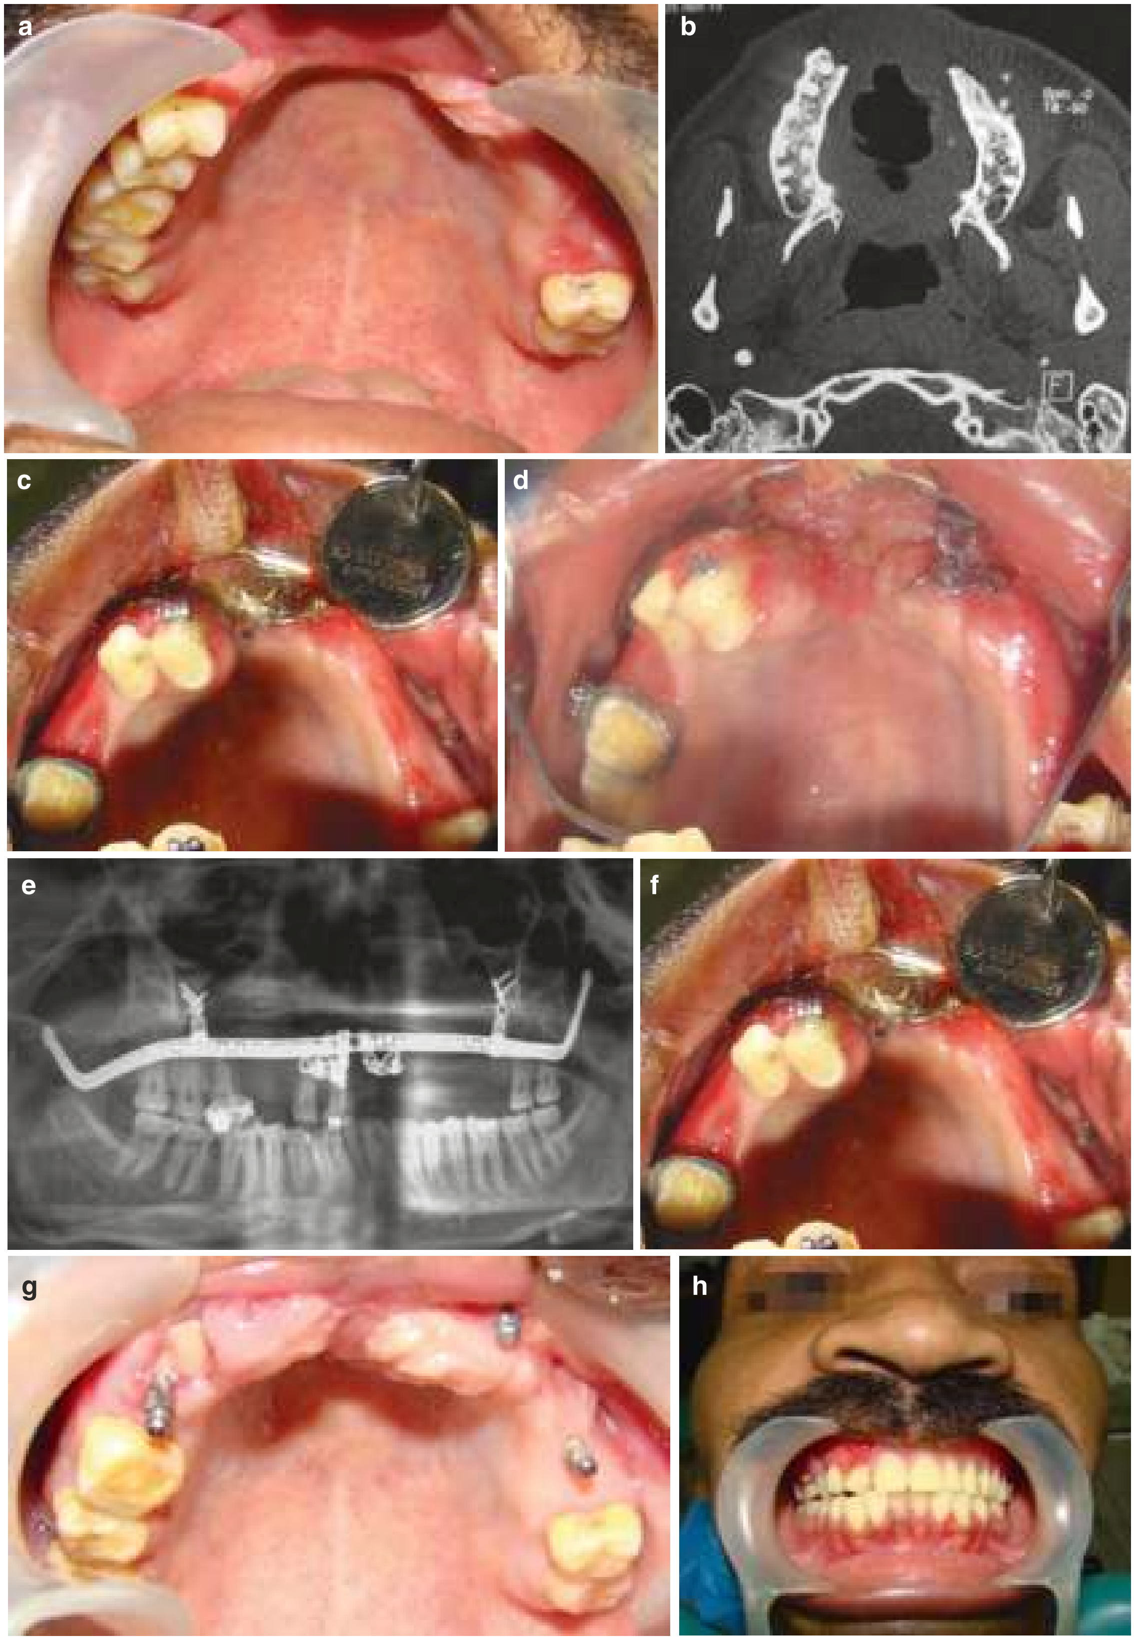

Fig. 87.25 (**a**) A case of continuity defect across midline following gunshot injury in a soldier. (**b**) CT image of case in 25 a. (**c**, **d**) Trifocal distraction in progress. Table 87.3 Complications of TDO

Biological complications of TDO
• Hypotrophic regenerate. • Drifting of teeth. • Relapse. • Straight regeneration across midline.
Mechanical complications of TDO
• Misdirected vector. – Sagittal deviation. – Coronal deviation. • Midline consolidation.

87.15.3 Relapse

Relapse of the new bone regenerate can occur resulting in contracture of the regenerate that could be avoided either by using an acrylic space maintainer or by placing a fixed partial denture immediately after the intended length of bone regenerate is formed across abutment teeth on either segment. It is a wise practice to retain the teeth in the transport disc for this purpose.

87.15.4 Straight Regeneration

Straight regeneration occurs while transporting the disc across the midline because the collagen fibers does not follow arc architecture of the defect in the midline; instead they get stretched in a straight direction, similar to an elastic band (Fig. 87.29a, b).

Misdirected vector in sagittal and coronal plane can occur when the guidance rod is not kept parallel to the occlusal plane. When such misdirection takes place, it can be allowed to proceed in the same vector until the intended length of bone regenerate is achieved, which could be corrected by callus molding before consolidation of the regenerate. The callus is molded by the rate and rhythm of the distraction and plating is done to achieve stability of the device. IMF is done to keep the occlusion intact on the contralateral side (Fig. 87.30a, b, c, d, e, f).

87.15.5 Midline Consolidation

The major limitation that we have with this modality of reconstruction is midline consolidation in both mandible and maxilla with arched regeneration. The transport segment freezes by the time it reaches a point lateral to midline on the opposite side. The concept of midline consolidation is that as the distraction proceeds beyond canine across the midline, the buccal cortex of the transport segment expresses greater movement than the lingual cortex for the same degree of rotation, as with the long and short arm of a clock suggesting lingual cortical tipping movement less than the required 1 mm per day. This results in lingual consolidation. This can be overcome by further re-distracting the transport segment after performing a lingual cortical osteotomy alone (Fig. 87.31a, b, c, d, e).

(**e**) Re-distraction after lingual cortical osteotomy (*red line indicates the site where callus will be formed after distraction*)

87.16 Role of Exogenous Growth Factors and Platelet-Rich Plasma (PRP) in TDO

Studies have highlighted that the transforming growth factor-beta, basic fibroblast growth factor, and insulin-like growth factor I are the chief upregulated factors during TDO. These factors are present in the bony matrix, in the cytoplasm of the cells, in osteoblasts, and in a few mesenchymal cells. Distraction at faster rate shows stronger presence of the growth factors but clinically a poor regenerate. An optimum distraction rate, presence of the growth factors, and strict adherence to the biomechanical principles of DO remains the key to successful clinical outcome. Currently, external administration of the exogenous growth factors remains controversial and is a subject of further research, with evidences both for and against it. It may be concluded that the optimum TGF-beta1 is present during the distraction phase in vivo and its exogenous administration may not be recommended based on the evidences from future research. Injection of platelet-rich plasma (PRP) is found to have more favorable clinical outcome to enhance bone healing during distraction osteogenesis. PRP releases platelet-derived growth factor and transforming factors (TGF-1 and TGF-2). Platelet-derived growth factors are the initial growth factors present in a wound and initiate connective tissue healing, bone regeneration, and repair. Platelet-derived growth factors are a cost-effective and safe alternative to enhance mineralization of the distraction chamber.

In our experience with bioregulators, limited to PRP, we have found that injecting PRP into the site of new bone regenerate chamber after achieving the desired length through TDO, we can reduce the time of consolidation phase by one-third compared to consolidation phase without PRP. PRP has proved to hasten the mineralization of the regenerate and we can achieve the quality of bone that is usually expected in 6 weeks without PRP in 2 weeks' time itself, thus reducing the duration of treatment [13].

87.17 Conclusion

As we understand, microvascular surgery is not restricted to a particular specialty and is a technique that can be mastered by any surgeons of any specialty. However, it requires a steep learning curve, whereas bone transport doesn't require any additional training or equipment. It involves only the routine plate bending and fixing. So, to conclude, distraction osteogenesis is a continually evolving field of research and study and an aesthetically and functionally acceptable option for managing extensive maxillomandibular defects and those not amenable to conventional methods. It is akin to "old wine in new bottle" especially brewed to the taste of oral and maxillofacial surgeons, for it is the only contemporary modality of reconstruction that we maxillofacial surgeons can master ourselves and also one that we can call with pride as "our own (Refer Figs. 65.14, 65.15, and 65.17 for TMJ ankylosis cases where distraction osteogenesis has been used as a part of the overall treatment plan)."

Hard Tissue Reconstruction of the Maxillofacial Region

88

Srinivasa R. Chandra and Vijay Pillai

Abbreviations

ACS	acellular collagen sponge
BFGF	basic fibroblast growth factor
BMP	bone morphogenic protein
IGF-1,2	insulin-derived growth factor 1,2
PDGF	platelet derived growth factor
rh BMP-2	recombinant human bone morphogenic protein-2
TGF-β	transforming growth factor beta

88.1 Introduction

The maxillofacial skeleton can be visualised as a three-dimensional structure, and its integrity is essential for neurovisceral function like vision, airway conduction, nutritional luminal support, etc. The location and the size of the defect determine the hard tissue reconstruction and the donor site selection.

88.2 General Principles [1]

- The bone graft recipient site should have viable vascular and infection free environment.
- Adequate evaluation of the donor site morbidity has to be undertaken.
- Evaluation for vascular versus nonvascularized bone graft has to be done with adequate immobilization and if required vascular anastomosis.
- Comorbidities of the patient and surgical appropriateness have to be prioritized. Smoking, cicatrization, radiation, pain issues and functional status are considerations as well.

88.3 Principles of Reconstruction

- Age is a factor but not a contraindication for reconstruction.
- There is no 'ideal reconstruction' but there is 'optimal reconstruction'.
- Patient comorbidities and future adjuvant radiation should be strongly weighed.
- 'Like to like tissue' reconstruction especially hard tissue substitution is optimal.

88.4 Terminology

Autograft: Transplant between areas within the same individual.
Allograft: Transplant between individuals (same species).
Xenograft: Transplant between individuals of different species.
Isograft: Transplant between monozygotic twins.

Osteoconduction is the phenomenon of bone regeneration which needs a scaffold for ingrowth of capillaries, osteoprogenitor cells and perivascular tissue. The ingrowth of capillaries from the recipient bed causes differentiation of the osteoprogenitor cells and results in the formation of new bone. There are materials which promote osteoconduction as

grafts or scaffolds. These can be autologous or alloplastic, homologous, xenogeneic bone particles, bone glass and hydroxyapatite ceramic material.

Osteogenesis is the spontaneous growth of new bone. It can either be *spontaneous* from progenitor cells in the area of the bone defect, or it could be *transplanted* osteogenesis arising from grafted progenitor cells.

Osteoinduction is auto induction by differentiation of mesenchymal cells from the native bed into osteoblastic tissue. This requires inductive stimulation, either from the grafted bone material (there is natural bone morphogenetic protein release with the resumption by osteoclastic activity on the middle matrix) or by the addition of recombinant bone morphogenic protein-2. This results in recruitment from the surrounding bed of mesenchymal cells, which then differentiate. This is mediated by graft-derived factors, viz. recombinant human bone morphogenic protein-2 (rhBMP-2), in situ BMP, TGF-ß, IGF-1 and IGF-2, BFGF, PDGF.

Clinical Pearls

Key concept in bone grafting which is a part of hard tissue reconstruction is the extent of ostial induction, ostial conduction and osteogenesis caused by the graft. The main tenet is that only autologous bone graft grafts can promote osteogenesis due to its volume of biocompetent viable cells. Allo- and xenografts do not have osteogenic potential.

88.5 Bone Grafts [2, 3]

88.5.1 Cortical vs Cancellous Grafts

Cancellous grafts revascularize more rapidly when compared to cortical grafts. For example, cranial bone revascularizes more rapidly than other cortical bone.

Mechanism of healing:

- Cancellous: Apposition and subsequent resorption.
  - Cancellous grafts repair more completely.
  - Cortical bone incompletely resorbed/remodelled
- Cortical: Resorption then apposition.
  50% reduction in strength at 6 weeks–6 months.

88.5.1.1 Considerations in Usage of rhBMP-2 [4]

In March 2007, the US Food and Drug Administration (FDA) approved the use of rhBMP-2 in maxillofacial surgical procedures for intraoral ridge augmentation.

Biologic concept—the mechanism is through osteoinduction by chemotactic osteoprogenitor cellular proliferation and differentiation causing osteoid maturation.

Technique—BMP is carried in the acellular collagen sponge (ACS) to the defect where the formed osteoid matures into an ossicle about 6 months after the cycle of resorption and remodelling. There are multiple case reports of allogenic freeze-dried, crushed cancellous bone with BMP and platelet-rich plasma used in large maxillofacial reconstructions. rhBMP-2 is a lyophilized powder mixed with prepackaged sterile water. Concentration of 1.5 mg/mL of rhBMP-2/ACS is advised. For molecular binding the mixture is kept soaked for 15 minutes. To prevent desiccation and protein loss, rhBMP/ACS mixture must be used within 2 hours. Informed consent, warning of swelling and tension-free closure are important considerations.

Indications: Approved by FDA—spinal fusions (2002), treating open tibial fractures (2004) and oral and maxillofacial sinus and ridge augmentations (2007).

Contraindications and precautions:

- Local health advisory or FDA issued black box warning.
- Pregnancy.
- History of malignancy.
- Active infection.
- Hypersensitivity to BMP or collagen matrix.
- Unknown evidence of safety in children and females of childbearing age.
- Proximity to airway due to severe oedema postoperatively.

88.5.2 Bone Graft Carriers and Fixation Techniques

- Mesh.
- Custom fabricated cribs, implants, plates, etc.
- Titanium plates and screws.
- Lag screws.
- Autologous or allogenic bone cribs (Fig. 88.1).

Autogenous Bone Donor Sources

The choice of donor site depends on:

(a) Quantity.
(b) Quality.
(c) Anatomical contour (height, weight, volume).
(d) Donor site morbidity.
(e) Patient and anatomical access to harvest.
(f) Type of carrier and fixation needed.
(g) Surgical competence.

Common Locations of Autogenous Bone Donor Sites

- Iliac crest (anterior and posterior).
- Costochondral rib graft.
- Cranial bone.
- Tibia.
- Scapula.
- Maxilla.
- Mandible.

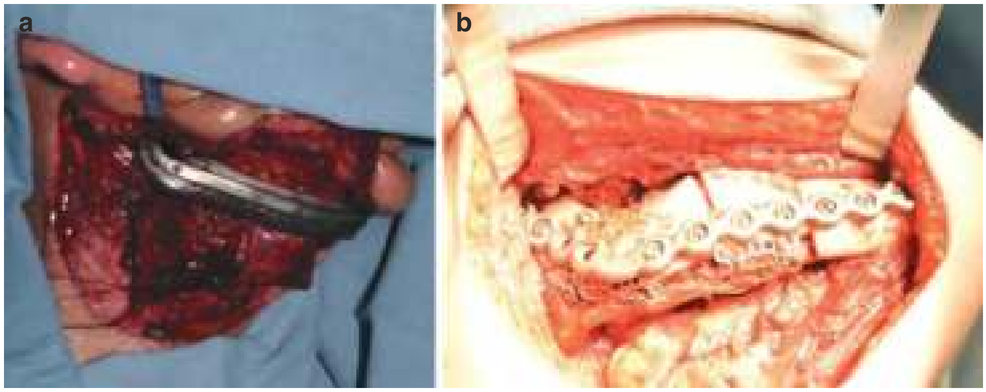

Fig. 88.1 Bone graft carriers and fixation techniques(**a**–**b**) custom made implants compared to stock prosthesis. (**a**) Custom-built bone graft carrier and plate as patient specific implant—note that this can be planned for optimal areas of fixation (anchoring the crib to the plate, the span and width of the screws, etc.). (**b**) The figure shows a reconstruction bar adapted with stock titanium mesh for carrying a non-vascularised iliac bone graf

88.5.3 Costochondral Graft

The costochondral rib graft came into vogue with the concept of transplanting a growth centre to the recipient site in reconstruction. This was initially used for temporomandibular joint arthroplasty and extended to the ramus condyle subunit, as it was a substitute for the growth centre at the condyle and was needed to maintain the growth potential of the joint.

88.5.3.1 Technique

A submammary incision is placed around the 5th–seventh rib, taking care not to extend beyond to avoid a flail segment. The incision is made in the mid-clavicular line, placed more medially if a costochondral graft is needed. It is deepened down to bone, and a circumferential subperiosteal dissection is done with a stripper. If the cartilage is harvested, a sleeve of periosteum is retained. Subperiosteal dissection is done avoiding pleural damage. Once the graft is removed, inspect the cavity with saline and check for any air leaks. A layered closure is performed with a drain.

88.5.3.2 Indications

Laryngotracheal reconstruction, nasal reconstruction, auricular reconstruction, facial augmentation in syndromic disorders.

Clinical Pearls
- Good cartilage yield.
- Superior strength.

Pitfalls
- Inferior pliability.
- High tendency for warpage.
- Subcostal scar, pneumothorax.

88.5.4 Autologous Rib Grafts

Rib grafts are a good source of corticocancellous membranous bone that can be used as onlay bone grafts for the craniofacial skeleton. Being soft and flexible, it is unable to withstand zones of high stress placement.

The harvest is similar to the costochondral graft; however, leaving the periosteum in situ would allow for regeneration of the rib but would reduce the take of the rib graft.

Pitfalls
- Subcostal scar.
- Pneumothorax.
- Atelectasis.
- Higher incidence of resorption if used as onlay grafts due to the higher cancellous component.

88.5.5 Iliac Crest

The ilium is a rich source for cortical, cancellous and a combination of corticocancellous bone grafts.

It is primarily utilized for arthrodesis, bony non-unions and alveolar clefts.

The anatomy of the ilium with the dense cortical bone permits grafts for high stress areas like the long bones and hands and also allows for rigid fixation. The outer table has numerous muscular attachments, thus is not preferred. The inner table is commonly harvested.

The iliac crest allows the harvest of large amounts of cancellous bone.

The cartilaginous apophysis in children must not be disturbed as it contributes to the normal growth and development.

88.5.5.1 Technique

The anterior approach is the most commonly utilized with the incision being placed after careful palpation to ensure the scar lies on the lateral aspect of the crest.

The incision is deepened through the skin, fascia, muscle and periosteum up to the bone. Ideally the inner or medial table is preferred for harvest as it does not cause disruption of the muscle attachments on the lateral side. The bone cuts should be placed preserving the crest so that it is hinged laterally and can be repositioned once the desired bone has been harvested. Maintaining the periosteal attachments of the crest would preserve its blood supply and further fixation would not be needed.

Good haemostasis, meticulous-layered closure with a drain in the subcutaneous tissue can help prevent a postoperative haematoma. It is also common practice to place an epidural catheter into the bed to permit infusion of a long acting local anaesthetic agent for the first 24 hours.

Most of the disadvantages of iliac bone harvest can be circumvent if the amount of bone graft needed is not too excessive by using the trephination technique.

Pitfalls
- Postoperative morbidity depending on the extent of bone harvested.
- Injury to the lateral femoral cutaneous nerve with prolonged post- surgical pain.
- Haematoma.
- Gait disturbances.

88.5.6 Tibia

88.5.6.1 Tibial Autogenous Cancellous Bone Harvest

This was first reported by Catone [5] in 1992 and is used in maxillofacial bone grafting techniques with a harvest volume of about 25–40 cc from a unilateral site. Harvest can be performed under local or general anaesthesia. The anatomical access to the tibial proximal head can be medial or lateral. Paediatric harvest has been reported, but the growth plate of the tibial plateau should be mature for adequate safety. The contraindications for tibial bone harvest cited are metal prostheses, athletes and history of knee trauma.

88.5.6.2 Technique

As mentioned the approach can be medial or lateral to the midline patellar tendon. In the lateral approach—Gerdy's tubercle is the bony prominence which is palpated between the midline patellar tendon and the lateral proximal head of the fibula. This bony prominence has the attachment of the iliotibial fascial tract. In the medial approach, there is no significant bony prominence, and the only overlying structures to the tibial proximal head are just skin and subcutaneous tissue. Accordingly, an incision on either side goes through the skin and subcutaneous tissue and a self-retaining retractor can be used for retraction.

Once the tibial head is identified, using a narrow drill with a postage stamp technique, a window is created either supra or subperiosteally. This cortex can be left attached to the periosteum and repositioned at the end of the harvest if cortical bone is not needed. Cancellous bone can be curetted with adequate care not to perforate the superior tibial plateau entering the knee joint. Adequate haemostasis with local cautery should be used to prevent any postoperative haematomas. Deep and superficial layer closures are performed. No immobilization is recommended, but active weight bearing is avoided for a couple of days. If there is any concern for superior tibial plateau perforation or knee joint violation, an orthopaedic review is mandated.

88.5.7 Cranial Bone [2]

It is well-known through craniofacial surgery that paediatric skull defects less than 1 cm with an intact pericranium can cause adequate bone healing with osseous regeneration. Calvarial bone grafts can be performed as mono- or bicortical harvest based on the surgeon's competence. Cortical bone shavings are commonly utilized. Just off the midline of the skull sagittal plane, parietal cortical calvarial bone is accessed through skin and the scalp layer incision. Adequate retraction is performed with a self-retaining retractor or assistance. The amount of bone needed is identified in the subperiosteal plane and marked with round bur of a narrow diameter. Adequate outer beveling is performed (as depicted in the figure) using a straight fissure bur for a flat osteotomy technique as parallel to the outer surface. Multiple fissuring osteotomies in a parallel fashion can be performed too. The intracortical medulla is carefully traversed through osteotomes and if any small dural perforations are made, they can be covered with artificial allografts or even haemostatic material. A neurosurgical review is needed in case of dural tear. Haemostasis with bone wax or electrocautery and good pericranial adjacent tissue rotational coverage and closure of the scalp layers leads to reduced postoperative haematomas. The bone harvested can be contoured with a crimping forceps as shown in the figure (Fig. 88.2a and b).

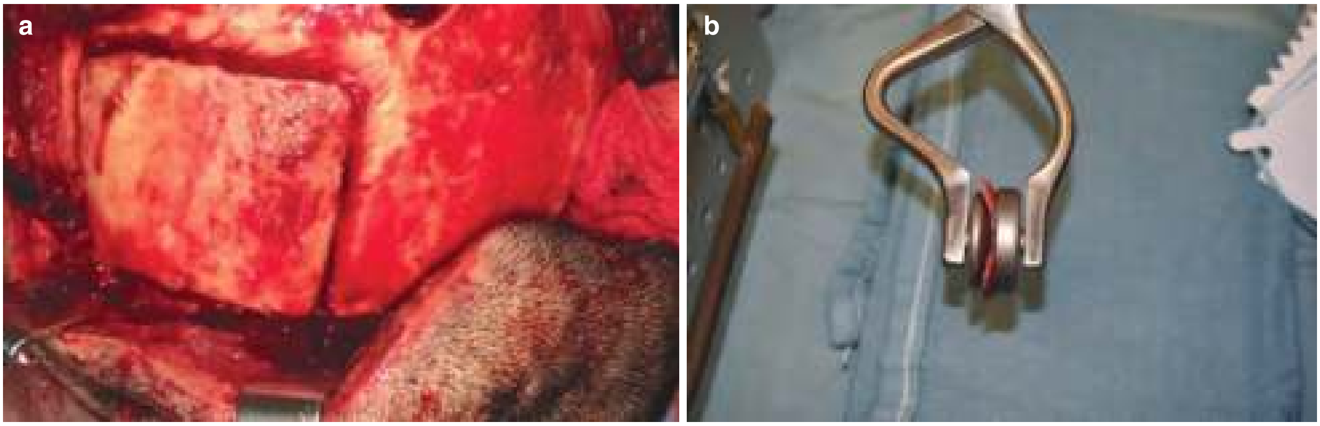

Fig. 88.2 (**a**) Cranial bone graft harvest with circumfrential trough and beveling. It is ideal to harvest this in the parietal area. Narrow strips are ideal for harvest. (**b**) Cranial non vascular bone graft being contoured with pinch forceps

88.6 Microvascular Free Tissue Transfer

Most hard tissue grafting using this technique is a 'composite' bone and soft tissue transfer by arteriovenous anastomosis. This transferred bone is usually held in place by plates and/or screws. There is osteogenesis at the interface of the native and grafted bone interface. Current techniques of vascular free tissue using microvascular anastomosis along with minimal donor site morbidity have a success rate close to 98 percent. There is a potential for failure due to anastomotic complication. The vascularized free transferred tissue is resistant to infection and radiation to a degree of volume. There are concepts of creating a vascular envelope and subsequent allogenic or xenogeneic grafting for better osteoconduction by vascular ingrowth.

88.6.1 Osteocutaneous Radial Forearm Free Flap (OCRFFF)

The popular workhorse fasciocutaneous radial forearm free flap is very well-known for most reconstructive surgeons. Whereas an osteocutaneous variant of this flap is not the 'go to' flap in composite reconstructions. There is significant donor site morbidity with about 70% postharvest strength and an increased fracture risk of the distal radius. Distal radius can be reinforced with a prophylactic plate by internal fixation. Figure 88.3 shows osteocutaneous radial forearm free flap for maxillary reconstruction including the orbital rim. Figure 88.4a and b shows radial forearm flap for reconstruction of maxillary and mandibular defects.

Fig. 88.3 Osteocutaneous radial forearm free flap for maxillary reconstruction including the orbital rim

88.6.1.1 Indications

Periorbital, nasal and maxillary subunit reconstructions are the common indications for an osteocutaneous radial forearm free flap. It is a real alternative if other donor sites are not viable.

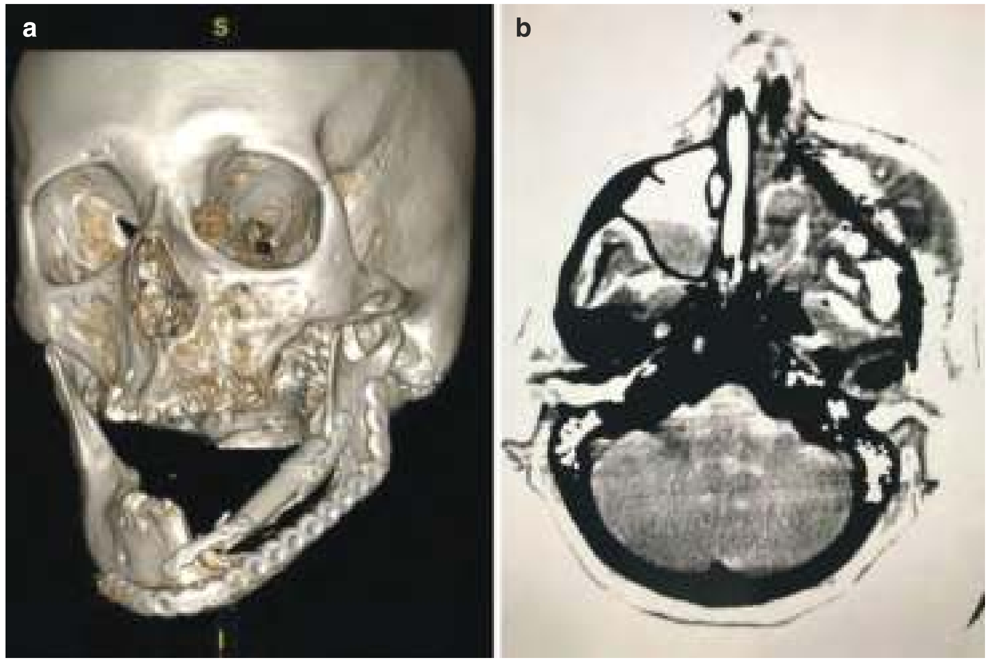

Fig. 88.4 (**a** and **b**) Radial osteocutaneous flap as an alternative in mandible (**a**, 3D rendering) and (**b**) maxillary reconstruction (left maxilla CT)

88.6.1.2 Technique

Surface markings of the soft tissue from the distal wrist skin crease as the horizontal line, the radial pedicle and the cephalic vein are outlined. The osseous part of the anterior lateral radius segment between the insertion of the pronator teres and the brachioradialis is harvested up to 10–13 cm in length and about 40 percent in circumference. The distal styloid aspect of the radius should have at least 2 cm to complete a bone plate fixation after the flap harvest. The fascial and muscular periosteal vascularity is retained in harvest. The flap can be raised from the radial or the ulnar side in a subfascial plane. The brachioradialis is retracted laterally protecting the superficial branch of the radial nerve. A sharp incision is made down to the periosteum preserving the attachment of the intermuscular septum. On the medial side, the flexor carpi radialis muscle is reached and retracted medially so the median nerve is protected. The muscle bellies of the pronator quadratus and the flexor pollicis longus are carefully dissected distal to proximal preserving enough muscular cuff to retain perforators to this segment perfusing from the radial artery in its lateral intermuscular septum. Once the radius periosteum is incised in length noting the curve of radius bone, multiple drill holes are used to outline the osteotomy. A boat-shaped harvest is completed of the cortex protecting the radial vasculature after distal ligation and the muscular perforators to the osseous part. The proximal harvest is completed of the pedicle similar to radial forearm harvest by radial artery and vena comitans ligation. A prebent compression plate is adapted and fixated using bicortical screws across the site of harvest (Fig. 88.5). Osteotomy scan be performed of this donor segment with close attention for orbital rim reconstruction if needed.

Fig. 88.5 Post-radial osteocutaneous flap harvest with orthopaedic internal bicortical fixation of radius as prophylaxis for prevention of radial shaft fracture

88.6.2 Scapula Free Flap [6]

Theoretical conceptualization of the scapular flap was first described by Saijo in 1978 and popularized by Dos Santos [7] in 1979. This scapular system which got described includes a myriad of options based on the subscapular vessels. It can be used as two types of bony composite flaps with the utilization of angle of the scapula and the lateral border. The major branches of the subscapular system are the circumflex scapular artery and the thoracodorsal artery. Circumflex scapular artery and its associated vein with the lateral border of the scapula are the classical osseous flap. Scapular and parascapular flaps offer the most flexibility with combinations of osseous, muscular, fasciocutaneous free tissue transfer based on the subscapular vascular system. Approximately 10–14 cm of the length with a thickness of 0.5–1.5 cm bone composing the lateral aspect of the scapula and or the angle of the scapula can be harvested.

Figure 88.6 shows the advantage of this flap: independence of soft tissue pedicle in relation to the bone.

It can also be harvested using the angular artery, a branch of the thoracodorsal artery obtaining a longer vascular pedicle and teres major muscle along with the scapular tip. The medial border of the osseous scapular flap has been described; the flexibility of the overlying fasciocutaneous part is not very pliable. The medial border is comparatively narrow even in males for placement of osseointegrated implants.

Tips for donor site confirmation to the defect:
- Contralateral lateral border of scapula for mandibular reconstruction.
- Ipsilateral scapular tip for the palate and maxilla.
- The angle of the scapula can also be used for the mental prominence reconstruction.

Studies have shown good conformance between the scapular tip and the palate. The tip can be used horizontally for a palate and vertically for anterior maxillary reconstruction. There are reports of nonvascular scapular tip being used for orbital floor reconstructions.

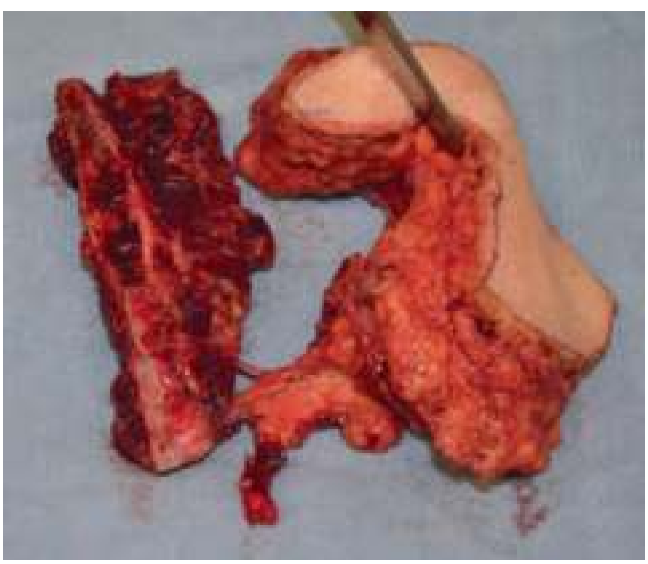

Fig. 88.6 The osteocutaneous scapular free flap. The great advantage of this flap is the independence of the soft tissue pedicle in relation to the bone

88.6.2.1 Indications

Composite and complex midfacial defects of the orbit, maxilla, skull base and mandible can be reconstructed using this chimeric flap.

88.6.2.2 Advantages

- Minimal donor site morbidity.
- Useful in elderly patients with peripheral vascular disease.

88.6.2.3 Disadvantages

- Concurrent flap harvest during ablation is not possible, as patient needs to be in the lateral decubitus or prone position.
- Inadequacy of the bone stock for osseointegrated implants.
- Variation in the anatomy with the circumflex scapular arising from the axillary artery.

88.6.2.4 Technique

Clear understanding of the scapular arteriovenous system and its branches composing the circumscapular, descending branch and parascapular vessel anatomy is essential.

The osseous branch of the circumflex scapular artery to the lateral border runs directly into it along with the vein. There is a gap between this and the cutaneous perforator which provides the flexibility of the skin paddle.

Patient can be positioned in a lateral decubitus or prone position for access between the axilla to the midline spine. The author's choice is use of a beanbag under the ipsilateral side and a protected axilla for the contralateral side. To increase the flexibility of the pedicle in relation to the lateral border of the scapula, a scapular or parascapular skin paddle can be based on the circumflex artery. The triangular space is made by the teres minor superiorly and teres major inferiorly, and the long head of the triceps laterally is identified using a Doppler 2 cm superior to the posterior axillary fold edge. The fasciocutaneous flap elevation is medial to lateral superior to the muscular fascia until the omotricipital triangle is reached. The circumflex vascular pedicle can be followed proximally to the subscapular and axillary arterial system with dissection between the teres minor and major muscles superiorly. The circumflex scapular artery is dissected in the lateral aspect of the scapular border with preservation of the muscular perforators to the bone by medial retraction of the teres minor and inferior retraction of the latissimus dorsi. An incision parallel to the lateral border of the scapula is made through the teres minor and infraspinatus muscle and periosteum. Protecting the vascular pedicle laterally on the glenohumeral joint superiorly osteotomy can be performed using a saw to the desired length with or without the angle of the scapula. Scapular angle can be harvested independently with identification of the angular perforators. Adequate care is taken to protect the underlying subscapularis musculature. Teres major muscle is reattached with multiple drill holes to the new border of the lateral scapula donor site to prevent winging. Perioperative drain and post-operative immobilization of the arm after primary closure of the defect site are commonly utilized along with physiotherapy.

88.6.3 Fibula Free Flap [8, 9]

Taylor et al. first introduced the fibula flap in 1975 for extremity reconstruction but was reintroduced for mandible reconstruction by Hidalgo. Though designed as an osteocutaneous free flap, the initial reports of unreliability of the skin paddle did not find favour in its use as an osteocutaneous flap.

Clinical Pearls

- Ease of simultaneous two team harvest.
- Consistent anatomy.
- Reliable usable bone length of around 24 cms, with the capability of performing multiple osteotomies.
- Variable design as bone only, osteocutaneous or with cuff of flexor hallucis longus or soleus muscle and with accompanying fat and fascia.
- Adequate length of vascular pedicle and suitability of the peroneal vessels for anastomosis.
- Accepts dental implants and osseointegrates.
- Minimal donor site morbidity.

88.6.3.1 Anatomy

The fibula is a triangular bone in cross section, around 40 cm in length and 1.5–2.0 cms in diameter, articulates proximally with the tibia and distally with the tibia and talus and has dense cortical bone with a small amount of cancellous bone.

Blood supply: Dual endosteal and periosteal. The dominant endosteal nutrient pedicle enters posterior to the interosseous membrane at the junction of the upper and middle thirds of the fibula. It is the segmental periosteal blood supply arising from the peroneal artery that permits multiple osteotomies. Average pedicle length depending on the bone length harvested is from 5 to 10 cms with a diameter of 1.8–2.5 mm and venous drainage via paired venae comitantes.

Skin paddle: The skin territory for the flap harvest on the lateral aspect of the leg can be up to 25 cm in length and around 15 cms in width and is supplied by perforators from the peroneal system which can be either septocutaneous or musculocutaneous passing through the flexor hallucis longus and soleus. The number of perforators is around 4–8.

88.6.3.2 Preoperative Assessment

- History of trauma or surgery to the lower limb, any peripheral vascular disease which might coexist.
- Examination of the circulation with the dorsalis pedis and posterior tibial pulse.
- *Imaging*: MR angiography, CT angiography to rule out peronea magna and also identify perforators. If angiographic studies are contraindicated, perform an arterial and venous duplex ultrasound demonstrating the flow pattern.

Figure 88.7 shows the fibula free flap reconstruction for the left mandibule of the body, angle and ramus. Figure 88.8a–c shows the planning and execution for fibula free flap on a stereo lithographic model. The closing osteotomies are made with measurements using a ruler template; the smallest fibula segment is noted as marginally more than 2 centimetres. In Fig. 88.8b, one can see a sterile ruler held at the lateral fibula harvest with pedicle attached proximally and skin paddle. In Fig. 88.8c, the osteotomized fibula is immobilized to a reconstruction plate at the lower extremity donor site with the pedicle flowing intact.

88.6.3.3 Technique

Prepare the whole lower limb circumferentially from the calf downwards and the opposite limb for a skin graft. Perform the surface markings of the fibula, with the design of the skin paddle centred along the posterior border that corresponds to the intermuscular septum. Design the skin paddle after the perforators have been mapped out using a Doppler probe. Preserve at least 4–5 cm bone proximally and distally for the stability of the knee and ankle joint and to avoid injury to the

Fig. 88.7 Fibula free flap reconstruction for the left mandible of the body, angle and ramus

Fig. 88.8 Maxillary reconstruction planning for fibula osteotomies. (**a**) Planning for fibula free flap on a stereo lithographic model. The closing osteotomies are made with measurements using a ruler template; the smallest fibula segment is noted as marginally more than two centimetre. (**b**), the template being transferred to the fibula area for planning the closing osteotomies. You see a sterile ruler held at the lateral fibula harvest with pedicle attached proximally and skin paddle; (**c**) The osteotomized fibula immobilized to a reconstruction plate at the lower extremity donor site with the pedicle flowing intact

superficial peroneal nerve. Carefully apply a tourniquet and exsanguinate the lower limb.

The incision begins anteriorly on the skin paddle deepened into the subfascial plane over the peroneus longus and brevis and dissected to identify suitable perforators. The incision is extended in a curvilinear manner proximally, and dissection in the lateral compartment is done keeping a cuff of peroneus muscle cobblestoned on the bone.

The next step is the dissection in the anterior compartment of the extensor hallucis longus and extensor digitorum longus up to the dense interosseous membrane which is incised. The anterior tibial vessels are seen anterolateral to the fibula and preserved.

Proximal and distal osteotomies are performed using a reciprocating saw, preserving the superficial peroneal nerve superiorly. Distally ligate the peroneal vessel once the bone is osteotomized.

The posterior compartment dissection is performed between the tibialis posterior and flexor hallucis longus which identify the peroneal vessels. Keep a cuff of flexor hallucis or soleus muscle onto the graft depending on the soft tissue requirement and if the skin paddle is centred along the mid bone.

The posterior design of the skin paddle is made in a similar manner deep to the fascia over the soleus and lateral gastrocnemius preserving the saphenous vein and sural nerve.

Identify and preserve the posterior tibial vessels and tibial nerve 1–1.5 cm medial and parallel to the peroneal vessels.

Perforators to the soleus must be ligated, and additional length of the pedicle can be obtained by a subperiosteal dissection or ligation of the lateral posterior tibial vein.

Shaping of the fibula can be done on the benchside or while still connected with the circulation using either a prebent plate, cutting guides with virtual surgical planning. Closing wedge osteotomies are performed and fixation done.

Donor site closure should be meticulous with good haemostasis; suction drains closing the proximal and distal skin incisions and grafting the remaining donor site. Immobilization with a posterior splint with the ankle in 90 degrees flexion is recommended though not routinely practiced.

Postoperative physiotherapy for the lower limb can commence by the second day and with accompanying gradual weight bearing.

Pitfalls

- Vascular anomalies and variations can preclude the use.
- A double barrel segment might be needed due to inadequate bone height.
- The soft tissue component may be inadequate for extensive resections.

88.6.4 Deep Circumflex Iliac Artery-Based Composite Flap or Vascularized Iliac Crest Flap (DCIA)

Similar to the fibula the DCIA can be planned virtually. Opening osteotomies are performed instead of closing osteotomies in maxilla-mandibular reconstruction (Fig. 88.9a, b, c, d).

This flap can be harvested as an osseous or an osseocutaneous with the soft tissue component of the muscle and skin. This flap is based on the deep circumflex iliac artery and vein with the pedicle length as long as 8 cm with a diameter of the vessels between 1.5 and 3 mm. The iliac crest osteocutaneous free flap (ICFF) was described separately by Taylor [10] et al. and Sanders and Mayou in 1979 and popularized by Urken in 1989 for mandibular reconstruction and by Brown [11] in 1996 for maxillary reconstruction and use of internal oblique muscle [11]. The deep circumflex iliac artery and vein vessels arise from the external iliac vessels. The bone quality and quantity are excellent for both the maxillary as well as mandibular reconstruction.

Maxilla and mandibular segments can be reconstructed using the iliac crest bone based on the deep circumflex branch of the external iliac artery. The authors prefer a harvest using the superior approach in reference to the spermatic cord or the round ligament. Donor site morbidity is not significant, and the patient can be supine allowing a two-team approach. Up to 14 cm of bicortical bone with internal oblique muscle can be harvested. The thickness can vary between 0.5 cm and 2.5 cm.

88.6.4.1 Indications and Contraindications

This composite flap offers optimal volume of bone for endosteal implants as well as segmental mandibular defects with need of reconstruction of the dentate contour. Maxillary palatal contour and the regional complex subunits after maxillectomy can be reconstructed. The relative contraindications for this harvest are inguinal hernia, obesity, hip prosthesis and polyparity in women.

88.6.4.2 Vascular Anatomy

Just above the inguinal ligament, the deep circumflex iliac artery (DCIA) branches off the posterolateral aspect of the external iliac artery. As it traverses laterally parallel to the inguinal ligament, the ascending branch takes off 1–2 cm medial to the anterior superior iliac spine. This is located between the internal oblique on the transversalis fascia with penetrating perforators. The DCIA has a diameter averaged at 2 mm and a pedicle length of 5–6 cm. Vena comitans accompanies the artery draining into the external iliac vein. The position of the DCIA is about 2 cm inferior to the surface of the iliac crest at the fusion of the transversalis fascia and iliacus muscle. The two variations reported are the ascending branch takeoff in medial relation to the anterior superior iliac spine (1–2 cm versus 2–4 cm) and multiple ascending branch perforators instead of a single identifiable ascending branch of the DCIA.

88.6.4.3 Technique

With the patient supine, a soft hip support is placed and the skin prepped from the midline pubis laterally to the midaxillary line, superiorly from the subcostal margin to the anterior thigh inferiorly with the greater trochanter included in the field. This includes the planned cutaneous paddle. The cutaneous perforators are concentrated 5 cm lateral to the anterior superior iliac spine and 4 cm superior to the iliac crest midpoint. Only internal oblique musculature for lining of the oral mucosal lining is included. Incision is made in a superomedial elliptical fashion through the Scarpa's and Camper's fascia up to the external oblique musculature. This is identified in its orientation from the lateral to medial direction, and as this is incised, the underlying 90 degree medial to lateral internal oblique muscle is identified. The external oblique musculature is included with the osteocutaneous

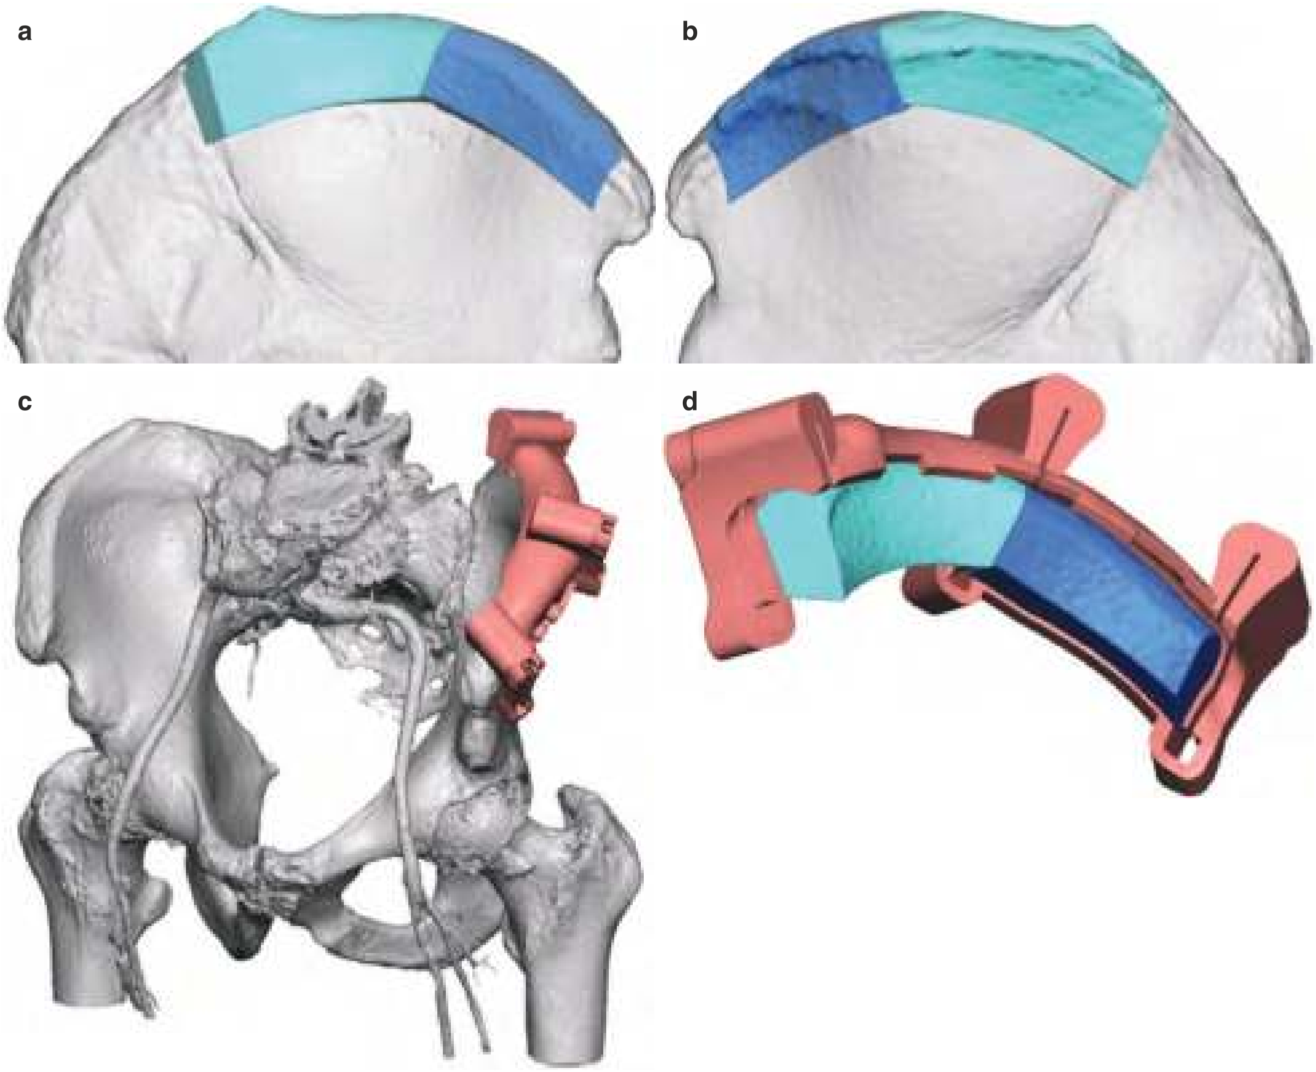

Fig. 88.9 (**a**, **b**, **c**, **d**) Similar to fibula DCIA can be planned virtually. Opening osteotomies are performed instead of closing osteotomies in maxilla-mandibular reconstruction

flap. The external oblique incision extends from the lateral entirety of the whole length up to the border of the inguinal ligament. The superior part of the flap is retracted and the internal oblique muscle exposed, and the amount of this internal oblique muscle inclusion is identified for harvest superior to the iliac crest attachment. The internal oblique and transversalis fascia is dissected sharply from the superior lateral aspect to the inferior lateral direction with superior retraction and access. The ascending branch is visualized and dissection is directed to identify the DCIA itself. The ileacus muscle is visualized and preserved based on the pedicle position and harvesting about 2 cm of it. At least 4 cm of the internal oblique muscle is harvested lateral to medial towards the ilioinguinal ligament. The vein runs over the DCIA medially to the external iliac vein.

The bone harvest is performed after detaching the gluteus medius muscle from the outer aspect of the ilium. The medial bone cut is made depending on the inclusion of the anterior crest of the ilium. The template as shown in the figure (anterior maxillary virtual finding figure) is used for making medial and lateral cuts using an oscillating saw. The medial side should be protected for pedicle integrity and peritoneum. If osteotomies are needed of the bony pedicle, they're performed with adequate care to gently greenstick the components.

The abdomen is closed in layers after adequate haemostasis of the donor osseous margins of the osteotomies. Multiple postage stamp holes are made in the bicortical iliac cortex and the residual muscular layers reattached with thicker nonresorbable sutures. And non-resolvable mesh can be used to reinforce the harvested internal oblique defect, and this can be sutured to the cortical holes as described above. The cutaneous closure is performed over suction drainage with multiple layer closure.

The quality and quantity of the bone of this flap are ideal for maxillofacial defect reconstruction. Maxillary reconstruction may need a rather lateralized bony segment harvest to gain adequate pedicle length for anastomosis into the neck. If the mandibular angle is to be reconstructed, the anterior iliac crest is included. An entire hemimandible can be reconstructed using the unilateral iliac crest.

88.6.5 Vascularized Rib Graft

There are other osteocutaneous flaps which are described like posterior costal osteocutaneous flap similar to the harvest of the costochondral part of the rib. These vascularized grafts can be from the right fifth rib in the ventral surface and up to the ninth rib in the dorsal surface. The intercostal vascular pedicle and subcutaneous venous pedicle or even the internal mammary perforators medially are used. The ribs can also be a part of the pectoralis major osteomyocutaneous flap, latissimus dorsi, serratus and trapezius muscular harvest with their pedicles. Of course the isolated rib graft with or without the costochondral graft has been the work horse for temporomandibular reconstruction for decades. The harvest has been documented well in surgical literature over the years.

88.6.5.1 Lateral Femoral Condyle Free Flap

The choice of this flap is for novelty in maxillofacial surgical needs. Femoral internal condyle with the descending genicular artery and vein as a pedicle can be harvested as free flap. The bony corticocancellous segment measuring up to 8 × 1.5 × 1.5 cm can be harvested [12].

88.7 Conclusion

In conclusion the hard tissue regeneration and reconstruction have been a primary focus in clinical and research interests for all reconstructive maxillofacial surgeons. The techniques and molecular science have ongoing updates persistently for the optimal and ideal technique. The understanding of intercellular and molecular behaviour of regeneration and grafting procedure is sought by biomedical scientists by research. And with virtual surgery and planning with guided navigation, the future of hard tissue reconstruction is poised for technically predictable results.
