A useful clinical staging system was introduced by Schobinger [20] in 1990. This system is widely used for describing the clinical presentation and evolution of AVMs:

Stage I (quiescence): pink-bluish stain, warmth and arterio-venous shunting by way of Doppler examination

Stage II (expansion): same as stage I, plus enlargement, pulsations, thrill, bruit and tense/tortuous veins

Stage III: the same as stage II, plus dystrophic skin changes, ulceration, (destruction) tissue necrosis, bleeding or persistent pain

Stage IV: the same as stage III, plus cardiac failure (decompensation)

Undiagnosed AVMs of bone are occasionally the cause of increased bleeding during/after extraction of teeth in a dental office, which can lead to life-threatening airway and haematological problems if not treated immediately (Fig. 31.13). These warrant urgent transfer to a hospital and embolisation or ECA control.

Hereditary haemorrhagic telangiectasia (HHT) is autosomally dominant and presents with the formation of expanding arterio-venous fistulas. These patients usually present with superficial (skin, mucosal) or deep (visceral) telangiectatic lesions. They may sometimes present with aneurysms causing epistaxis or intra-cranial haemorrhage.

Kaposiform haemangioendotheliomas (KHEs) are large lesions (greater than 5 cm), which are present in the neonatal period. They are extremely rare and have a low incidence of occurrence. Hence, there are no clear guidelines on their management. These are aggressive vascular tumours, which can be complex in their management due to thrombocytopaenia secondary to platelet trapping. This phenomenon is known as KMP (Kasabach-Merritt phenomenon). 70% of patients with KHEs demonstrate this phenomenon [21].

31.5 Radiological Assessment

Clinical and radiological assessment go hand in hand to accurately diagnose and manage these diverse groups of head and neck vascular anomalies. Selection of the imaging should be tailored according to the indication, advantages, disadvantages and availability of resources. Good knowledge of all the available radiological modalities is essential to treat these lesions.

Commonly used imaging modalities are
Ultrasound (US)
Coloured Doppler ultrasound
Computed tomography (CT) with contrast
Digital subtraction angiography (DSA)
Magnetic resonance imaging (MRI)
MRI angiogram
Multi-planar dynamic contrast enhanced MRI

US (Fig. 31.14) is the least invasive modality of imaging available for assessment of vascular anomalies. It is used as a baseline investigation for superficial head and neck vascular lesions. In addition to the above, the US has a high sensitivity in diagnosing these lesions. The disadvantages of the US are its limitation in detecting deeper soft tissue and bony lesions.

Doppler ultrasound (Fig. 31.15) is used to demonstrate high-flow lesions. Flow towards the ultrasound transducer is seen in red and away from the transducer seen in blue. The arterial feeder is usually identified by increased colour flow, high doppler shift and low resistance.

CT (Fig. 31.16) is used to diagnose bony lesions, provide cross-sectional details and detect the presence of calcifications like phleboliths in venous malformations and haemangiomas. Most scans can be done in less than a minute with quick acquisition time. Reduced imaging time and low cost compared to MRI make contrast CT widely used for diagnosing soft tissue vascular lesions. Surveillance imaging with CT is not recommended due to increased exposure to ionising radiation.

MRI (Fig. 31.17) is the most preferred and accepted imaging for diagnosing and monitoring soft-tissue vascular lesions of head and neck. Its superior contrast resolution, in-depth soft-tissue assessment and non-exposure to ionising radiation, makes it the investigation of choice for these lesions. Haemangiomas and VMs show intense enhancement with MRI. AVMs and LMs show minimal enhancement.

Fat-suppressed T2-weighted imaging is used to discriminate these lesions among each other. Intense T2-weighted signal is seen with VM's and macro-cystic LM's due to cystic spaces within them and pooling of slow-flowing blood or lymph. Moderate signal intensity is seen with haemangiomas and vascular neoplasms due to their cellular composition. Mild T2-weighted signal is seen with AVM's reflecting tissue oedema.

Long acquisition time (at least 30 min) and increased cost of imaging limit its use [22]. Use of sedation or anaesthesia is required for infants, children and uncooperative adults.

Angiography (Fig. 31.18) is usually reserved for therapeutic endovascular interventions. Angiography includes arteriography, venography and injection of direct intralesional contrast agent. This provides good resolution (spatial and temporal) of the vascularity and also permits catheter-induced percutaneous therapy. Arteriography is used for the evaluation of high-flow vascular lesions. Its use is limited due to the invasive nature and use of ionising radiation.

DSA (Fig. 31.19) should be reserved for patients undergoing endovascular treatment. DSA is used for diagnosis of AVM's where the feeding artery, draining vein, nidus connecting artery and vein can be clearly imaged [23] and simultaneous embolisation can be performed, by an interventional radiologist.

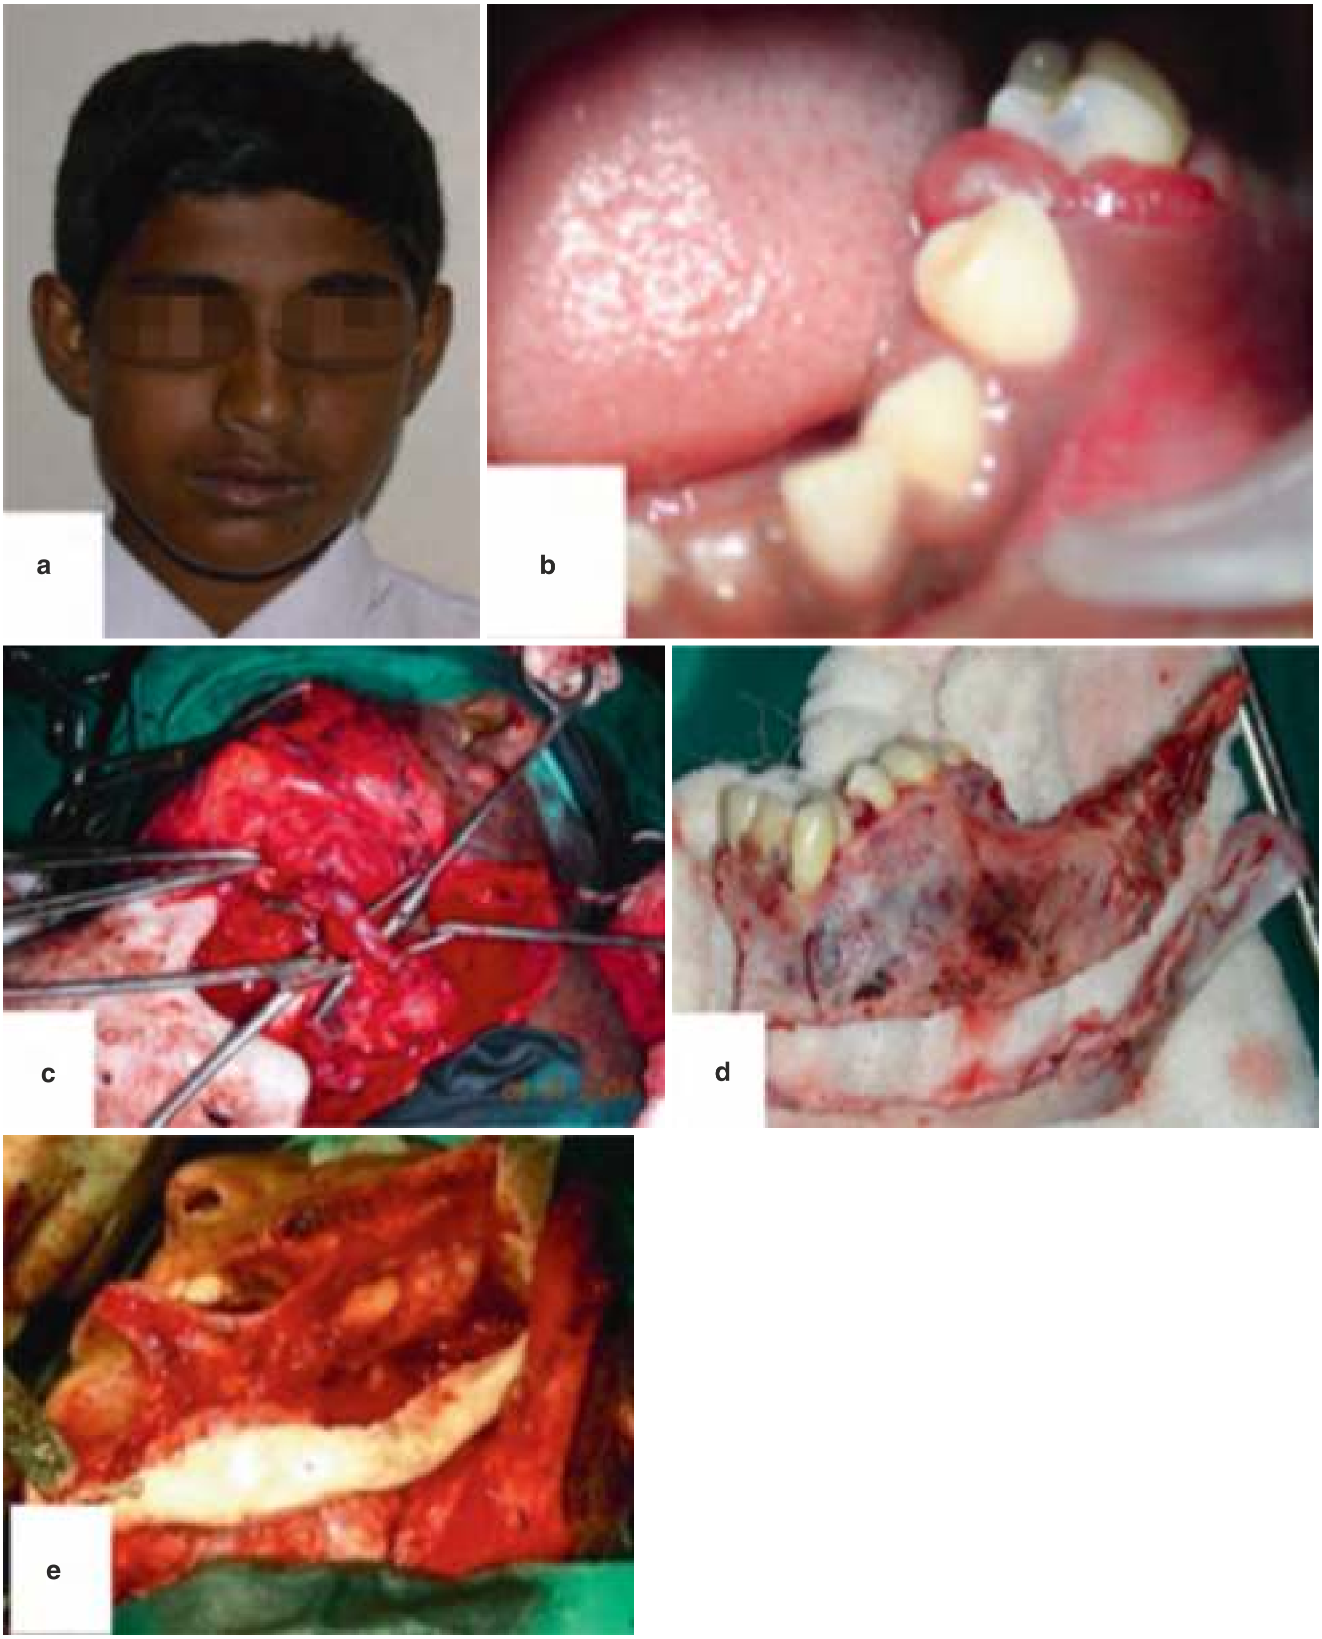

Fig. 31.13 Bleeding following dental extraction—Extracorporeal currettage of high-flow bony vascular lesion and fixation of mandible ((**a**) pre-operative, (**b**) intra-oral, (**c**) ligation of main feeder, (**d**) extra-corporeal currettage and excision of diseased bone and (**e**) fixation of mandible as the free graft)

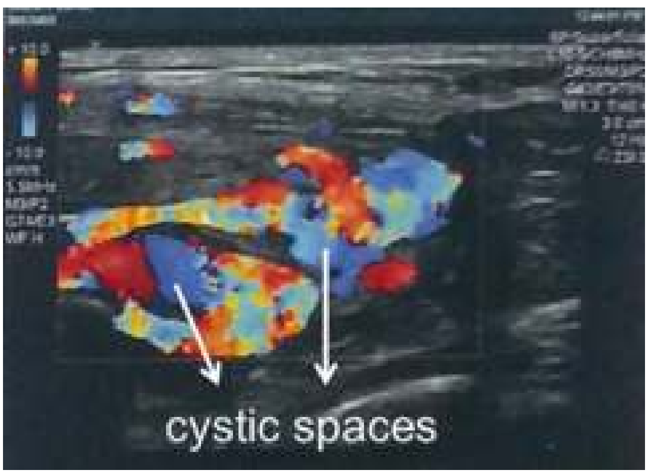

Fig. 31.15 Coloured Doppler Ultrasound image of AVM of neck showing multiple cystic spaces filled with colour (flow towards the transducer seen in 'red' and away in 'blue', lighter shades of colour depict higher velocity)

Multi-planar dynamic contrast-enhanced MRI is preferred for extensive vascular malformations of the head and neck, especially in lesions involving aerodigestive tract, neural and vascular structures.

31.6 Medical and Interventional Management

Correct diagnosis is important for selecting the appropriate therapy for vascular anomalies.

> The aim of managing complex vascular lesions should be to relieve acute symptoms like pain, swallowing and airway problems, prevent and treat thromboembolic events and correct the cosmetic impairment caused by them.

> The type of vascular anomaly and its flow characteristics, determine the mode of management.

> These mostly fall into:
>
> - Medical line of management,
> - Interventional therapy and
> - Surgical management.

Congenital haemangiomas, low flow venous malformations and lymphangiomas can be considered for treatment with systemic and sclerotherapy. Residual and large lesions are usually treated with surgery. AVM's and high-flow malformations have been mostly treated using embolisation with or without surgical excision/debulking successfully.

The author's wide experience in the surgical management of most low- and high-flow lesions has provided acceptable and predictable results.

In *haemangiomas*, a '*wait and observe*' strategy is preferred. Involution is seen in more than 85% of patients. If a malignant lesion is suspected, a biopsy with a request for GLUT-1 immunostaining is required to confirm its true nature [24]. Active intervention is considered if the lesion is

- Large in size causing obvious facial asymmetry
- Multiple with systemic changes like high-output cardiac failure.
- Adjoining or involving important structures like airway, eye and ear causing—vision, hearing, airway or swallowing problems.
- Recurrent and persisting ulcerations

Propranolol (Fig. 31.20) is the first line of treatment and is best to involve a paediatrician to monitor the dosage and systemic complications associated with it. Propranolol causes vasoconstriction and possibly reduced expression of pro-angiogenic factors of the haemangioma growth phase, leading to apoptosis of capillary endothelial cells.

Treatment during the proliferating phase is given to prevent impending functional or aesthetic complications especially

Fig. 31.20 Rapidly involuting congenital Haemangioma (RICH) of right face treated with propanolol therapy ((**a**) pre-treatment, (**b**) post-treatment)

near vital areas like eyes and ear. In the absence of contra-indications to propranolol like sensitivity to beta-blockers, bronchospasm, hypotension or bradycardia and after having a routine haematological and biochemical assessment by the paediatrician, a dose of 1 mg/kg/day in three divided doses may be initiated and titrated up to 2 mg/kg/day. This is given for 12 months or longer according to the response. Meticulous dose adaptation is important to prevent adverse effects. These could be bradycardia, increased airway resistance, bronchial obstruction and hypotension.Long-term effects of propranolol are still not known and other drugs like timolol have been tried for superficial and peri-ocular lesions. Invasive therapies are almost never required to treat these lesions.

Although propranolol has replaced the use of *systemic steroids* as the first line therapy for haemangiomas, intralesional therapy for localised lesions with, Triamcinolone may be used with a dose of 2 mg/kg every 4–6 weeks depending on the response. It is known that one-third of patients do not respond to treatment with steroids. Systemic steroids are sometimes given in conjunction with propranolol after consulting with the paediatrician.

Rebound growth being a problem with systemic therapy using propranolol and/or steroids, the dose is always preferred to be tapered-off before discontinuing following resolution of the lesion.

Embolisation is considered in patients with high-output cardiac failure and large-aggressive lesions causing problems with haemostasis.

Surgery is considered between 2 and 4 years of age after having attempted medical treatment to minimise deformity involving eyes, nose and lips and other areas of face.

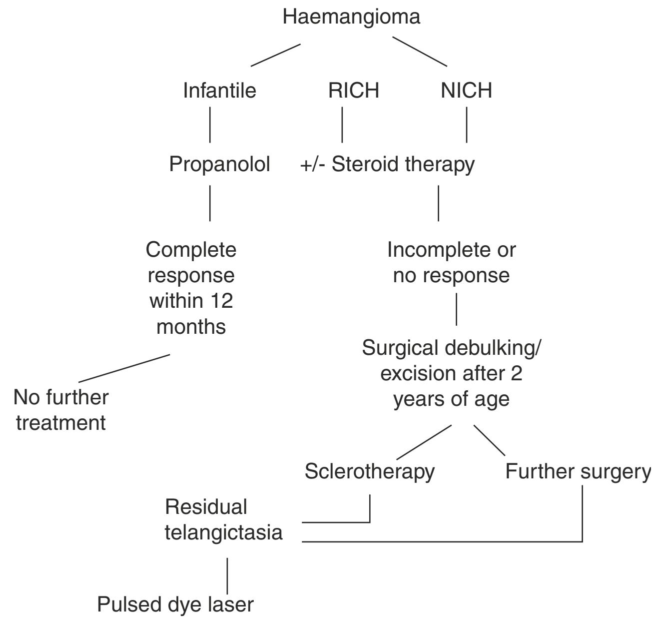
Pulsed dye laser was used in past for coagulating the surface of ulcerated lesions. This is now used for the treatment of surface residual telangiectasia, usually after 10 years of age (Algorithm 31.1).

Minimally invasive percutaneous sclerotherapy is used widely for the treatment of venous malformations. A wide range of agents are known to be used in the literature. There is no consensus on choice of sclerosant to be used. Commonly used sclerosants [25] are pingyangmycin (PYM), absolute ethanol, OK-432 (picibanil), ethanolamine oleate, bleomycin, polidocanol, doxycycline and STS (Sodium tetradecyl sulphate).

PYM [25], also known as Bleomycin A5, is the most commonly used single-drug therapy for the treatment of cervicofacial malformations. Transient fever and swelling are commonly seen side effects. Skin ulceration and subcutaneous tissue atrophy are scarcely seen complications.

Absolute ethanol [25] causes alteration in cellular proteins and hence damages the endothelium of the vascular wall leading to obliteration of its lumen. Common complications include, nerve injury, necrosis and ulceration of skin.

OK-432 [25] is a lyophilised preparation of low-virulence bacteria, group A Streptococcus pyogenes, incubated with benzyl- penicillin. It causes, induction of various cytokines. The inflammatory response caused by this remains localised and causes endothelial damage. The complications include local swelling and transient facial nerve palsy.



Algorithm 31.1 Management of Haemangioma

Ethanolamine oleate [25] is an emulsion of fatty acids, which induces thrombosis and damages the endothelium. Complications like ulceration and necrosis of skin are known but infrequently observed.

Bleomycin [25] was first used in the treatment of cystic hygromas (now lymphatic malformation). It is now used widely for management of lymphatic and venous malformations. It inhibits DNA synthesis and has a non-specific inflammatory reaction on the endothelial cells. Adverse effects of bleomycin are minimal and transient, mostly being localised pain and swelling. Skin infections in the area of injection are seen less commonly. Some people report with occasionally severe nausea.

Polidocanol [25] is a non-ionic detergent, causes absorption at the cell membrane and leads to lysis of endothelial lining. Superficial necrosis of skin or mucosa is a known complication with Polidocanol.

Doxycycline [25] belongs to the tetracycline group of antibiotics. Its mode of action is not yet clear, but its effects are known to be due to inhibition of matrix metalloproteinases and cell proliferation. It also causes suppression of vascular endothelial growth factor during angiogenesis and lymphangiogenesis. This further leads to dense adhesions and fibrosis due to collagen and fibrin deposition. Macrocystic LM's show a better response to treatment with doxycycline in comparison to micro-cystic LM's. Haemorrhage, cellulitis, pain and transient oedema are commonly seen complications. Scarring, skin excoriation and horner syndrome are seen less commonly. These adverse effects are self-limiting and likely to be related to the sclerosing effect rather than a side effect of the medication itself.

STS [25], also known as *sotradecol*, causes denaturation of proteins like clotting factors due to disruption of the normal architecture of the lipid bilayer in cell membranes of endothelial cells. This causes fibrosis and occlusion of vessels. It is not known to have any major complications so far.

Lymphatic malformations are treated depending on the type and location in head and neck. As mentioned previously, these lesions can cause pressure on the airway, aerodigestive tract and enlarge due to repeated infection or haemorrhage into the lesion. In the majority of patients with macro-cystic LMs, sclerotherapy with *Picibanil (OK-432)* has shown good results. Patients may develop inflammation at the site of injection and fever, which is managed symptomatically. Micro-cystic LMs may require systemic therapy with *Sirolimus* or surgery as they do not always respond to Picibanil. Sirolimus is a natural macrolide secluded from Streptomyces genus (Streptomyces hygroscopicus). It causes a decrease in the vascular endothelial growth factor (VEGF) and is a key regulator in lymphangiogenesis and angiogenesis.

Bleomycin is used widely for the treatment of VMs and microcystic LMs. The mechanism of action on micro-cystic disease is not completely understood and may involve derangement of tight junctions between endothelial cells or induction of endothelial mesenchymal transition. The overall response is favourable but complete response is seen in only about 20–57% [25]. The author follows a protocol of intralesional injection of 15 IU Bleomycin in 5 ml of fresh normal saline, administered every 15 days. Most patients show a response in 3–4 sittings (Fig. 31.21). Lymphatic malformations are known to cause sec-

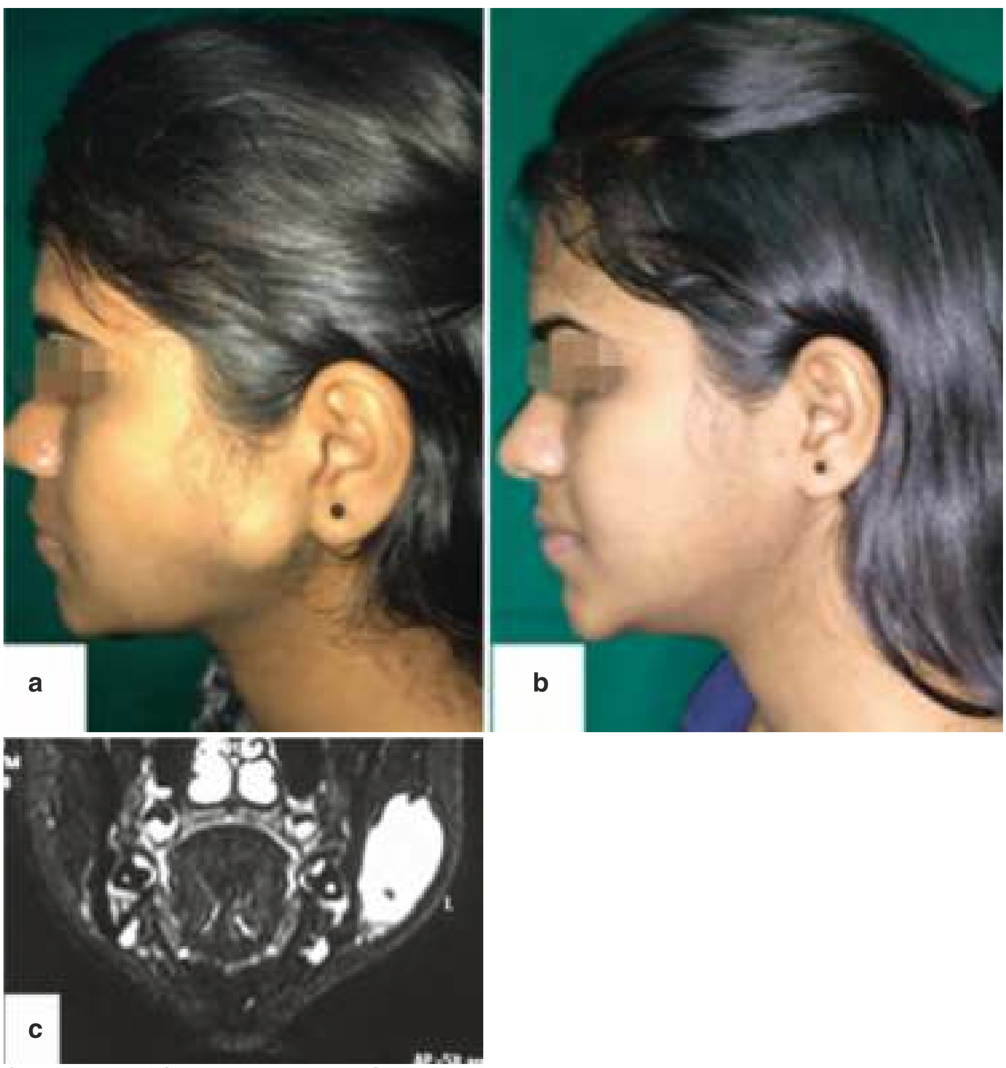


Fig. 31.21 Venous malformation-Left cheek ((**a**) before sclerotherapy, (**b**) after sclerotherapy, (**c**) pre-treatment T2-weighted MRI image)

ondary skeletal deformities, which are addressed due to functional or cosmetic reasons as necessary.

AVMs are the most challenging type of vascular malformations to manage due to their aggressive nature. They tend to cause progressive facial deformity and pose a significant systemic risk. They are high-flow lesions that typically demonstrate a nidus with arterial feeders, arteriovenous connections and enlarged veins. Schobinger's class III and IV demand aggressive management with combined embolisation, surgical excision and reconstructing the residual defect. Trans-arterial and trans-venous catheter angiography are commonly used for assessment, examination of the nidus and location of arterio-venous shunting. A few lesions can be controlled with frequent embolisation. The nidus must be treated to get control over the lesion. *Catheter embolisation causes* obliteration of the nidus in order to prevent a further increase in size and haemorrhagic complications. This can be either *endovascular* (Fig. 31.22) as used for large AVM's with aberrant feeders or *percutaneous* (Fig. 31.23) used for more superficial lesions. The feeders are sequentially embolised from distant to proximal feeders. Embolisation can be used for pre-surgical occlusion of feeder vessel on the same day of planned surgery to minimise intra-operative blood loss.

> Commonly used embolic agents are:
>
> Ethanol,
> Cyanoacrylate (glue),
> Coils, polyvinyl particles,
> Onyx—a liquid ethylene vinyl alcohol copolymer.

Kaposiform Haemangioendotheliomas (KHEs) are treated with hematological agents such as *vincristine, steroids or sirolimus*. These systemic medications help in the resolution of KHE and associated KMP (Kasabach Merritt phenomenon). Surgical management of these lesions is usually not required but small lesions can be removed in toto with early intervention.

31.7 Surgical Management

Unlike in the past, most low- and high-flow vascular anomalies are amenable to surgical management by either excision or debulking. Smaller-sized lesions are almost always excised completely. In contrast, larger-sized lesions are mostly debulked and need multiple procedures. External carotid artery (ECA) control is used to have reasonable control before and during procedures involving high-flow lesions. This is partly because of collateral blood supply from the opposite side.

For simplicity, the author's own anatomical classification is followed as it makes the understanding of the surgical approaches and the rationale behind them more lucid and comprehensible. Also, the concept of 'Corset suturing' will be explained, which has been proved to be an asset in management of large low-flow vascular anomalies.

31.7.1 Surgical Anatomy

An understanding of the different layers and planes of dissection in the head and neck is important to approach and treat these vascular anomalies. The commonest areas involved in the head and neck are cheek, lower and upper lips, eyelids, pre-auricular, mandible, submandibular, submental, upper neck, posterior and lateral oropharynx. The glottis, sub-glottis and lower neck are less commonly involved. Lymphovascular malformations are seen occupying scalp and orbit commonly.

Layers of face from superficial to deep are—skin, subcutaneous tissue, SMAS layer, parotid fascia (pre-auricular)/deep cervical fascia (sub-mandibular), salivary gland (parotid and sub-mandibular regions), muscle, periosteum and bone. The scalp has a loose areolar plane and all other tissues attached. The neck has vital structures like the carotid artery, jugular vein, spinal accessory nerve, cervical plexus and other muscles superficial and deep to them.

31.7.2 Case Selection

According to the author's classification, vascular malformations were categorised into five types based on their anatomy and depth of location in the head and neck. This is a good guide for selecting the type of surgical management and reconstruction.

- In type-I, superficial lesions require excision of skin or mucosa. Local or regional flaps have been used in reconstruction of the residual defect.
- Type-II, sub-mucosal lesions require complete excision after elevation of skin flaps.
- Type-III, lymphovenous malformations or venous malformations involve salivary glands and are excised along with the affected gland.
- Type-IV, intra-osseous lesions require excision with removal of involved bone and reconstruction of the residual defect as necessary.

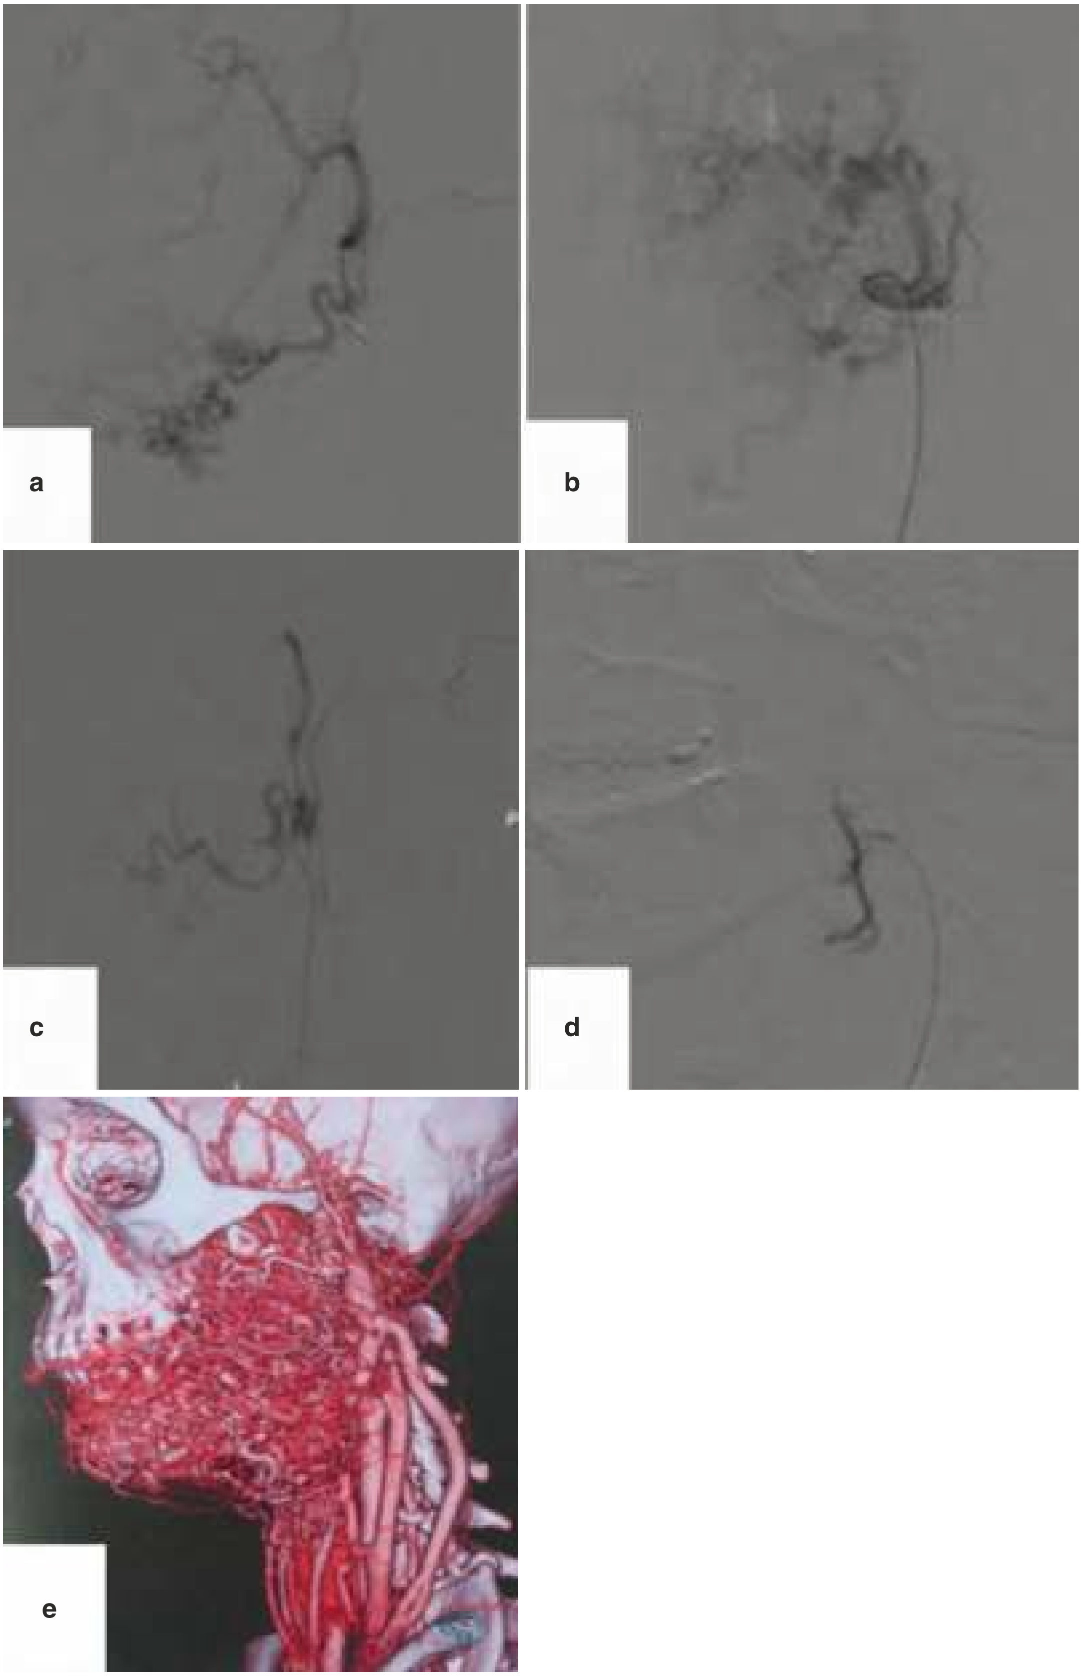

Fig. 31.22 Sequential endovascular embolisation of left cheek AVM ((**a**–**d**) progressing blockage of blood supply to AVM, (**e**) 3D reconstructed view of the vascular network)

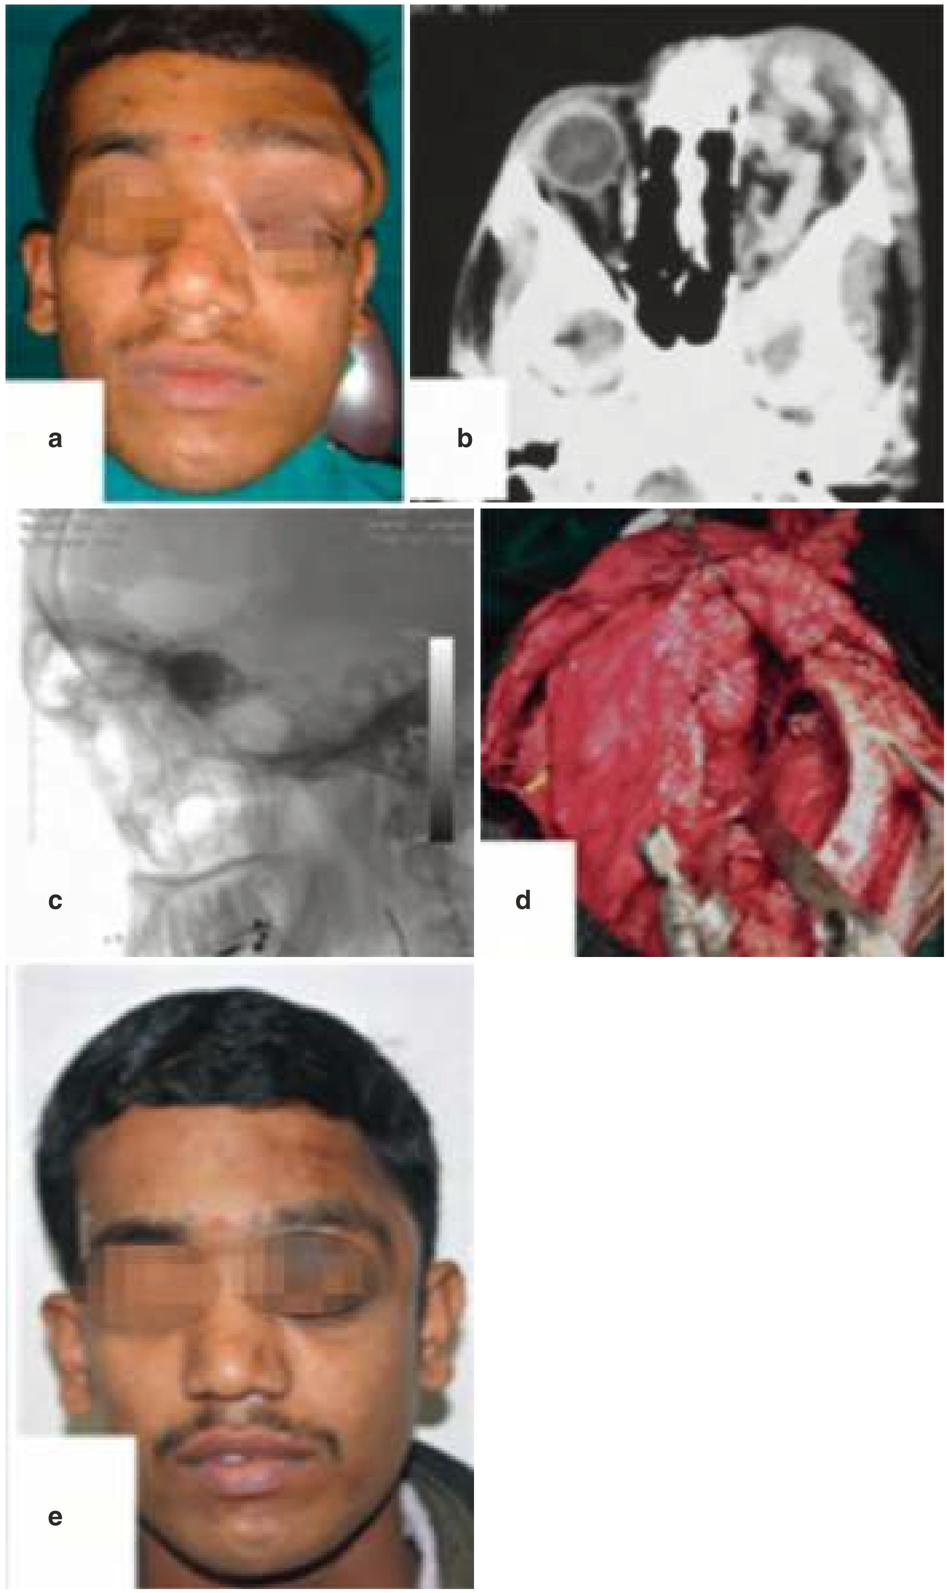

Fig. 31.23 AVM of left supra-orbit ((**a**) pre-operative, (**b**) CT with contrast, (**c**) percutaneous embolisation, (**d**) Surgical excision via haemicoronal approach, (**e**) post-operative)

- Type-V lesions involve deep visceral spaces, such as the parapharyngeal or infra-temporal fossa and usually require mandibular access osteotomy for complete exposure and complete removal of the lesion.

The above procedures can demand either endovascular embolisation, intra-lesional embolisation or ECA control prior to attempting excision or debulking of these lesions.

31.7.3 Technique of External Carotid Artery (ECA) Control (Fig. 31.24)

The ECA of the involved side is exposed through a cervical incision, which often forms, part of the access for removal of the malformation. The sternocleidomastoid muscle is retracted posteriorly at the level of the greater cornu of the hyoid bone, exposing the carotid sheath. The external carotid distal to the carotid bifurcation is identified. The vessel is snared with a vascular sling passed through a rubber catheter. Gentle strangulation of the vessel can be accomplished by advancing the catheter. This additional compression of the vessel serves to reduce blood flow to the lesion. In demanding situations, the ECA can be ligated. Many times due to risk of collateral blood supply to these lesions, ECA control is an adjunct to achieving haemostasis along with aggressive local control.

Fig. 31.24 ECA control. Copyright: Authors own publications from IJOMS 2011

31.7.4 Corset-Suturing Technique (Fig. 31.25)

Corset suturing [26] is a proven technique in management of large low-flow venous malformations of head and neck, especially in lesions where complete excision is not practically possible and also those in close proximity to important structures like airway, facial nerve, spinal accessory nerve, internal jugular vein and in medically compromised individuals.

'Corset', is a garment worn to hold and train the torsoin to a desired shape for aesthetic or orthopaedic purposes. The procedure employed is raising a flap in the sub-SMAS or sub-cutaneous plane depending upon the type of lesion followed by placement of a bioresorbable suture (polydiaxanone) that runs in a continuous vertical looping fashion from sub-cutaneous to deep layer and from one end to another, incorporating the lesion within the suture. The suturing is advanced at regular and equidistant intervals to involve the bulk of lesion resulting in compression of the vascular spaces and causing obstruction of the afferent and efferent vessels. This reduces the risk of bleeding, swelling and size of lesion. The blood supply gets interrupted due to obstruction of afferent vessels. In large lesions, this suturing should be done parallel to each other covering the whole lesion from superior to inferior and medial to lateral, which would occlude the regional vascular channels, interrupting and obstructing the blood circulation in the tumour. These sutures must be tightened cautiously, slowly and progressively to achieve gradual and complete strangulation of vascular channels until complete closure of their lumen is assured. This procedure decompresses the lesion completely and reduces the risk of post-operative haemorrhage. The excess skin flap is excised, drains are secured followed by primary closure. The final scar is fairly acceptable, as all incisions are originally placed within the skin tension lines.

31.7.5 Approaches and Excision/Debulking

Superficial Type-I (Fig. 31.7) lesions mostly derive from the reticular dermis and is treated with direct excision and closure or local-flap reconstruction. Care is taken to place incisions along the skin tension lines of the face and neck to avoid unaesthetic results. It is challenging to select these lines in young individuals and every attempt is made to lay these incisions on prominent skin creases like nasolabial, mentolabial, pre-auricular and lower skin crease of neck.

Type-II (Fig. 31.8) lesions are approached by raising skin flaps using the following incisions, commonly—pre-auricular with either neck skin crease extension or temporal extension, neck crease incision alone, nasolabial skin crease incision, mid-face Weber-fergusson incision and coronal approach. Every attempt is made to maintain a sub-SMAS

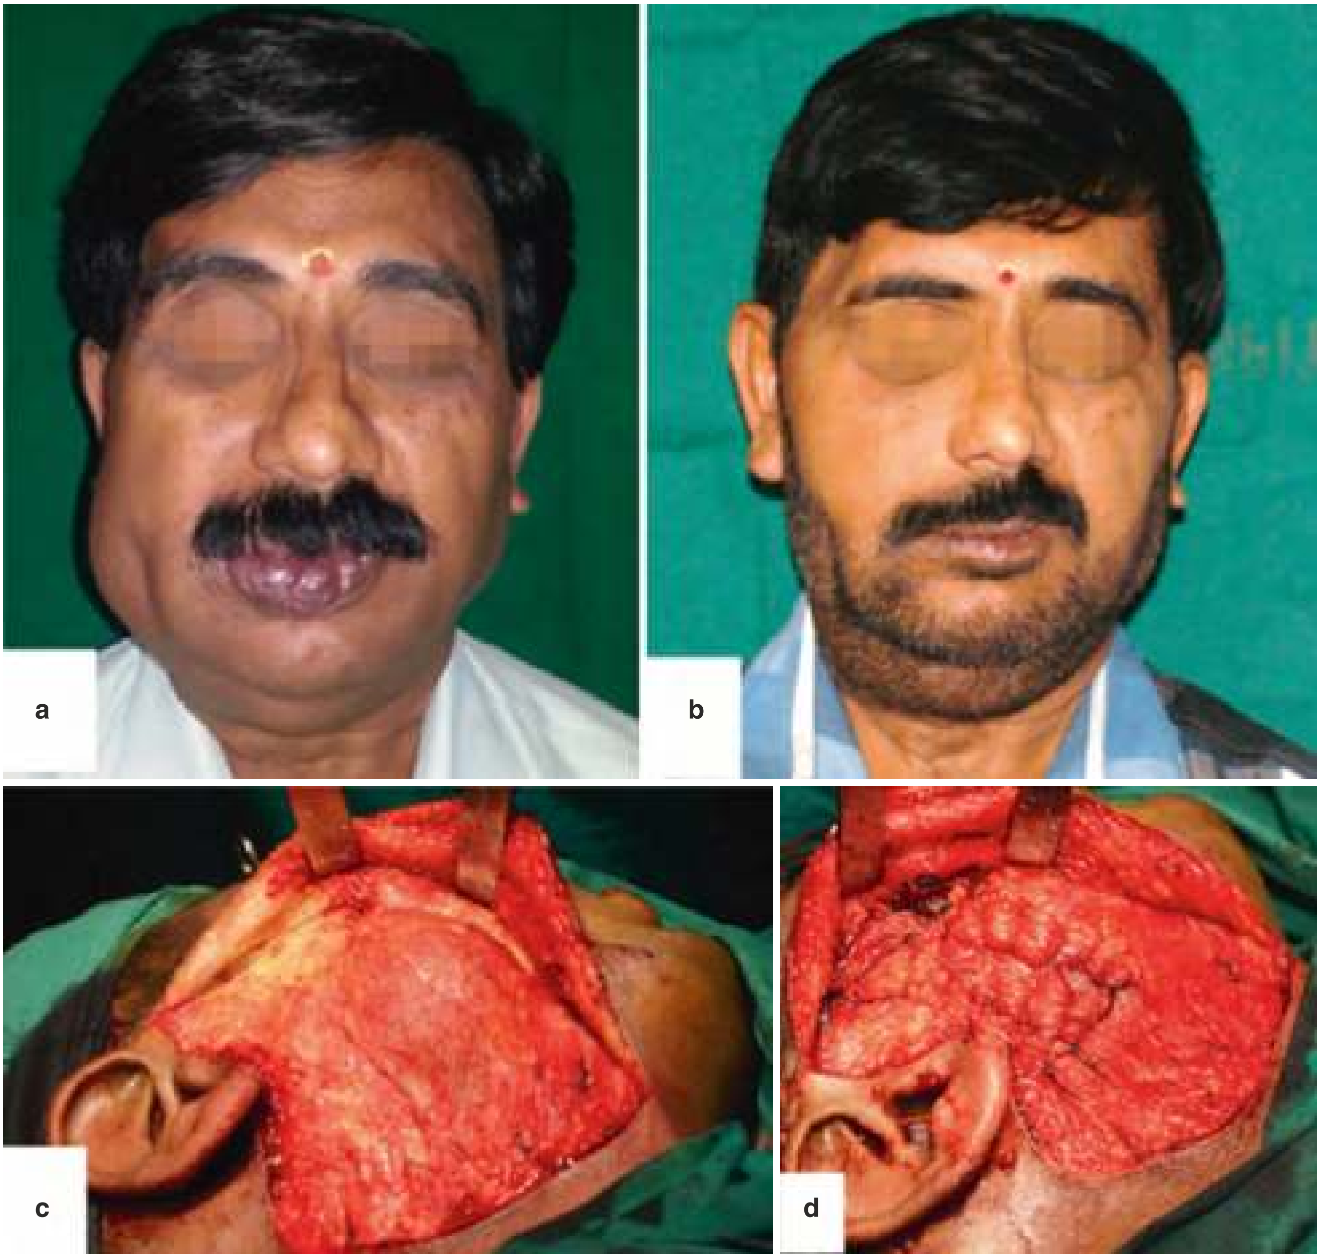

Fig. 31.25 Venous malformation right face, lower lip ((**a**) pre-operative, (**b**) post-operative, (**c**) lesion exposure and (**d**) corset suturing of lesion). (Fig. 31.25 a,b,d - copyright authors own publication IJOMS 2018)

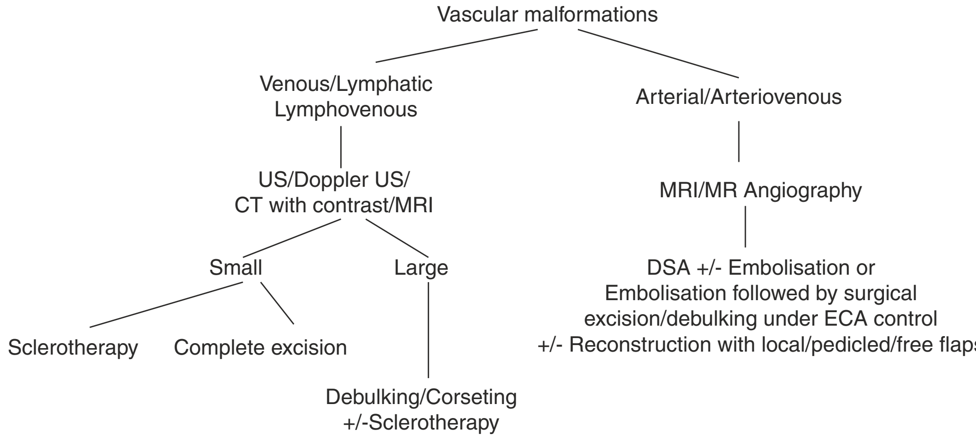
plane but vascular anomalies being composite in nature can demand modifications. There is always a risk of thinning the skin flap excessively and care should be taken to avoid button-holing and avoiding avascular necrosis. The lesion is excised completely or debulked depending on the size. Corseting is used for large low-flow malformations as described above.

Tongue lesions are mostly excised in toto or debulked in a V shaped fashion to achieve primary closure.

Type-III (Fig. 31.9) lesions are approached the same way as Type-II. Being deeper in nature, the gland is sacrificed with some risk of permanent facial nerve damage. Use of 'corseting' in these cases has shown good results with complete recovery of facial nerve weakness over a period of 1 year.

Type-IV (Fig. 31.10) lesions like other types are rarely seen on their own and are usually in combination with Type I, II or V. These lesions are treated with curettage or segmen-

Algorithm 31.2 Management of Vascular malformations



tal resection of bone followed by reconstruction (Fig. 31.13). There are reports of extra-corporeal curettage of segmentally resected lesions and re-fixation to maintain bone continuity.

Type-V (Fig. 31.11) lesions commonly require access to osteotomies like mandibulotomy, segmental or complete Lefort-I, rhinotomy or zygomatic swing osteotomies to gain adequate access. The lesions are uncapsulated and rarely excised completely but improve the quality of life and reduce risk of mortality due to airway obstruction and haemorrhage. In the authors' experience, use of corseting has proven to be beneficial in these cases.

Excess skin flap is always excised to give a near normal appearance. Use of an adequate number of drains and meticulous haemostatic closure is imperative to achieve acceptable and aesthetic results.

Most large lesions require further excision and debulking procedures as the age advances until growth is achieved. Large low-flow lesions have potential to be excised completely secondarily, following prior corset suturing.

Algorithm 31.2 summarises the management of vascular malformations.

31.8 Complications

Vascular lesions can have complications ranging from none (like in haemangiomas) to bleeding, ulcerations and infection. Superficial lesions and ulcerations benefit with the use of pulsed-dye laser. Bleeding can usually be managed with compression dressings.

Large venous and lymphatic malformations can cause local swelling, pressure effects on trachea and oesophagus, pain and infection, demanding immediate treatment like embolisation or surgical debulking along with control of airway and infection.

The two common complications of LMs are bleeding within the lesion and infection. Bleeding can be seen spontaneously or as a result of trauma. This further causes immediate and painful enlargement of the lesion with associated ecchymosis. Analgesia and observation usually suffice for symptomatic management. Prophylactic antibiotics can be given in the case of profuse bleeding. Long-term intravenous broad spectrum antibiotics may be necessary covering pathogens of head and neck, especially in high-risk patients. Haemorrhage and infection can sometimes transform a macro-cystic lesion into a micro-cystic type with associated scarring. LMs are known to increase in size in the presence of a viral or bacterial infection. This is usually self-limiting and thought to be due to changes in the lymphatic flow. Bacterial superinfections can be fatal causing ascending cellulitis and septicaemia. Any infection in cervicofacial LMs can cause obstruction of the upper airway and oesophagus causing dyspnea and dysphagia.

Incompletely treated AVMs tend to recur and continue to grow. They should not be underestimated.

31.9 Recent Advances

Micro-cystic lymphatic malformations have always been challenging cases to be treat, especially involving extra- and intracranial areas of head and neck. Currently available treatments have limited effectiveness and high risk of complications. Techniques using lymphography and idiocyanine green have been used to locate the exact location of afferent and efferent lymphatic flow and performing a lymphatic-venous anastomosis has been described in treating these lesions [27].

Vascular-disrupting agents (VDA's) [28] are a group of 'vascular targeting' agents that show selective activity against tumour vascular networks, causing severe obstruction in their blood flow and subsequent necrosis. These have been investigated for a long time but haven't yet actively been used in the treatment of vascular lesions of the head and neck. Micro-tubule-depolymerising agents are the largest group of small molecular weight VDAs, which include lead compound disodium combretastatin A-4 3-O-phosphate (CA-4-P) [28], and are under clinical development for cancer. VDAs can also interfere with angiogenesis and can be potentially used as novel drugs for the treatment of conditions with excessive angiogenesis, in addition to cancer.

3D remodelling and bioprinting of areas affected by vascular anomalies with their feeder vessels are under study, for training and familiarising one with possible complications during procedures like embolisation and surgery.

31.10 Conclusion

Vascular anomalies are a diverse group of lesions requiring knowledge and skill to identify, accurately diagnose and treat adequately. Most of these lesions present as a complex problem with a combination of different types and other systemic complicating features. This demands a multi-disciplinary team comprising maxillofacial surgeon, vascular surgeon, pediatrician, reconstructive surgeon, anaesthetist and speech and language therapist with extensive training, understanding and experience to tailor an appropriate treatment plan. Selection of sclerosants should be with caution to minimise their side effects. Surgery has an important role in achieving quicker and long-term stable results in most cases.

32 Non-surgical Modalities of Facial Rejuvenation and Aesthetics

Arun Kumar Panda and Aarti Chowdhary

32.1 Introduction to Ageing Face

32.1.1 Facial Changes Due to Ageing

The Face is a mirror of what we are from inside. It is like an opera that reveals a person's inner self, nature, personality and health. The signs and symptoms of age, illness, deficiencies and personality traits show on our faces. A lot can be postulated by just observing the different facial expressions of a person. A minuscule defect on the face engraves an exaggerated long-lasting impression on a person's mind and soul.

Ageing is a process which cannot be defied. With the passage of time, every individual goes through a phenomenon of complex transformations which takes away the youthfulness. The various signs of ageing seen on the face include recession of hairline, wrinkles on the forehead, drooping of the upper eyelid, hollowness in the under-eye area, deepening of nasolabial fold, folds on the face, sagginess of skin at the border of mandible, etc. (Fig. 32.1). Today, with the changing cultures and requirements in the profession, every individual wants to look better than what he or she is.

As the saying goes "Beauty has no age", more and more elderly people also want to have their face rejuvenated. So, today we have a range of patients of vast age variations who want to have a more rejuvenated look. The various modalities for rejuvenating the ageing face require fine skill and artwork combined with scientific knowledge and understanding of the whole face including scalp, forehead, periorbital area, perioral area, neck, etc., so as to achieve a more youthful appearance.

Time and technology has evolved. For many years the standard had been chemical peels as the non-invasive procedure to facelift as the invasive modality for face rejuvenation. Today, we have a vast range of procedures and technologies to counter ageing phenomenon and provide a rejuvenated appearance. We shall discuss the various non-surgical modalities in this section which physicians are adopting to treat patients with a wide range of Facial Aesthetic concerns.

The ageing of human face is a highly complex, irreversible and progressive biologic phenomenon that occurs with the ticking of time. The main factors leading to facial ageing include gravity, bone remodelling, subcutaneous fat redistribution and loss, hormonal imbalance, chronic sunlight, pollution and smoking. Other environmental factors that allegedly affect facial appearance include mental stress, nutritional deficiencies, work habits, drug abuse and disease. This dynamic process is a synergistic effect of various factors and actually takes place at 4 distinct levels (the 4 S levels): Skin, Subcutaneous tissue, SMAS and facial Skeleton.

32.1.2 Ageing of Skin

The epidermis contains keratinocytes and dead corneocytes. The basal cells at the stratum basal divide to form keratinocytes, produce keratins and drift upwards as they mature. By the time keratinocytes reach the most superficial layer, they lose their nucleus and cytoplasmic organelles and are known as corneocytes. In a total period of 40–50 days, the keratinocytes come to the surface and corneocytes exfoliate. This time taken for the process of keratinisation, that is maturation of keratinocytes along with shedding of corneocytes, is known as the turnover time.

The natural process of desquamation sheds off the dry, old, hardened skin cells and gives way to the new cells to

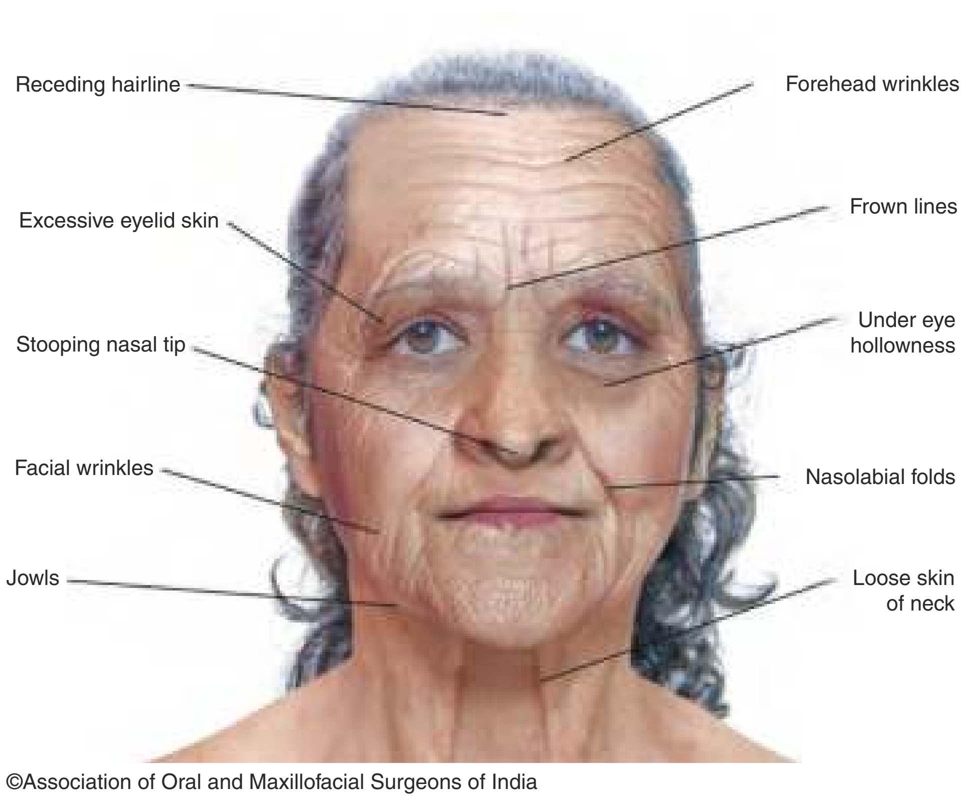

Fig. 32.1 Various signs of an ageing face include but not limited to forehead wrinkles, droopy eyelids, under-eye hollowness, deep nasolabial folds, jowl formation, loose neck skin and thin lips

come to the surface. This process also eliminates damaged and contaminated cells that carry pollutants and microorganisms from the environment.

The specialised fibroblasts in the dermal layer produce two key proteins-collagen and elastin. Collagen constitutes 80% of the dermis and provides strength and firmness to the skin. While elastin, as the name implies, provides elasticity to the skin and enables the skin to bounce back to its original shape after it is stretched, thus preventing wrinkles.

Skin ageing is a dynamic mechanism that transpires due to two basic factors:

- Intrinsic or Innate factors are insidious deteriorating elements that are influenced by internal metabolic processes, genetic programming, cellular metabolism and hormones;
- Extrinsic or Exogenous factors include Ultraviolet rays in the sunlight, cigarette smoking, environmental pollution, etc.

Intrinsic ageing is an inevitable natural ageing process which commences as early as mid-20s. It consists of internal physiological factors that cause inherent degenerative process in the body. Dead corneocytes do not desquamate as swiftly as expected and the turnover of new epidermal cells decreases somewhat. In the dermis, the production of collagen and elastin slows down. The cumulative effect which is seen in case of the inherent ageing includes fine wrinkling, parched, thin and transparent skin and depleted elastic nature of the skin.

Extrinsic ageing is because of the aggregated damage caused by environmental factors such as sun's UV radiation, gravity, sleeping posture, pollution, smoking, exposure to chemicals, etc. These exogenous factors along with the innate factors cause premature ageing of our facial skin. The face, which is most commonly exposed part of the human body to the UV radiations of the sun, undergoes ageing prematurely than any other part. Photoageing with recurrent sun exposure causes the skin to lose its capability to renovate and thereby accumulating damage. Recurrent and continual UV exposure disintegrates collagen and impedes the synthesis of new collagen. Alongside, there is a breakdown of elastin. This causes the facial skin to become slack, wrinkled and leathery much earlier than a sun-protected skin.

Gravity constantly works on different parts of our facial skin. As the skin elasticity reduces with age, the effects become evident. It precipitates jowls, nasolabial fold, drooping of eyelids, elongation of ears, etc. (Fig. 32.2).

Sleep lines are wrinkles that are etched on the facial skin of the people who sleep with the face pressed on the cushion or sleep on the sides.

Cigarette smoking over a period of time causes many biochemical alterations in our body. It has deleterious effects on skin and expedites the ageing process. The nicotine causes vasoconstriction thereby impairing the supply of oxygen and

©Association of Oral and Maxillofacial Surgeons of India

Fig. 32.2 Influence of ageing on skin. Facial wrinkling, jowls and droopy eyelids clearly demonstrate the ageing process

important nutrients, such as vitamin A to the skin. Many of the over 7000 chemicals released from the burning cigarettes cause increased production of matrix metalloproteinases (MMP) that causes degradation of collagen and causes abnormal creation of elastosis materials. These cause premature facial skin wrinkling.

32.1.3 Ageing of Subcutaneous Tissue

The subcutaneous fat gives the volume and shape to the face. As explained by Rohrich and Pessa [1], the subcutaneous fat is distributed throughout the face in a multidimensional fashion and is highly compartmentalised. A youthful face is characterised by a smooth transition between these subcutaneous compartments. The superficial musculoaponeurotic system (SMAS) divides this fat into superficial and deep layers. As explained anatomically by Rohrich and Pessa [1], the external recess is in between the skin and SMAS while the internal recess lies under the SMAS and is adherent to the periosteum. The superficial and deep fat recesses are as explained in Fig. 32.3.

Furnas in 1989 first described the osteocutaneous ligaments within the cheek that anchor the dermis to the underlying fibro-osseous structures [2]. He outlined the zygomatic ligaments (McGregor's patch), the mandibular ligament, the platysma auricular ligament and the anterior platysma-cutaneous ligament that anchor the dermis and also support the midface soft tissue. Two theories explain the characteristic soft tissue changes that are distinguished during the mid-face ageing. The gravitational theory advocates that with the attenuation of the osteocutaneous ligaments, there is vertical descent of facial soft tissue which contributes to the deep creases of the ageing face [3]. The diminished strength of the ligaments is because the age-related elastosis and also because of the repeated animation of the muscles of facial expression.

Donofrio explained the volumetric theory in 2000. He suggested that it's the corresponding volume loss or gain in the adjoining areas of the face is what creates the deep creases of age [4]. This theory was later in 2007 reinforced by Lambros who stated that the ageing process was due to the relative deflation of certain fat pads, especially the deep fat pads [5].

32.1.4 Ageing of SMAS

The superficial musculoaponeurotic system is a multidimensional scaffold of organised fibrous tissue that connects the facial muscles with the dermis [6]. This fibromuscular layer also segregates the superficial and deep facial fat pads. Anatomically, the SMAS lies in the midface, inferior to the zygomatic arch and superior to the muscular belly of the platysma. It blends with the superficial temporal fascia and frontalis muscle superiorly, and with the platysma muscle inferiorly. Since it connects the facial muscles to the dermis, its purpose is to transmit, distribute and amplify the activity of all facial muscles [7].

As we age, and with the continuous use of the muscles of facial expression, the SMAS weakens and the strength diminishes. So, the ability to hold up the muscles, fat and the skin gets impaired. Combined with the effect of gravitational forces, the weakening causes the structures of the face to slump. The youthful appearance of the face changes as jowls are formed, the nasolabial fold deepens and the mandibular line angle becomes ill defined.

32.1.5 Ageing of Facial Skeleton

The bony skeleton serves as a framework for the soft tissues of the face including the skin, muscles and subcutaneous fat. The facial skeleton keeps changing anatomically throughout life with only degenerative and catabolic changes occurring after adolescence.

With ageing, the facial skeleton keeps resorbing in a very predictable manner and that contributes to the appearance of an aged face. Areas with strong tendency to resorb include the periorbital area, the midface, the perinasal area and the mandible (Fig. 32.4).

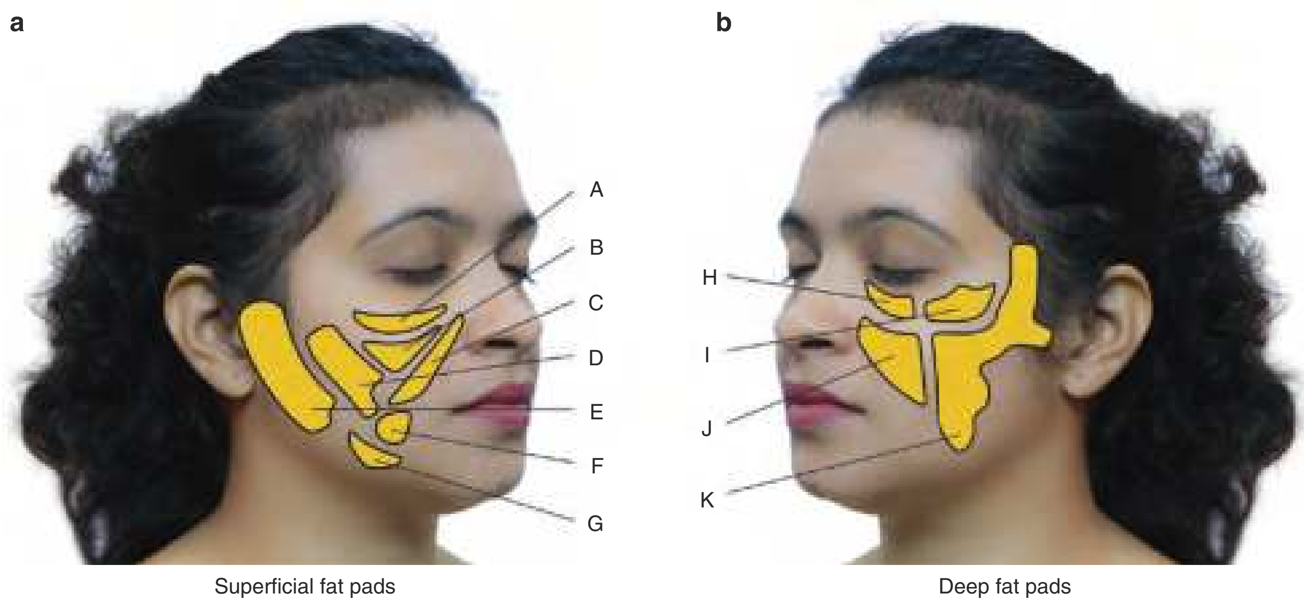

Fig. 32.3 (a, b) (**A**) Infraorbital fat, (**B**) Medial cheek fat, (**C**) Nasolabial fat, (**D**) Medial cheek fat, (**E**) Lateral cheek fat, (**F**) Superior jowl fat, (**G**) Inferior jowl fat, (**H**) Medial sub-orbicularis fat, (**I**) Lateral sub-orbicularis fat, (**J**) Deep medial cheek fat, (**K**) Buccal fat

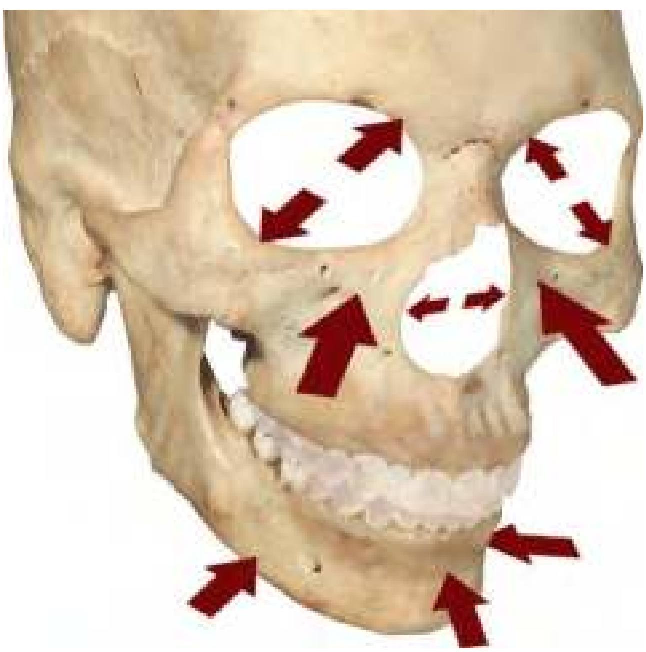

Fig. 32.4 Various areas of facial skeleton as marked are predominantly destined to resorb contributing to the appearance of aged face

The orbital aperture enlarges with age in all dimensions. The superomedial and inferolateral aspects tend to recede more which imparts the stigmata of periorbital ageing such as increased prominence of the medial fat pad, elevation of the medial brow and lengthening of the lid cheek junction [8].

The midface skeleton is formed by the maxilla medially and the zygoma laterally. With age, the maxilla recedes and the maxillary angle decreases by about 10° between the age of 30 and 60 years [9]. The piriform aperture enlarges with age, as the edges of the nasal bones recede [10]. The anterior nasal spine also retreats which reduces the skeletal support and thereby contributing to retraction of the columella, with a downward rotation of nasal tip and apparent lengthening of the nose [11]. In regards to the mandible, it is well established that the mandibular angle increases, the ramus height and mandibular body height and length decreases with age [12]. The above-mentioned skeletal resorption patterns contribute significantly to the appearance of an ageing face.

In the recent years, the demand for facial rejuvenation has increased exponentially. Individuals from every socioeconomic strata and from all age groups today desire a younger and rejuvenated look. Evolution of numerous surgical and non-surgical procedures has led to an increase in patient demands and expectations. Every aesthetic physician should understand the facial anatomy and the facial ageing process well so as to perform the procedures that would best suit the requirement of the individual to deliver the best of the results. The various non-surgical modalities of facial rejuvenation include the use of Botulinum toxin, dermal fillers, thread lifts, platelet concentrates and radiofrequency waves. Botulinum toxin and fillers are elaborated in the subsequent chapter. The following is a detailed description of the role of thread lifts, platelet concentrates and radiofrequency waves in achieving facial rejuvenation.

32.2 Non-surgical Facelift with Threads

Age-related changes on the face include remodelling in the facial skeleton and reorganisation of musculature, connective tissues, fat and skin. The dynamic process of ageing is unstoppable and it induces an ever-progressing slackness in the soft tissues that leads to a ptotic brow, jowl formation, ill-defined mandibular margin and deep nasolabial folds.

Gravity is an important factor that causes drooping of the upper, mid- and lower-facial soft tissue, which adds to the effect of an aged appearance. The hollowness of the midfacial and infra-orbital area is because of the downward shift of the malar fat pad. To manage this ptotic situation, surgical facelift procedures have been the most effective treatment as they not only excise the redundant tissues but also haul the soft tissue in the opposite vector of ageing process. The other non-invasive procedures cannot be as effective as the facelift procedure. But because of the significant downtime, cost and risks involved, facelift is not accepted by patients very readily. To have a way in between the surgical and non-invasive modalities, thread lift has become a popular procedure to manage drooping tissue of the face because of ageing.

32.2.1 Introduction to Thread Lift

Thread lifting modality is a minimally invasive cosmetic procedure that utilises a biocompatible implant placed into the deeper layers of face to predictably shift and realign tissues in a predetermined direction or vector. When compared to a surgical facelift procedure, this elevates the drooping tissues with least amount of risks and complications, immediate results and rapid recovery.

Historically, Ruff in Durham, North Carolina, in 1992 and Sulamanidze et al. in Moscow, Russia, in 1996 independently developed barbed sutures for correcting facial ptosis. FDA in 2004 approved Ruff's clear, barbed, unidirectional, polypropylene sutures for treating ptotic skin of face and neck [13].

32.2.2 Classification

(A) Depending on the modality of their action (Fig. 32.5):
- Redefinition of the facial contours—Barbed threads
- Induction of collagen production—Mono PDO threads

Fig. 32.5 Various types of polydioxanone threads are mono threads for facial rejuvenation and cogs threads for redefining facial contours

(B) Depending on pattern of resorption of implant material:
- Permanent/Non-resorbable threads—Polypropylene threads like Aptos threads, Silhouette lift threads, etc.
- Resorbable threads—Polydioxanone threads like Alfa aqualift, and Poly-L Lactic acid threads like silhouette soft threads, etc.

(C) Depending on mode of Fixation:
- Anchored: Wherein the thread is anchored to a proximal fixed place like the deep temporal facia or mastoid facia.
- Free floating: They are not fixed and cause the pull because of the thread design.

(D) Depending on the surface texture of the thread:
- Barbed
- Non-barbed

The Barbed threads are of 3 types:

- Unidirectional barbed threads—these are anchored on to a fixed point like the deep temporal facia, e.g. Contour thread
- Bidirectional barbed threads—these are placed in the treatment area by a canula and stretch the skin because of the design, e.g. Aptos threads.
- Cogged threads—these can be unidirectional, bidirectional or multidirectional and they lift the skin towards the point of entry once tissues get entangled with the cogs.

The Non-barbed threads can be:

- Plain
- Spiral or spring

32.2.3 Mechanism of Action

From a clinical point of view, the barbed sutures simply work by grasping and mechanically pulling the ptotic skin. These barbs get entangled in the subcutaneous tissues and as the thread is pulled backwards, the tissues get squeezed along the barbs and stay there as the thread outside is cut off.

From a histologic aspect, a basic mechanism of mechanical transduction happens when the polydioxanone threads are placed in the tissues. A torrent of intracellular signals in the surrounding cells through which the polydioxanone threads pass is triggered by the mechanical stresses instigated by the threads thus influencing the metabolic responses and encouraging cellular growth and survival and modulating tissue morphology and architecture [14].

There are 2 major types of collagen proteins that are found in our skin. The type 1 collagen or the fibrous collagen makes up about 70% of the total collagen while the type 2 collagen or the reticular collagen makes up to about 5–20%. Both of them provide structural support to the skin. Today, most of the aesthetic procedures are aimed at a phenomenon of biostimulation. The main intention is to improve on the plasticity, resilience, flexibility, firmness and turgor of the skin tissues that are normally lost with ageing due to the loss of proteins like collagen and elastin. This is achieved by penetrating the dermis with substances that would encourage the production of these proteins [15]. The biostimulation caused with PDO threads is due to neocollagenesis, i.e. the production of type 1 collagen which is essentially fibrotic in nature. The PDOs resorb in 6 months and till that time it keeps inducing collagen. The fibrotic collagen exhibits a retracted effect improving the skin appearance. Concurrently, the compaction and stiffening of the collagen fibres also determine the functional damage [16].

32.2.4 Indications

There are 2 major indications for the threads treatment:

- Skin rejuvenation
- Elevating the sagging skin

Skin rejuvenation can be done with the use of plain polydioxanone threads. It also increases the volume in certain areas where there is minimal volume loss.

The barbed threads are indicated in areas where there is ptosis of the tissues. The barbs work as cogs and by engaging the tissues along its path, it mechanically pulls the tissues upwards thereby reducing the ptosis.

The plain polydioxanone threads can be used for facial rejuvenation and are mostly utilised for the following indications (Fig. 32.6):

- Fine lines and wrinkles in any part of the face like the periorbital area, malar areas, perioral areas, chin, etc.
- Skin tightening—Under the neck, cheek lifting, lines around and under the mouth.
- Crepey skin
- Acne scar filling
- Outlining of Lips to create a fuller look naturally (Fig. 32.7)

The barbed threads can be used to lift the ptotic skin and hence be utilised in the following areas (Fig. 32.8):

- Nasolabial folds
- Eyebrow lift
- Upper and lower cheeks
- Neck & Jawline
- Marionette lines

32.2.5 Treatment Protocol [4]

Choosing the ideal procedure for rejuvenation depends on the grade of skin ageing.

(A) Mild skin ageing
  - Rejuvenation—Apply Plain or screwed PDO threads (Fig. 32.9)
  - Lifting
    - for a "natural look" lifting—apply PDO cogs along with plain PDO threads.

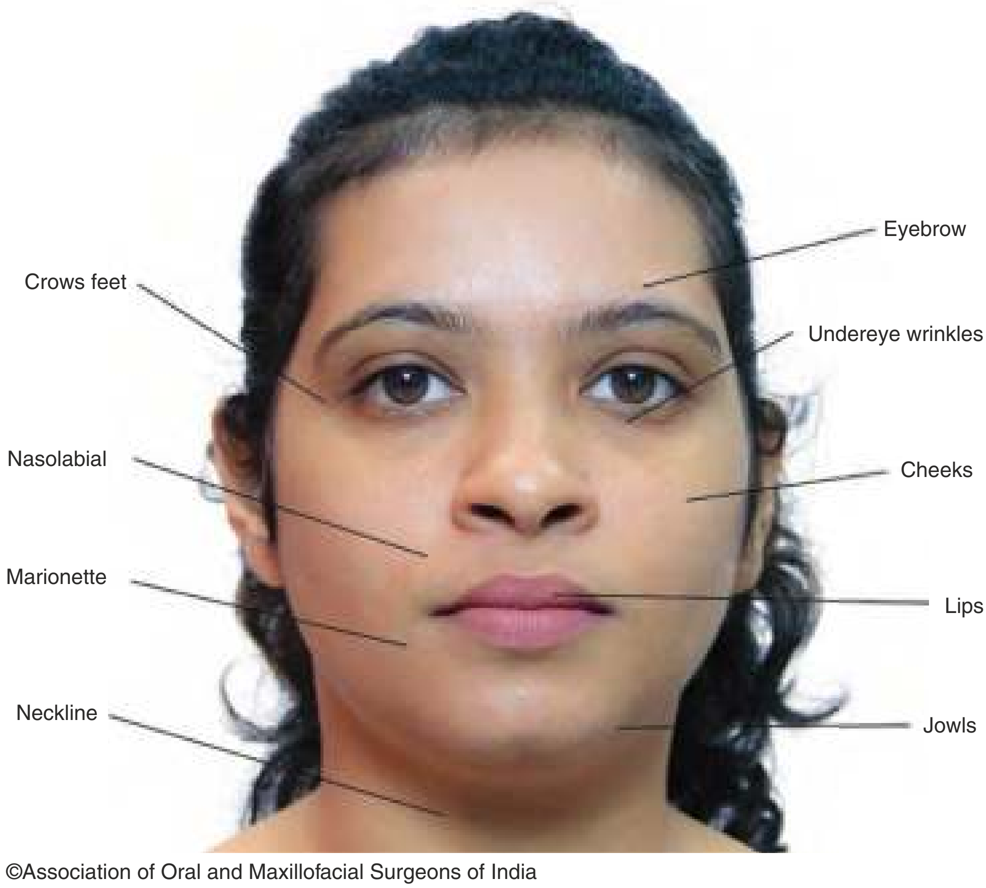

Fig. 32.6 Various indications of mono polydioxanone threads for facial rejuvenation

Fig. 32.7 (a, b, c) Mono polydioxanone threads can be used to create the lip borders and also to create a fuller looking lip

– for heavy lifting—apply anchored sutures or long suture technique.

(B) Moderate to severe skin ageing
- Rejuvenation—Apply short PDO cogs along with plain PDO threads (Fig. 32.10).
- Lifting—Not recommended.

32.2.6 Procedure

The Polydioxanone thread used in facial rejuvenation are basically of 2 types: Mono PDO thread and Cogs PDO thread

(A) The Mono PDO thread—These are 5-0 or 6-0 suture materials which are essentially monofilament and

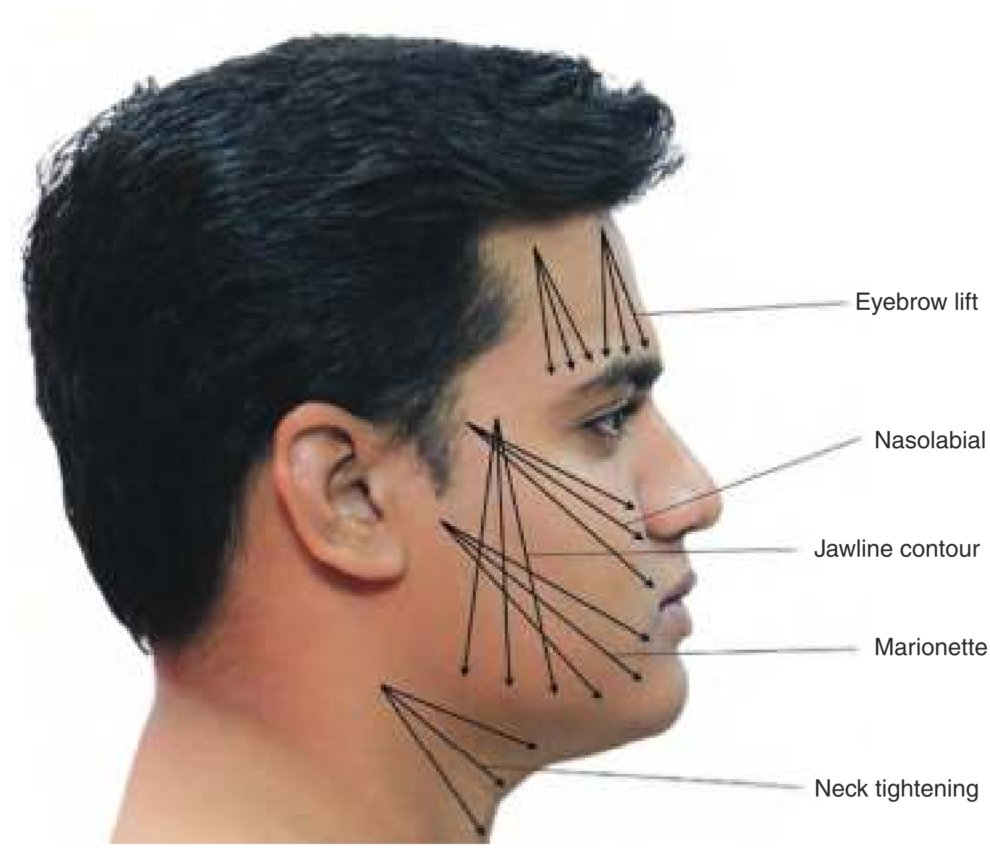

Fig. 32.8 Various indications of barbed PDO threads for redefining facial contours and lift the ptotic tissues

Fig. 32.9 Mono PDO threads for facial rejuvenation

Fig. 32.10 Cogs thread for lifting nasolabial folds. Note the lifted up right nasolabial fold only as the thread has been applied only on that side. Left side is still untreated

non-barbed. It can also be braided to a spring to provide more tensile strength [17]. The thin suture material forms a V-shape when inserted to a needle of 26–30 g, with one half of the thread inside the calibre of the needle and the other half on the outside. Once the needle with the suture material is inserted into the dermal layer, the thread gets buried into the tissues and at the removal of the needle, the thread stays back intact.

These types of threads are placed in the dermal layer where they cause collagen formation.

EMLA cream must be applied 45 min prior to the procedure. The full face was cleansed with povidone iodine solution. Once ready, the mono PDO threads are placed in the dermal layer making up meshes in the areas of indication. One must keep observing for any threads that stay outside the skin. It must be removed immediately by grasping it with a needle holder so that it doesn't cause any infection or granuloma.

(B) The Cogs PDO thread—Cog PDO thread has small barbs or spikes all along its length, which get engaged to the tissues when inserted and lifts it once pulled back.

Depending on the direction of the spikes, cog PDO thread is classified as unidirectional, bidirectional or multidirectional.

The cog thread is actually 3-0 suture which has barbs and this thread is mounted on an 18 g canula or needle. The canula is considered safer as it does not damage the blood vessels and nerves.

The barbed threads must be placed in the subcutaneous layer so as to prevent any palpability of the implant material.

Local anaesthesia should be given with 2% lidocaine with epinephrine. The full face is cleansed with povidone iodine solution. The path of insertion of the canula is marked on the skin with a sterile marking pen. The vectors are checked by manually stretching the skin upwards. Point of insertion is marked on a line 1.5 cm in the preauricular area. A small opening is made with an 18 g needle for the insertion of the canula. The barbed thread mounted on the canula is then passed along the vector in the subcutaneous plane all the way till the nasolabial fold or the marionette line. Once in place, the end part of the thread gets hooked in the subcutaneous plane, and the canula is pulled back and taken off the skin. The thread stays entangled in the subcutaneous plane. Once all threads are positioned in the skin, the distal part of the suture is held in one hand and the skin is pushed in the opposite direction to fully engage the threads and lift the tissues. The end part of the suture is then cut very close to the skin with help of sharp scissors so that the ends go into the tissues to prevent any future granuloma formation (Figs. 32.11a–d).

Post-operatively, ice packs are applied to minimise edema and bruising. Oral antibiotics are prescribed for 5 days after the procedure.

Anti-inflammatory tablets should be avoided as the more the inflammation at the site, the better would be the results. Patients generally do not require anti-inflammatory drugs post-surgery. Within the first 3 weeks after the procedure, the patients are advised against any strenuous movements of the muscles of midface such as yawning, wide smiling and laughing.

32.2.7 Complications and Management

The various complications that could occur with the PDO barbed threads include:

1. Bruising—Bruising is quite common while placing the PDO threads. Post-procedure application of ice prevents further bruise.
2. Pain and Swelling—Thread lift surgery causes very mild to moderate post-operative pain and swelling. Patients are generally asked to apply ice externally to reduce inflammation and pain. If a patient complains of severe pain, anti-inflammatory may be advised. In case of serious swelling, the patient must be evaluated for hematoma and infections.
3. Infection—Proper aseptic protocol needs to be followed to prevent any type of skin infection. However, it is better to prescribe oral antibiotics for 5 days for the thread lift surgery.
4. Palpability of the thread—If the threads are placed too superficial, they become palpable from outside the skin. The barbs or cogs should always be placed in the subcutaneous layer.
5. Hematoma—Since the placement of threads is a blind procedure, the chances of damage to a blood vessel is always there. The patient should always be informed prior to the procedure regarding hematoma. Pressure application and cold compressions should be immediately given. After a period of time, the skin over the hematoma may turn bluish then brown and yellow as the blood is dissolved and absorbed. It may take 1–4 weeks for the hematoma to subside.
6. Nerve damage (Fig. 32.12)—There is always a chance of trauma to the branches of facial nerve since the placement of the threads is in close vicinity to the nerve, especially the marginal mandibular and frontal branches. Thus, the muscles of facial expression can be impaired. Fortunately, the nerve damage resolves soon and motor functions are restored.
7. Asymmetry: Pre-existing asymmetries on the face should be explained to the patient prior to treatment. It's

always a good practice to let the patient seat vertically straight while inserting the barb threads and making the patient participate while retracting the tissues by visualising with a mirror to avoid any potential problems of asymmetry later on.

8. Dimpling: This normally would happen if the depth of the advancing thread is too superficial. A depression or an irregular contour would occur at a portion where the barb is located close to the skin. Most cases normally resolve spontaneously. But remarkable dimples need to be managed by manual reduction at that time itself.
9. Rippling and puckering: The skin would ripple over the thread and cause visible folding if tightened too much while retracting the tissues. This typically resolves itself in a few days if the thread has been placed in the correct tissue plane.
10. Granuloma: Higher incidences of granuloma formation are essentially seen if the threads placed in a more superficial plane and they are not cut very close to the skin.
11. Thread loss: With mono PDO thread, if there is a protruding thread, the end should not be cut as with barbs and cogs, but grasped firmly and removed. It's safer to remove a monofilament thread than leaving it there, thus risking the formation of granuloma. Barbed and cogged threads are very difficult to retrieve and hence excessive care should be taken to place them in the right plane.
12. Thread breakage: This can happen during the tightening of the barbs and cogs just before cutting at the skin level. Hence, careful manipulation should be done to avoid breakage during insertion and tightening.
13. Thread exposure: Repeated inflammation and migration of the thread to superficial layers can cause thread exposure. It can be prevented by placing the threads in proper plane.

Fig. 32.11 (**a**, **b**) Placement of cannula with cogs threads along the vectors for nasolabial folds and after removal of cannula the cogs threads in place. (**c**, **d**) Pulling the cogs threads to lift the ptotic nasolabial fold tissues and final twisting and snipping the threads just below the skin level

Fig. 32.11 (continued)

32.2.8 Conclusion

The PDO thread lift is a non-invasive procedure that actually gives a “lifted effect” of the ptotic skin. It has been widely accepted as a standard procedure for patients who do not want to opt for a more aggressive surgical facelift. Patient selection is of prime importance. Only patients with mild to slightly moderate levels of ptosis should be selected for polydioxanone cogs thread lift. The patient should be given a realistic expectation of the lift of no more than 1 cm. Patients who are too chubby or who are too skinny should not be considered for thread lift. Overall, every aesthetic practitioner should have knowledge of thread lift as it is a simple and versatile anti-ageing procedure.

32.3 Biostimulatory Lift with Platelet-Rich Plasma

Today, Platelet-rich plasma (PRP) has been incorporated in many medical specialities including orthopaedics, general surgery, plastic surgery, dental surgery and dermatology because of its healing capabilities. Its usage in aesthetics and trichology has touched newer horizons as we have come to know about the healing cytokines present in the platelets which can be used for antiageing therapies and therapies for regenerative aesthetics.

Fig. 32.12 (**a**, **b**) Damage to frontal branch of the facial nerve during placement of cogs threads

32.3.1 Platelets and Platelet Concentrates

Platelets, also called thrombocytes, are enucleated fragments of cytoplasm that are derived from the megakaryocytes of the bone marrow, which are released into the circulation. They have a fundamental role in haemostasis and wound healing.

The platelets contain various secretory granules, namely the alpha granules, dense granules and lysosomes. The alpha granules are the most abundant ones and contain the coagulation factors, growth factors, also called cytokines, adhesion molecules, and a variety of other angiogenic factors which efficiently encourage the proliferation and activation of cells required for wound healing including fibroblasts, mesenchymal stem cells (MSCs) and facilitates angiogenesis [18].

The growth factors along with their function are listed below [19]:

1. PDGF (platelet-derived growth factor)—PDGF plays a role in embryonic development, cell proliferation, cell migration and angiogenesis.
2. TGF-β1 & β2 (transforming growth factor)—TGF is involved in regulating and mediating processes at the cellular level, including cell proliferation, differentiation, motility, adhesion and apoptosis as well as causes wound healing and angiogenesis.
3. VEGF (vascular endothelial growth factor)—Chemotactic and mitogenic for endothelial cells, mediates angiogenesis.
4. EGF (epidermal growth factor)—Mediates angiogenesis, causes proliferation of fibroblasts, endothelial cells and keratinocytes.
5. HGF (hepatocyte growth factor)—Mediates regeneration.
6. FGF (fibroblast growth factor)—Mediates tissue organisation and regeneration.
7. FGF-9—Aids generation of new follicles.

These growth factors or the “cytokines” are proteins, each of about 25,000 Daltons molecular weight. In response to the thrombocyte aggregation, as occurs in injury or surgery, the cell membrane activates the alpha granules which in turn unleash these growth factors via active extrusion through the cell membrane. The active secretion begins within 10 min during which 70% of stored growth factors are released and more than 95% of the presynthesised growth factors are secreted within 1 hour. Platelets then synthesise additional amount of growth factors for about 8 days till they die [20].

Platelet concentrate means plentiful amounts of platelets that are concentrated into a small volume of plasma. There are various types of platelet concentrates which can be formulated, all differing in the way they are made [21]. A general classification takes 2 key parameters into consideration: the presence of a cell content (mostly leukocytes) and the fibrin architecture.

There are 4 major families:

1. P-PRP
   Pure Platelet-rich plasma is a preparation without Leukocytes. It has low-density fibrin network after activation. It is used as liquid solutions or an activated gel form and can be injected. P-PRP is commonly used in sports medicine & aesthetic medicine.
2. L-PRP
   Leukocyte and PRP is a preparation with leukocytes in it. Even this has low-density fibrin network after activation. It is used as liquid solutions or an activated gel form and can be injected. L-PRP is used in aesthetic medicine, sports medicine, orthopaedics, trichology, etc.
3. P-PRF
   Pure Platelet-rich fibrin is a preparation without leukocytes. It has a high-density fibrin network and exists as a strongly activated gel form. It cannot be injected, but can be handled like a real solid material. It has been very commonly used in dentistry & maxillofacial surgery today.
4. L-PRF

Leukocyte and PRF is a preparation with leukocytes. It has a high density of fibrin network and exists as a strongly activated gel form. It cannot be injected and can be handled as a real solid material. It is today used in implant dentistry, periodontal surgeries, oral surgeries, treatment of skin wound ulcers, etc.

32.3.2 Mechanism of Action of PRP

PRP can be described as a biologic product derived from autologous blood with the plasma fraction containing platelets at a concentration of more than 3–5 times above baseline.

The scientific evidence suggests that wound healing enhancement is seen using concentrates of 1,000,000 platelets/μl. Any concentration lower than this cannot be depended on to enhance wound healing, and concentrations far more than this has not been scientifically proved to help and enhance healing [22].

So, PRP by virtue of its increased concentration of platelets and thereby an inflated amount of growth factors or cytokines have been theorised to encourage tissue repair and regeneration by neocollagenesis, neoangiogenesis and much more. It has been embraced as a frontline treatment modality for the management of facial ageing, androgenetic alopecia, acne scarring, etc.

32.3.3 Indications of PRP Therapy in Aesthetic Medicine

1. Facial rejuvenation.
2. Skin tightening and Antiageing therapy
3. Acne scar management
4. Alopecia
5. Skin lightening
6. Improvement of skin quality in under eye area.

32.3.4 Preparation of PRP

PRP is derived from autologous blood by using a centrifuge and can be performed under local anaesthesia under aseptic conditions. An anticoagulant, like citrate dextrose solution formula A (ACD-A) or sodium citrate 3.8%, is used to inhibit platelet aggregation.

Manual Double Spin Method (Figs. 32.13, 32.14, 32.15, and 32.16)
Whole blood is collected by venipuncture from antecubital vein in 15 ml polystyrene tubes under sterile conditions containing 3.8% sodium citrate as an anticoagulant. In each tube, 1 ml of sodium citrate is mixed with 12 ml of whole blood. Eight such tubes are taken to make up a volume of 104 ml. The tubes are slowly turned upside down twice to homogeneously mix the whole blood with the anticoagulant. All the 8 tubes are placed in the centrifuge (Remi 8c) and are centrifuged at 1500 rpm for 10 min. This is called the ‘soft spin’ which separates the whole blood into 3 layers. The erythrocytes settle at the bottom of the tube because of the highest specific gravity or density of about 1.090. Just above the erythrocytes, a hazy layer is seen which contains the leucocytes with a specific gravity of 1.060 and platelets with a specific gravity around 1.040. At the top, we find the clear plasma with the lowest concentration of platelets with a specific gravity of around 1.020.

The buffy coat is separated along with some amount of plasma and placed in a separate tube. At this time, if the buffy coat is separated along with the slightest superficial erythrocyte layer, it is referred to as L-PRP (leukocyte-PRP) and if it

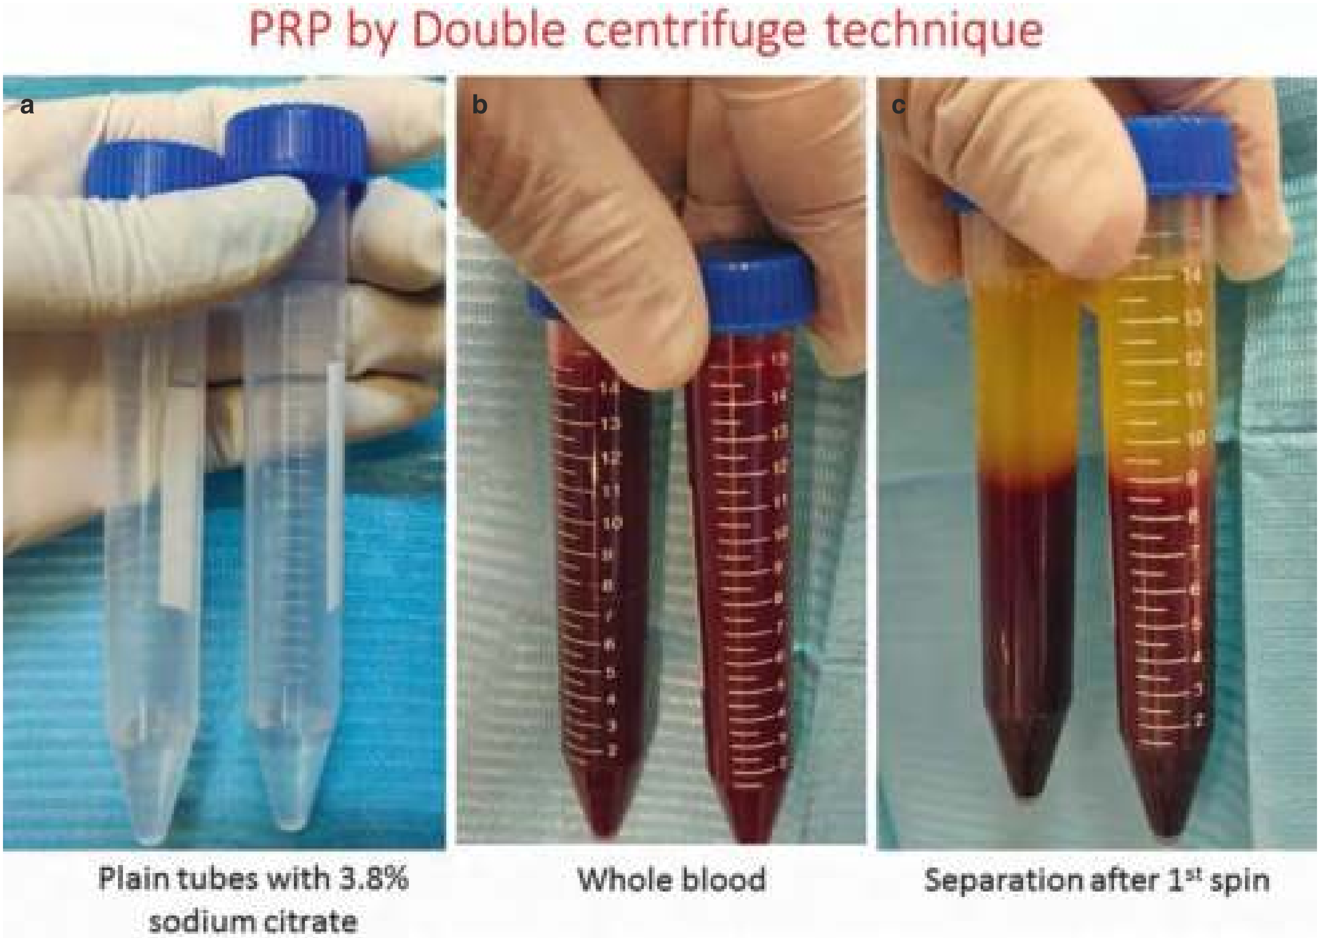

Fig. 32.13 (**a**, **b**, **c**) Primary separation of erythrocytes during the preparation of platelet-rich plasma using plain tubes containing sodium citrate 3.8%

is taken above the layer of erythrocytes, it is referred to as P-PRP (pure-PRP) depending on the kind of PRP preparation, i.e. with or without leukocytes. About 10 ml of these are taken in 2 tubes and placed in the centrifuge for a second spin called the 'hard spin' at 2500 rpm for 15 min. At the end of the spin, a platelet plug is found at the bottom of the tube. The top 3 quarter of the platelet poor plasma was discarded and the lowest quarter with the platelet plug was mixed and used as the PRP. This gives us a viable platelet count of 5 times the baseline. This was activated by mixing with calcium gluconate at a ratio of 9:1 in an insulin syringe and injected immediately.

Automated Devices (Fig. 32.17)

Numerous commercial devices of varying standards are now available for the preparation of PRP. Although time saving, these adapted kits can be quite expensive as compared to the manual process.

In general, a PRP tube typically contains sodium citrate as an anticoagulant along with a separating gel. This gel has a density of about 1.070, which is in between the erythrocytes and platelets.

20 ml of Whole blood is collected by venipuncture and added into two of these PRP tubes. The blood is homogeneously mixed with the anticoagulant by gently turning the tube upside down twice. The tubes are then placed in the centrifuge and spun at 3700 rpm for 9 min. The erythrocytes because of the higher density than the separating gel settle down below the gel, while the plasma along with leucocytes and platelets segregate above the gel. The superficial platelet poor plasma is discarded leaving behind 2–3 ml of plasma above the gel. The tubes can be turned upside down to mix the platelets as they get entangled in the gel. This would give a uniform concentration of platelets throughout. It is now mixed with calcium gluconate as an activator and injected immediately.

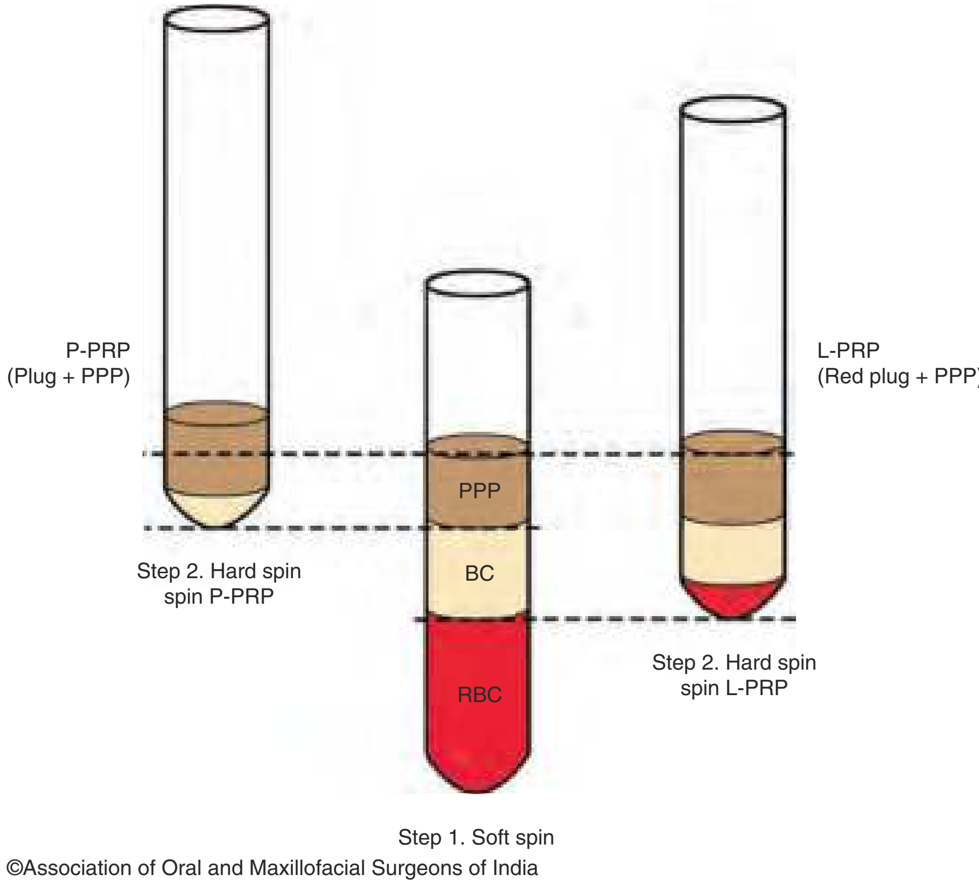

Fig. 32.14 Difference in preparation of L-PRP and P-PRP

32.3.5 PRP Injections for Facial Rejuvenation, Biostimulatory Lift and Acne Scar

Studies have shown that PRP by inducing neocollagenesis through activation of fibroblasts and by removing photodamaged extracellular matrix (ECM) components amplifies dermal elasticity via following molecular mechanisms [23, 24]:

- Encouraging proliferation of human dermal fibroblasts to induce new collagen.
- Increased expression of MMP-1 (matrix metalloproteinase-1) and MMP-3, resulting in the removal of photodamaged ECM.
- Enhanced creation of procollagen type I peptide and expression of collagen type I, alpha-I, resulting in the synthesis of fresh collagen.
- Increases expression of G1 cell cycle regulators resulting in accelerated wound healing.

PRP can be injected using an insulin syringe that has 31 g needle. Local anaesthetic in the form of nerve blocks should be given prior to the session. The facial skin should be cleansed with povidone iodine solution. Multiple intradermal injections of PRP after activating it are given all over the face including the infraorbital area. Three sessions each at a gap of 1 month of PRP therapy along with micro-needling (collagen induction therapy) with derma pen with a needle depth of 0.7–1 mm has been shown to give very good results for rejuvenating the aged skin and acne scars. Histologically, the treated skin showed improved length of dermo-epidermal junction, increased quantity of collagen and fibroblasts.

Post-operatively, patients are advised to apply ice on the face. Sun exposure should be avoided. Patient should be advised not to take anti-inflammatory tablets as the more the inflammation, the better the results are going to be. Most of the times, patients experience very mild post-operative discomfort.

PRP therapy can also be combined with CO2 fractional resurfacing to achieve excellent results in treating acne scars.

PRP has also shown excellent results in infraorbital rejuvenation where the skin is very thin and shows initial signs of ageing [25].

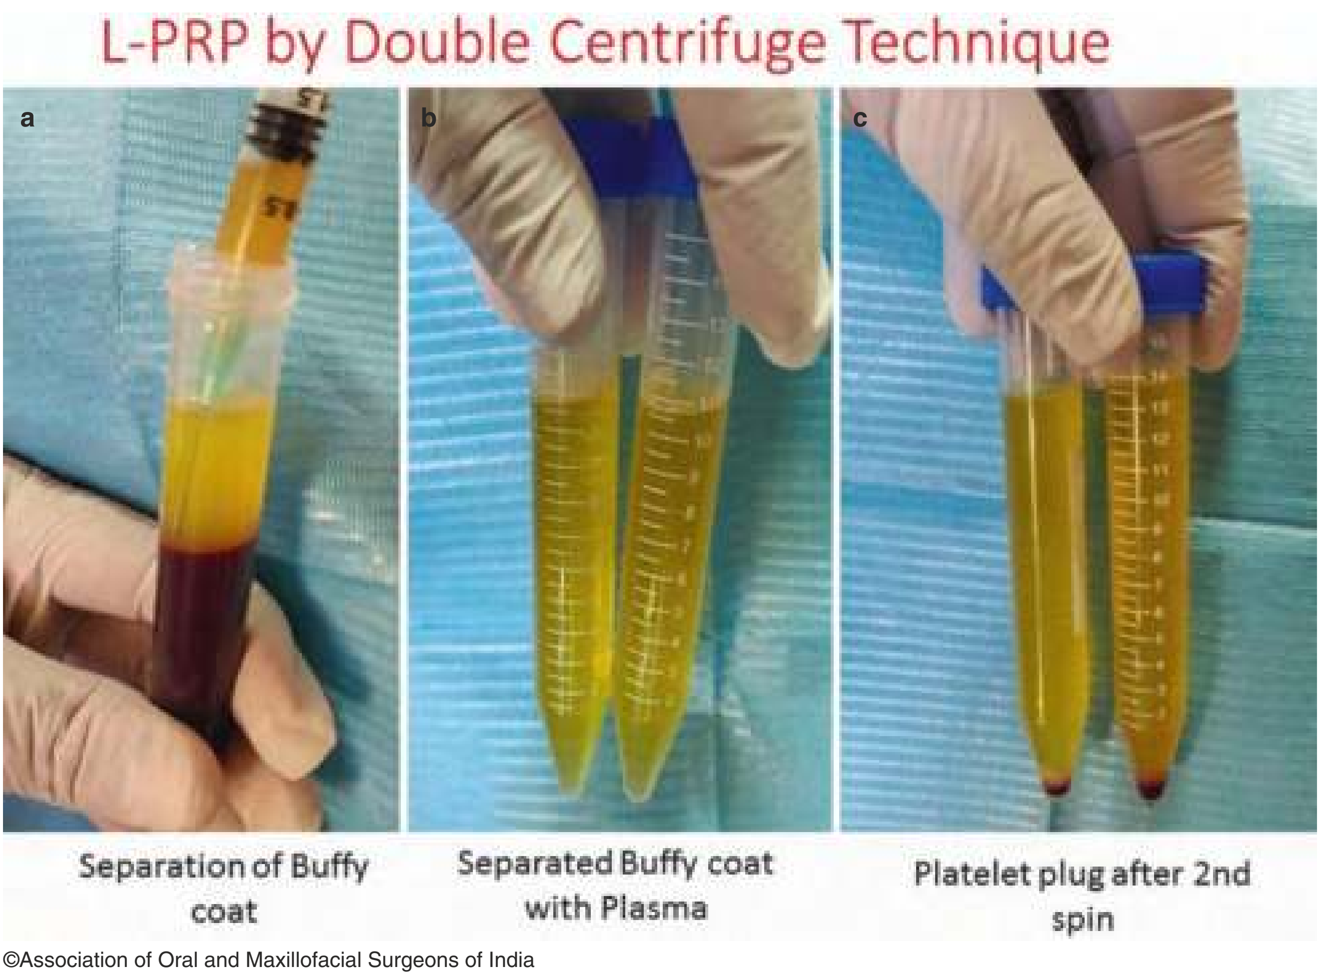

Fig. 32.15 (**a**, **b**, **c**) Platelet plug formed after the second spin during the preparation of L-PRP

32.3.6 Contraindications to PRP Therapy [26]

Absolute contraindications:

- Platelet dysfunctions.
- Thrombocytopenia (low platelet counts).
- Hypofibrinogenemia.
- Local sepsis.
- Hemodynamic instability.
- Septicaemia.
- Patient unwilling to accept risks.
- Patients on long-term anticoagulant therapy (warfarin or heparin).

Relative contraindications:

- Consistent use of NSAIDs and corticosteroids within 15 days
- Recent episode of infections, fever or illness.
- Cancer—especially hematopoietic or of bone.

32.3.7 Conclusion

The use of cytokines derived from platelet-rich plasma (PRP) is an effective modality to promote tissue regeneration and hence can be used in regenerative medicine including facial aesthetics and trichology.

PRP therapy is an inexpensive procedure as it does not require complex and voluminous equipment or extensive training for its execution. Furthermore, since the product is primarily autologous in origin, the patient's apprehension regarding the immunogenic reactions or disease transmission is abolished. Over three decades of its application to various fields and the multitude of studies with enormous positive results, PRP therapy today has become a gold standard for facial rejuvenation and hair loss therapy. The release of bioactive cytokines that help in neocollagenesis which takes care of the ageing process of wrinkle formation has made it a versatile tool for many anti-ageing therapies on the face.

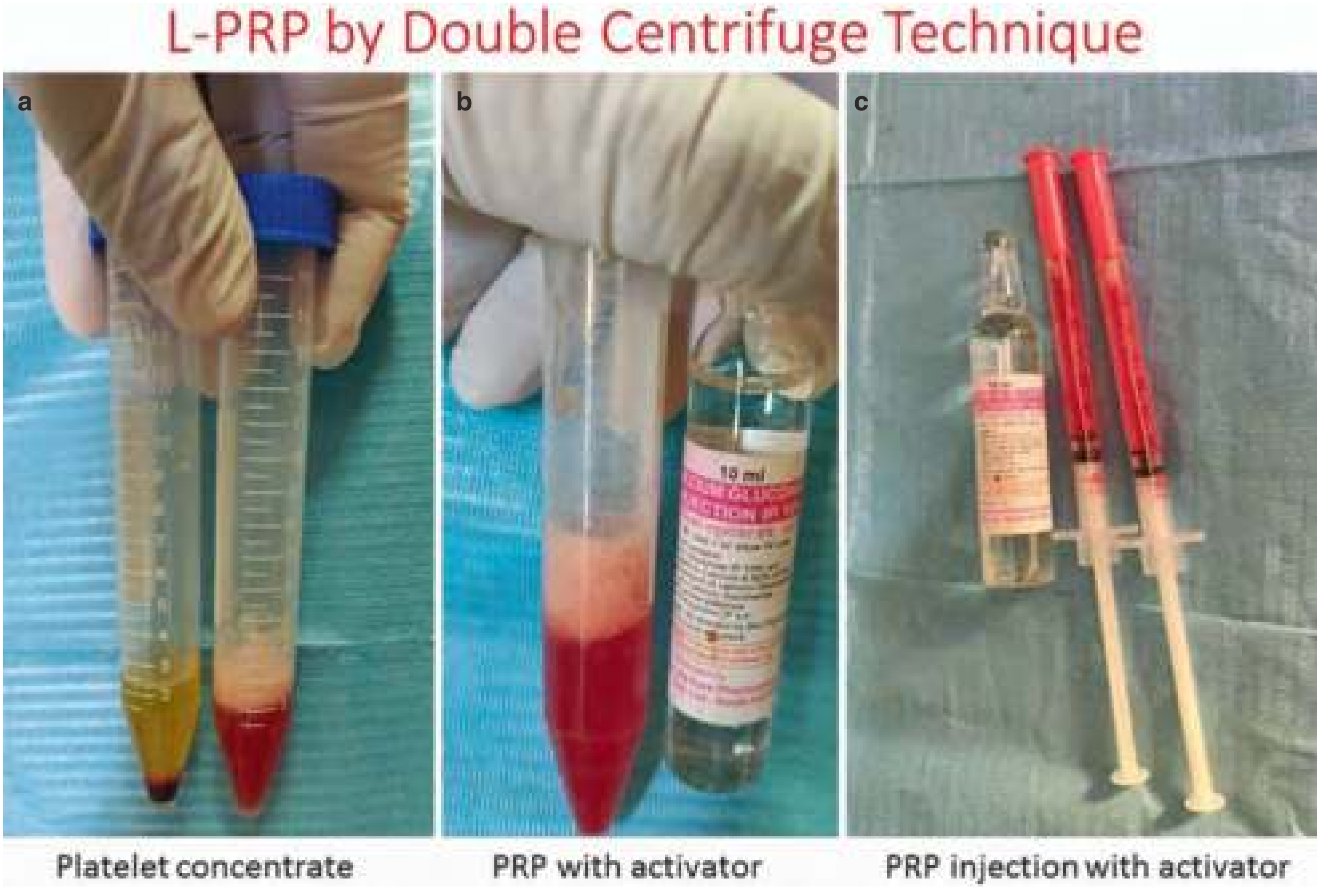

Fig. 32.16 (**a**, **b**, **c**) Platelet-rich plasma needs to be activated for release of cytokines from the alpha granules

32.4 Face Tightening with HIFU (High Intensity Focussed Ultrasound)

Facial wrinkles, reduced elasticity of the facial skin and sagging parts of the face are the most common concerns today an aesthetic surgeon encounters from the patients. In the present social scenario, facial skin laxity is considered highly disgraceful and has a great impact on a person's psychology and quality of life [27]. The natural process of ageing which is inevitable and the other external factors like sun's UV radiations, stress and worry, smoking, unhealthy diet, etc. are the major factors which cause the wrinkles and sagginess. We are aware that the loss of the important proteins viz collagen and elastin, which gives the strength, resilience and elasticity to the skin is the reason behind the loose skin and wrinkles.

Various treatment modalities have been utilised to manage these concerns of the face. Surgical excision of the redundant skin via facelift surgery definitely gives the best results. But with the increasing concerns over the complications and the downtime, the focus of therapeutic modalities is shifting towards non-surgical aspects.

Non-surgical treatment modalities like microdermabrasion, chemical peels, fractional lasers, etc. have been advocated in the past. In recent times, newer modalities like the HIFU and RF have come into limelight due to their non-invasiveness and low or no downtime for the treatment of sagging skin.

32.4.1 Introduction to HIFU

Ultrasound was introduced for its diagnostic ability. The capability of the focussed ultrasound energy to cause tissue regression and ablation has been well utilised today as a non-invasive modality to treat solid tumours and also being used to treat both primary and metastatic tumours as these can precisely locate the mass for ablation [28].

More recently this intense focussed ultrasound has also been utilised in many painful conditions including neuropathic pain and musculoskeletal degeneration [29].

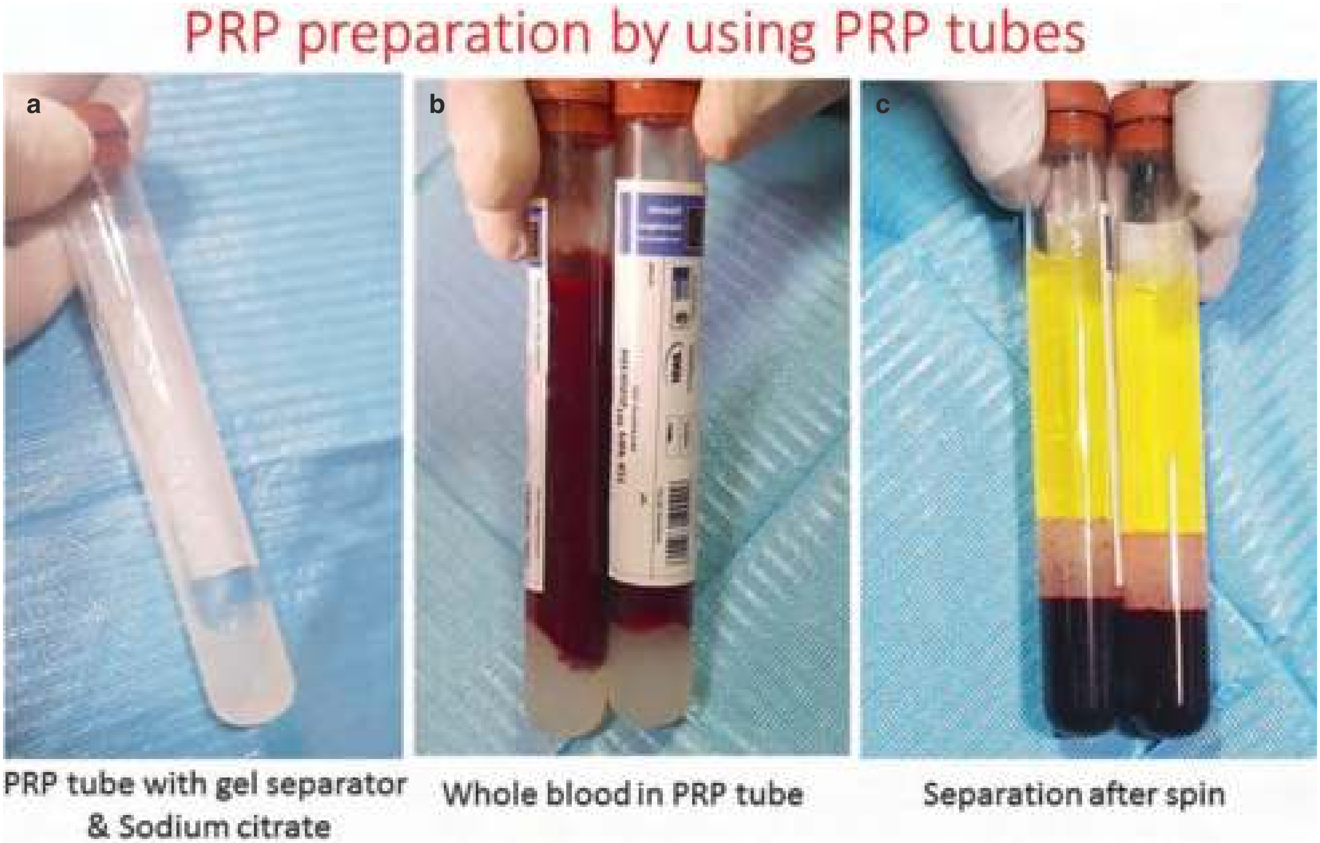

Fig. 32.17 (**a**, **b**, **c**) Preparation of Platelet-rich plasma with the help of PRP tubes containing anticoagulants and the separating gel

HIFU or high intensity focussed ultrasound was introduced into the field of facial aesthetics very recently to manage the facial wrinkles and periorbital rejuvenation.

FDA in 2009 approved the use of HIFU in brow lifting as the first dermatologic and aesthetic indication following the report by White et al. [30] in 2008. It was later in 2014 cleared as an indication to improve lines and wrinkles of the upper chest and neckline (décolletage). Currently, its use for facial rejuvenation, skin lifting and tightening and body contouring is considered 'off-label'.

32.4.2 Mechanism of Action

High intensity focussed ultrasound or HIFU embodies a piezoelectric transducer which produces focussed ultrasound beams. This transducer releases ultrasound waves over a length of around 2.5 cm which are focussed at 1.5, 3 or 4.5 mm depth. The 1.5 mm focusses the superficial or papillary dermis, while the 3 mm focusses the deep or reticular dermis and the 4.5 mm focusses the SMAS layer. Like a magnifying glass, the transducer focusses the ultrasound to the desired depth and at the focal spot, there is a swift rise in temperature to 60–80°C within a very short period (typically 1–20 s). This causes an immediate contraction of native collagen which is subsequently followed by cell injury and tissue shattering due to both coagulation necrosis and protein denaturation. These events occur at the deeper focussed zones, while the superficial tissues are left safe and unaffected [31] (Fig. 32.18).

The focussed ultrasound energy is absorbed by the tissues and this causes the molecules to vibrate rapidly. The friction due to molecular oscillations results in heat generation and a rapid rise of temperature at the focal zone. This thermomechanical process causes tissue injury at the site of focus. Supplemental to this, the ultrasound waves that propagate through the tissues cause continuous compressions and rarefactions that result in powerful shear forces. This microscopic but mighty shearing motion results in frictional heating [32]. Once tissue destruction is done, the inflammatory phase (in first 48 h) sets in wherein the damaged cells are removed and the WBCs, growth factors and enzymes create swelling, heat, pain and redness.

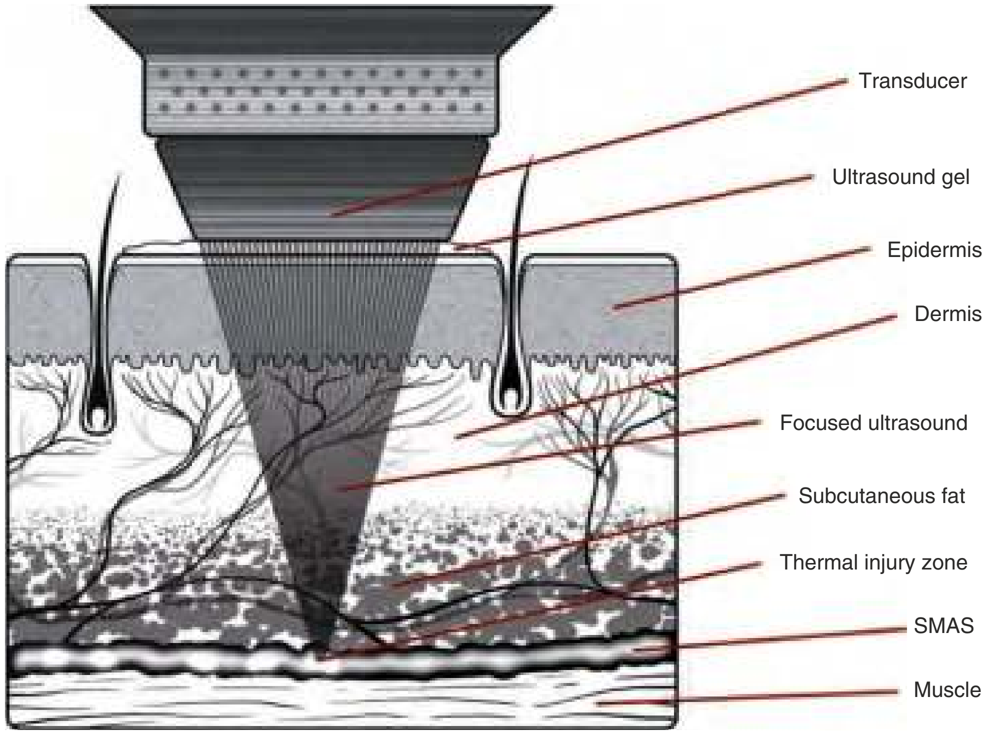

Fig. 32.18 Mechanism of high-intensity focussed ultrasound. Thermal coagulation zones are created due to the extreme heat produced by the ultrasound focussed to a particular depth

In the next proliferative phase (up to 6 weeks), there is tissue contracture due to the myofibroblasts which are built. New tissues made up of collagen and extracellular matrix are formed.

The last maturation phase (from 3 weeks to 6 months) shows collagen is remodelling from type III to type I. The collagen which was laid down during the proliferative phase is now aligned along the tension lines and also there is cross-linking of the collagen. A histological evaluation post HIFU treatment exhibited significantly regenerated and proliferated quantity of dermal collagen and elastic fibres [33]. This causes skin tightening over a period of time. The results keep improving and the best final results are seen by 6 months.

32.4.3 Armamentarium

The HIFU machine basically consists of 2 parts: the body and the transducer (Fig. 32.19).

The screen in the body keeps monitoring the number of shots, depth of shots, length of release of ultrasound waves and the energy of the ultrasound in real time. The transducer releases the focussed ultrasound waves. The following are the 3 transducers usually used on the face:

Fig. 32.19 High-intensity focussed ultrasound device

1. DS-4.5 4—Focussed ultrasound of 4 MHz frequency is transmitted to a depth of 4.5 mm to the SMAS layer, forming "thermal coagulation" spots. It is normally targeted to thicker skin, such as cheeks, etc. and is the most important aspect of midface tightening.
2. DS-3.0 8—High-frequency ultrasound of 8 MHz is focussed to the deep dermis layer at 3.0 mm depth and is responsible for activating the skin's collagen. It effectively reduces the appearance of wrinkles and also ameliorates large pores.
3. DS-1.5 10—Here, 10 MHz frequency ultrasound energy is focussed to the superficial dermis. It is used in thinner tissue in the periorbital area.

32.4.4 Indications and Contraindications in Facial Aesthetics

The numerous indications of HIFU are given below.

1. Brow lifting
2. Facial rejuvenation.
3. Fine and deep wrinkles of face.
4. Infraorbital area laxity.
5. Crow's feet.
6. Nasolabial folds (Fig. 32.20).
7. Mentolabial grooves.
8. Jowls.
9. Submental skin.
10. Double chin.

The contraindications are the following;

1. Open facial wounds or lesions in treatment region.
2. Pustular acne in the treatment region.
3. Active implants (e.g. pacemakers or defibrillators) in treatment region (no contraindications to Dental Implants).
4. Perform fillers and threads treatment after the HIFU session.
5. Pregnant or breast-feeding woman.
6. Directly over mechanical and permanent dermal implants.
7. Existing keloids in the treatment area.
8. Patients with active systemic and skin diseases like herpes, etc.
9. Unrealistic expectations of treatment.

32.4.5 Procedure for Face Tightening

32.4.5.1 Facial Rejuvenation - HIFU (Video 32.1)

The sequence for HIFU application includes the following:

1. Patient consent and explanation of the procedure, adverse effects and alternatives.
2. Removal of all makeup from face.
3. Cleansing the full face and neck area.
4. Application of local anaesthetics ointment like EMLA, Toplap, etc., and occluding it with plastic sheet for 45 min.
5. Markings of the skin for treatment.
6. Application of ultrasound gel on the skin and face and application of transducer tip at an angle perpendicular to the skin.
7. Start with 4.5 mm transducer, followed by 3 mm and then 1.5 mm with a number of shots and area as mentioned in the figures.
8. Removal of ultrasound gel and explaining post-operative instructions before discharging the patient.
9. Follow up on the next day to assess any complications and at 3 and 6 months to assess the results.

32.4.6 Adverse Effects

Severe adverse effects of HIFU are very rare and hence considered a very safe procedure to perform on an outpatient basis. The adverse effects that have been described may be:

- Pain—Transient discomfort may be experiences during the procedure which resolves within 2 h to 2 days. Tenderness is also possible and typically resolves in maximum 2 weeks.
- Erythema—May exhibit immediately after the treatment which resolves in few hours (Fig. 32.21).
- Edema—Skin may exhibit slight edema following treatment which settles in 3–72 h after treatment.
- Motor Nerve paresis—Symptoms of motor nerve paresis can be seen in the first 12 h of the treatment. It normally happens with the marginal mandibular and temporal branches of facial nerve which are pretty superficial. The HIFU could cause inflammation of these nerves and this may lead to disruption of motor function. The frontalis muscle and the muscles of perioral area are affected. The symptoms usually resolve in 2–6 weeks. Anti-inflammatory medications can be prescribed if symptoms of nerve paresis arise.

Fig. 32.20 (a, b) Lifting of nasolabial fold with HIFU

- Skin burns: This happens when inadequate ultrasound gel is not applied between the transducer and the skin. There is thus inadequate acoustic coupling and defocussing of the beam due to air entrapment and deposition of energy at the skin surface leading to skin burn (Fig. 32.21).
- Scarring: Rarely happens if correct treatment protocol and technique is not followed.

32.4.7 Conclusion

HIFU can be considered as a very effective, non-invasive and safe procedure for tightening the facial skin. The advantages over a surgical facelift are hard to deny. There are no incisions, no scarring and no downtime. Of course, it is much less expensive than a surgical facelift. If patients are chosen carefully, like patients with mild to moderate skin laxity, facial wrinkles, lower eyelid laxity, etc., HIFU can be an excellent option for facial skin tightening.

Fig. 32.21 Complication during HIFU—erythema and skin burn

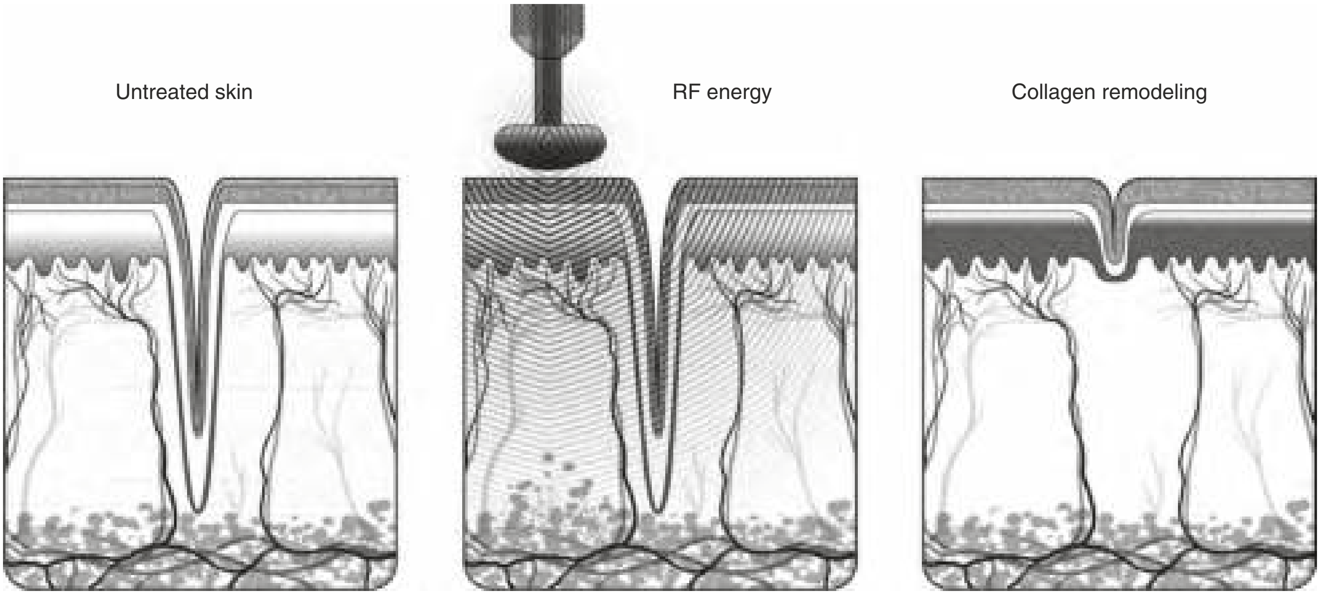

Fig. 32.22 Mechanism of action of non-ablative radiofrequency. Collagen remodelling takes place because of the heat generated due to the tissue resistance to radiofrequency energy

32.5 Skin Tightening with Radiofrequency

Non-ablative radiofrequency or RF is another non-surgical and non-invasive modality of skin tightening. The selective and controlled rise in tissue temperature is because of a high-frequency alternating current (0.3–10 MHz). The amount of energy applied and the tissue resistance determine the amount of temperature and the depth of heating [34].

Since electrical current produces the RF energy, the tissue damage like a laser is minimised and neither is the epidermal melanin compromised to cause hyperpigmentation.

RF therapy was first FDA approved as a non-invasive treatment modality in periorbital rhytids in 2002. Subsequently in 2004 it was cleared for full face. Since then, it has become a very popular non-invasive treatment modality for the facial skin tightening.

32.5.1 Principle of Action

High frequency (0.3–10 MHz) alternating current is utilised in a RF therapy. Intrinsic tissue resistance (impedance) to the passage of electrons converts the electric current to thermal energy causing heat generation. Ohm's Law relationships state that:

$$\text{Power}\left(P\right) = I^2 \times R \text{ and Energy}\left(E\right) = P \times T$$

Hence, Energy (E) = $I^2 \times R \times T$ (where I = current, R = tissue impedance and T = time of application). The level of energy of the alternating current and tissue resistance determines the amount of rise in temperature and the depth of heating. High tissue resistance as demonstrated by subcutaneous fat generate more heat [35]. The thermal damage thus caused stimulates the alterations in collagen configuration and produces neocollagenesis in deep layers of skin and subcutaneous tissue (Fig. 32.22).

Significant results can be observed 2 months post-application of radiofrequency energy. Histological pictures after each session demonstrated expansion of the papillary dermis due to oedema and vascular congestion, followed by accumulation of intercellular substance. Post 2 months treatment histological pictures showed escalated amount of collagen, elastic fibres and mucopolysaccharides [36].

32.5.2 Armamentarium

There are 2 major components of the RF machine: the RF generator and the handheld tips (Fig. 32.23). The membrane electrode functions by dispersing energy uniformly across the skin surface by a mechanism termed as capacitive coupling that creates a zone of raised temperature at depths of 3–6 mm [37]. The energy transmitted to the skin is by utilising the capacitive method (bipolar, tripolar or multipolar electrode). Montesi et al. (2007) described the main difference between the inductive and the capacitive method. It depends on the configuration of the electrodes that are applied to the skin that influences the energy transmission in the tissues.

The inductive method (monopolar electrode) uses an active and a passive electrode, in which the passive electrode acts as a grounding electrode. The active electrode transmits power to the tissue via a single point of contact. This enhances the penetration of the generated current.

In the capacitive method (bipolar, tripolar or multipolar electrode), energy alternates between 2 electrodes situated at a short distance from one another. In the tripolar and multipolar devices, bipolar energy switches between different poles at any given point of time. The energy is concentrated at the site of treatment and the achieved depth is half of the distance between the two electrodes [38].

Fig. 32.23 Non-ablative radiofrequency device

Parameters utilised by the device includes frequency ranging from 1 to 6 MHz and the power ranging from 40 to 240 W. All the parameters can be modified during the treatment. Throughout the procedure, the temperature of epidermis is maintained at 40 °C, whereas that of dermis rises to about 50–75 °C. This heating up of the dermis causes new collagen and elastin production.

32.5.3 Indications

The various indications of RF include the following:

1. Complete facial rejuvenation.
2. Wrinkles around eye
3. Fine lines on forehead.
4. Jowls
5. Nasolabial folds (Fig. 32.24)
6. Perioral fine lines
7. Undefined jaw line

Fig. 32.24 (**a**, **b**) Nonablative radiofrequency for tightening nasolabial folds

32.5.4 Advantages

The biggest advantage of RF is unlike lasers, the energy does not disturb the epidermal melanocytes and thus can be used for all skin types, i.e. type 1–6. The procedure can be performed frequently as per requirement without any adverse effect and different depths of tissue can be treated, allowing for ultimate collagen contraction and production of new collagen.

32.5.5 Procedure of RF for Face

Application of RF is done systematically and the various steps involved are mentioned below.

1. Patient consent for the treatment is mandatory after a detailed explanation of the procedure, side effects, benefits and alternatives.
2. Removal of all make-up from face.
3. Cleansing of the full face and neck area.
4. Application of prilocaine and lignocaine skin anaesthetic cream like toplap, prilido, etc.
5. Ultrasound gel is applied generously to the facial skin to establish uniform thermal and electrical contact between the treatment tip and the skin and to enhance proper energy conduction.
6. For each session, a total of 5–8 passes per treatment region can be given.
7. Removal of ultrasound gel and explaining post-operative instructions before discharging the patient. Post-operative instruction includes prevention of sun exposure by using sunscreen to promote healing.
8. Follow up on the next day to assess any complications and at 1, 3, 5 weeks to repeat the procedure and at 3 and 6 months to assess the results. The possible side effects of RF application are found in Box 32.1.

Box 32.1 Side Effects of RF Treatment

1. Burns
2. Permanent scarring
3. Skin pigmentations
4. Deeper skin fat loss.
5. Mild swelling of the treated skin.
6. Redness.
7. Sinking of the treated area.
8. Skin sensitivity.

32.6 Conclusion

Non-ablative radiofrequency is an effective and non-invasive modality for tightening and rejuvenating wrinkled, photo-aged facial skin and contour facial skin laxity. It works on the principle of stimulation repair process by producing new collagen and elastin and by reversing the clinical and the histopathological signs of ageing. The procedure has an added advantage of being relatively risk-free with little or no downtime.

Disclosure Authors have no financial conflicts to disclose.

32.7 Case Scenarios

32.7.1 Patient 1 (Fig. 32.25a–d)

A 48-year female approached us with complaints of sagging skin. She wasn't happy with her deepening nasolabial folds, loose skin in her neck and the fine wrinkling on her face.

Treatment options included surgical facelift, thread lift therapy and non-invasive therapies like HIFU and RF. The patient consented to undergo non-invasive treatment which included a session of High intensity focussed ultrasound (HIFU).

After cleansing the face, proper markings were made. The treatment was performed with sequential transducers of 4.5, 3 and 1.5 mm with number of shot as recommended, area wise. The patient was evaluated post-operatively and patient's satisfaction was recorded. Post-operative instructions were given before discharging. Patient was recalled for revaluation after 1 month.

32.7.2 Patient 2 (Fig. 32.26a–g)

A 52-year male approached us with complaints of loose skin on the face. His main concern was the deepening nasolabial folds and the fine wrinkling on the face. The treatment options included surgical facelift and thread lift therapy. The patient consented to get a thread lift procedure done. It was decided to use 3 COG threads along with 20 mono PDO threads on either side.

After cleansing the face with povidone iodine, vectors were marked to lift the nasolabial folds. Lignocaine with adrenalin was used as local anaesthetic agent. The thread lift procedure with COGS thread was performed with placement of the COGS in the subcutaneous layer for the proper lift and

Fig. 32.25 (**a**–**b**) Case Scenario 1. (**a**) Pre-op photograph. (**b**, **c**) Marking on face and neck, right side. (**d**) Post-op photograph

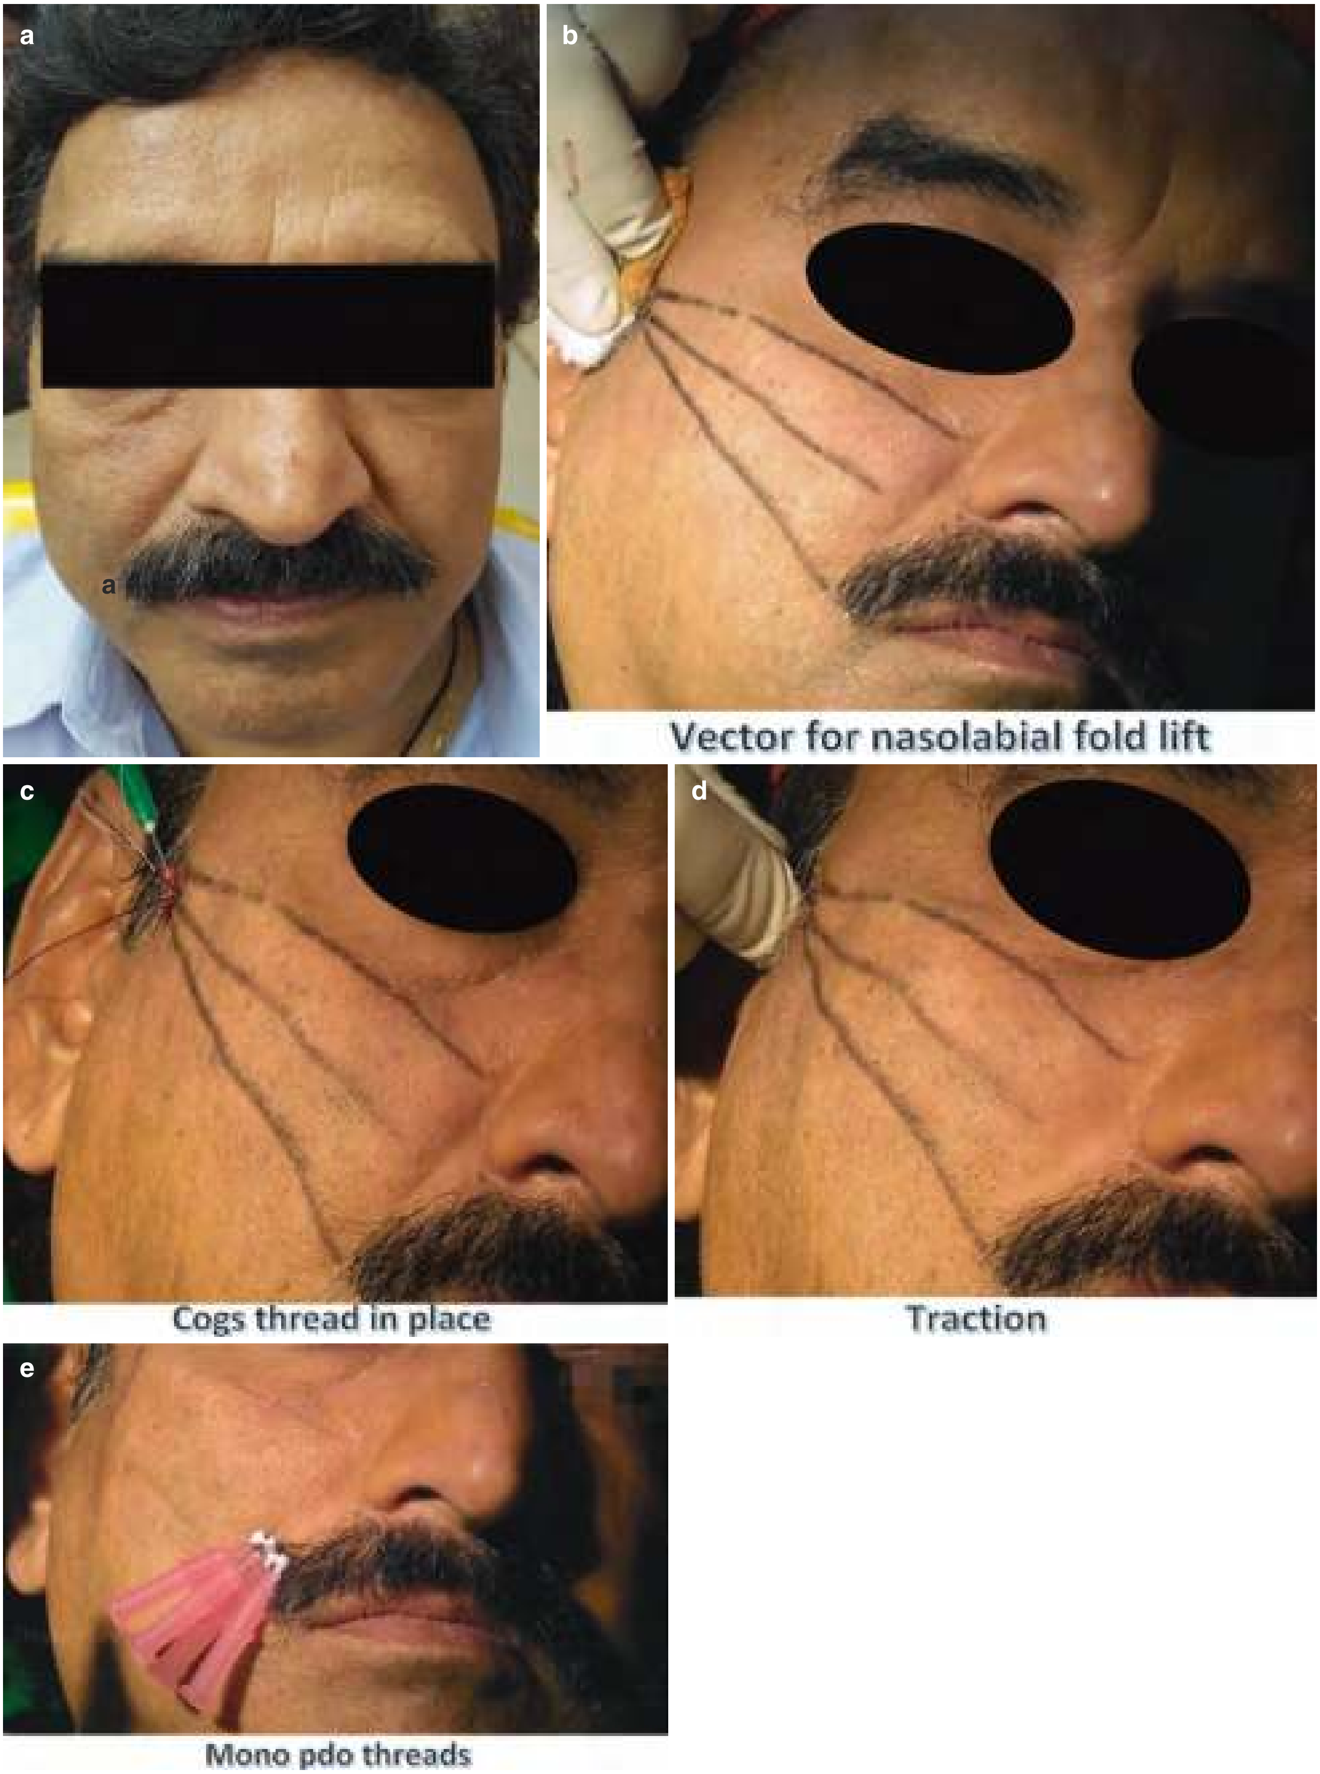

Fig. 32.26 Case Scenario 2. (**a**) Pre-op photograph. (**b**) Marking of vectors. (**c**) 3 cogs in place at subcutaneous layer. (**d**) The traction on threads lifts the nasolabials. (**e**) Placement of mono PDOS. (**f**, **g**) Post-op photograph (also see Fig. 32.10)

Fig. 32.26 (continued)

the mono PDO at the dermal layer for rejuvenation and fine lines.

The patient was evaluated post-operatively and patient's satisfaction was recorded. Post-operative instructions were given before discharging. Patient was recalled for revaluation after 3 days and after 1 month.

Botulinum Toxin and Fillers for Maxillofacial Esthetics

33

Sainath Matsa

33.1 Introduction

33.1.1 Facial Aesthetics

The field of cosmetology has steadily progressed over the past decade, and cosmetic procedures are moving towards a new era [1]. People are becoming more aware of the way they look, especially the face and are turning to medical and dental professionals to improve their appearance. Attractive facial aesthetics at any age has social and psychological benefits. Facial skin constitutes a major part in contributing to facial aesthetics. The skin is a reflection of several body characteristics, of which gender is a prominent one [1]. Age, genetic, hormonal and exogenous factors can affect both skin structure and function and are responsible for differences between different men and women. This chapter gives the basics and advances in the field of facial cosmetic and functional correction using Neurotoxins (Botulinum toxin) and Dermal Fillers.

33.1.2 Facial Skin Physiology, Muscular Anatomy and Mechanical Properties

In humans, skin including the epidermis and dermis is 1.428 times thicker in men than in women across 5–90 years of age [1]. However, women tend to have thicker subcutaneous fat. It has been found that, in men, it gradually becomes thinner with advancing age (12–93 years), whereas in women, the skin thickness remains constant till the fifth decade, after which it tends to decrease [2].

Gender plays an important role in facial wrinkling. In men, the incidence of forehead wrinkles is higher than in women. However, the incidence of upper eyelid wrinkles does not appear to be influenced by gender. Wrinkles in other parts of the face are found to be greater in men than in women, except above 65 years of age, when the incidence appears to equalise [3]. One study evaluated the skin morphology, elasticity and areas of sagging using photographs and a cutometer. The authors found that these were similar in both genders in the cheek region, but in the lower eyelids, sagging was more severe in males after middle age [4, 5].

33.1.3 Facial Muscles and Their Actions (Fig. 33.1)

A good understanding of the action of the various facial muscles is important for precise application of botulinum toxin. The muscles and their actions are tabulated (Table 33.1).

33.2 Botulinum Toxin

33.2.1 Botulinum Toxin-Type A

Botulinum Toxin type A was first used on the face by Carruthers and Carruthers in the late 1980s [6]. Following studies in the 1990s about its cosmetic use, botulinum toxin was approved by the USA Food and Drug Administration (FDA). This led to a revolution in treating ageing skin in recent years [1].

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_33) contains supplementary material, which is available to authorized users.

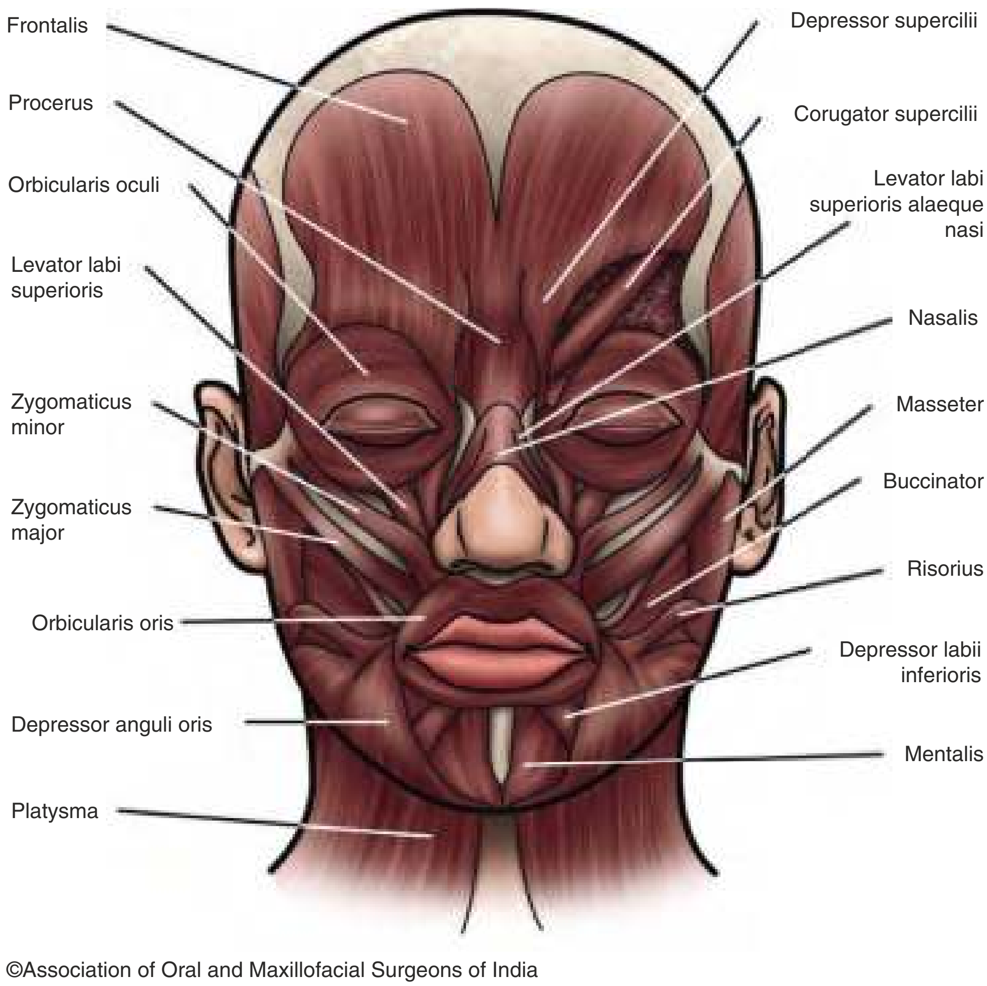

Fig. 33.1 Muscles of facial expression

Table 33.1 Facial Muscles and Their Actions

Frontalis—Raising the eyebrows; transverse wrinkling of the forehead
Corrugator—Vertical/oblique wrinkling of the forehead; draws the eyebrows together
Procerus—Pulls the glabellar skin in an inferior direction and causes transverse wrinkles
Depressor Supercilii—Pulls the eyebrow downwards on the medial canthal region
Orbicularis Oculi—Controls the sphincter of the eye
Risorius—Lateral movement of the corner of the mouth
Orbicularis Oris—Opening and closing of the mouth (sphincter action)
Levator Labii Superioris—Pulls the upper lip superiorly
Depressor Anguli Oris—Draws the corner of the mouth inferiorly
Depressor Labii Inferioris—Pulls the lower lip downwards
Modiolus—It's a union of muscles, situated lateral to the external commissure of the mouth, allowing symmetrical perioral expression.

33.2.2 Pharmacology and Mechanism of Action

Clostridium botulinum produces an exotoxin. It is an anaerobic gram positive bacillus (Fig. 33.2) which forms spores. It has eight types of strains which are labelled alphabetically: A, B, C, D, E, F, G, and H [7].

Two types of strains, A and B, are available currently. These result from the modification of the protein structure that has been used for a variety of medical and cosmetic purpose. Botulinum Neurotoxin causes denervation of the motor neuron temporarily, in the treated muscle and selectively inactivates the nerve terminals by blocking the release of acetylcholine and the target protein SNAP25, [8] leading to a temporary and reversible blockade of cholinergic transmission. In the neuromuscular junction, the blockade of the release of acetylcholine promotes muscle relaxation to muscular palsy [9] (Fig. 33.3a, b, c).

Reconstitution, Dilution and Dose:
Botulinum Toxin Type-A is available as lyophilised powder that must be stored frozen −4 °C or lower. Reconstitution of the powder may be done using 0.9% Normal Saline solution, which is isotonic. Once reconstituted, the solution must be used within 4–8 h, after which the potency of the drug may be lost, and contamination of the vials may occur.

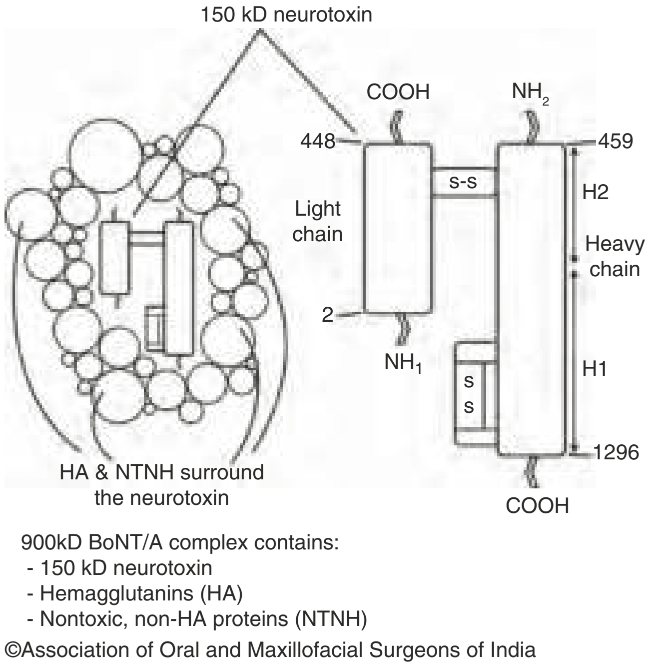

Fig. 33.2 Chemical structure

- Botulinum toxin A is marketed in two vials—50 and 100 U.
- In mice, the *Median Lethal Dose* is 1 U. The *MLD* in humans is estimated at 3000 U.
- For reconstituting 100 U, 2.5 ml of 0.9% Normal Saline may be used, which gives a concentration of 40 U/ml.

Many commercial brands are available for Botulinum Neurotoxin–A, like Siax®, Botox®, Xeomin® and Dysport® and every brand has variation in its dilution.

33.2.3 Indications

Botulinum toxin injections may be used in the clinical scenarios highlighted in Box 33.1.

Box 33.1 Indications of Botulinum Toxin
- Wrinkling of the face
- Facial rejuvenation of ageing face
- Gingival smile
- Masseteric hypertrophy
- Facial asymmetry
- Platysmal wrinkling and bands
- Hyperhidrotic conditions (excessive sweating)
- Blepharospasm
- Spasmodic torticollis
- Dystonia
  - cranial, lower facial, cervical, oromandibular.

33.2.3.1 Contraindications [10]

The use of Botulinum toxin injections is contraindicated in the following clinical situations:

- Pregnancy and breastfeeding.
- Individuals with an infection in the proposed area of the injection.
- Neuromuscular transmission disorders (myasthenia gravis).
- Individuals under medications that may influence neuromuscular transmission. These include Calcium channel blockers, Penicillamine, Quinine, Aminoglycosides, Pancuronium, Tubocurarine and Succinylcholine.
- Individuals under medications that interfere with coagulation like Acetylsalicylic Acid, Anticoagulants and Vitamin E.

Patient Selection:

In the present era, patients have increased awareness and knowledge about their health and skin conditions. They may be very ambitious and optimistic about the procedure and are likely to expect a high level of satisfaction with their personal appearance after the treatment. The goal of treatment is to achieve a better looking and natural appearance. The patients' psychological aspects and expectations should be understood and evaluated prior to the start of any cosmetic treatment.

33.2.4 Injection Techniques (Video 33.1)

The following techniques are used for injecting botulinum toxin into various areas of the face.

(a) *Glabellar lines injection technique* (Fig. 33.4a, b): Visualise an imaginary "X" formed by two lines that join the inner brows with the contralateral inner canthus [11]. The injection must be given at the midpoint of the 'X'. Conventionally, the Corrugator Supercilii muscle is visualised by observing the medial part of the eyebrow when the patient frowns. Botulinum Toxin is then slowly injected into the belly [11] of the muscle on either side. The needle must be maintained at 0.5 cm from the upper orbital rim, and lie internal to the mid-pupillary line. The total dose for glabellar line ranges from 10 to 15 U and can be increased to a maximum of 40 U based on the severity of the wrinkles.

(b) *Forehead lines Injection technique* (Fig. 33.5): The frontalis muscle is superficial and may be easily identified by asking the patient to raise and lower the brow. The extent of muscle movement is then assessed. Injections must be done in the superficial subcutaneous tissue, over the entire forehead from medial to lateral. The typical dose ranges from 2 to 3 U in each point of small dots represented on the upper and lower aspects of the forehead or

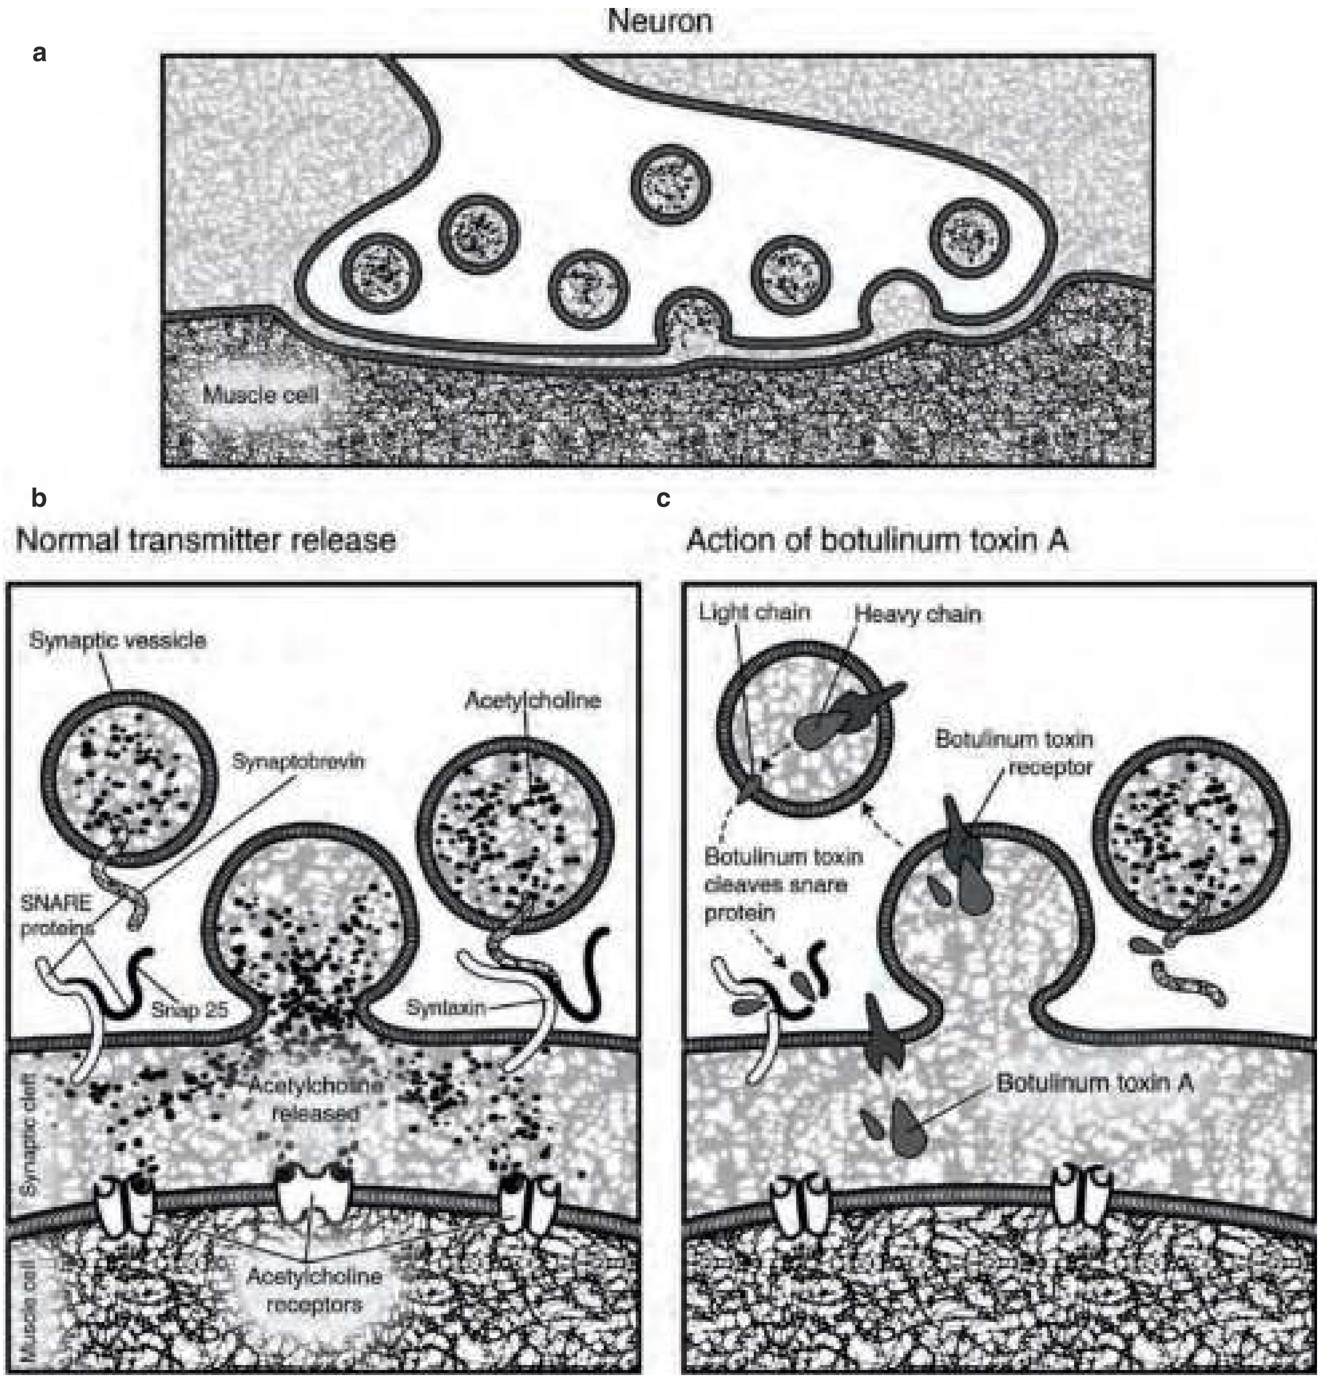

Fig. 33.3 (**a–c**) Action at the neuromuscular junction

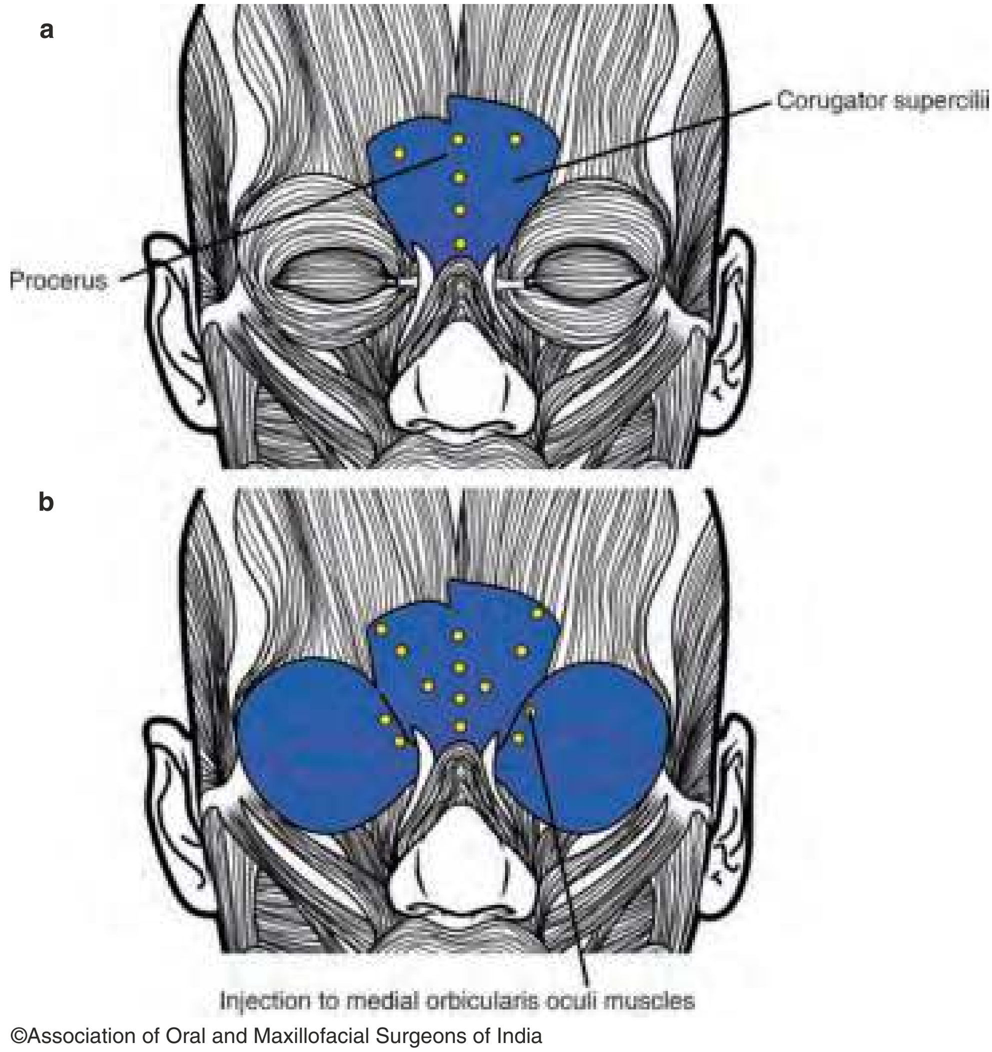
5 U per point of the middle aspect of the muscle, represented in a big dots as given below in the figure. Frontal injections and glabellar injections must preferably be done together, to avoid increased compensatory use of glabellar muscle, which are mainly depressors [12, 13]. The dose of the injections must be kept small enough to just weaken the muscle instead of producing total paralysis. This is because the frontalis is responsible for facial expressiveness, and total paralysis would cause brow ptosis [14, 15]. It is also important to preserve at least some frontal is muscle movement, responsible for facial expression and lift of the eyelids and brows.

(c) *Crow feet wrinkles Injection technique* (Fig. 33.6a, b): Three to four injections of Botulinum toxin-A may be

Fig. 33.4 (**a**, **b**) Glabellar lines injection technique



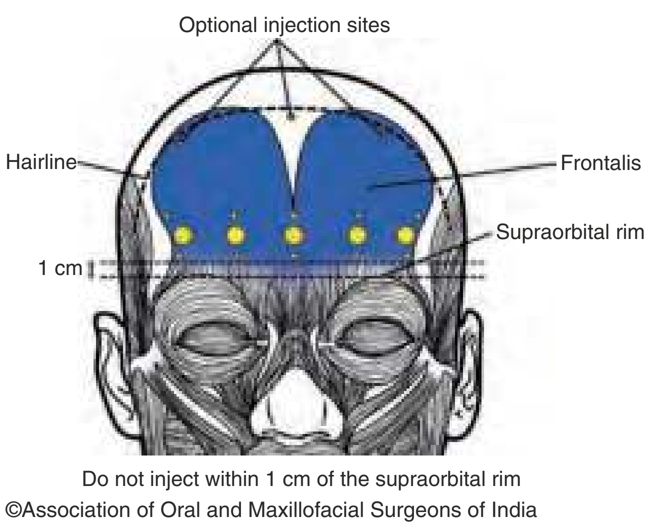


Fig. 33.5 Forehead lines injection technique

administered lateral to the eye, in the 'crow's feet' region that radiates out from the lateral canthi. Around 8–20 U may be administered on each side [16]. The injection must be placed 1 cm lateral to the orbital rim and must be above the canthal angle, to avoid upper lateral lag. To achieve this, one can place a guiding finger of the other hand at the lateral orbital rim. Owing to the superficial location of the muscle, the needle need not be advanced deep into the subcutaneous tissue. Botulinum Toxin has a wide zone of effect, and therefore a superficial dermal injection will minimise bruising, but will still give good clinical results [16].

(d) *Elevating Oral commissures and Smile line Injection technique* (Fig. 33.7): Depressor anguli oris is the muscle to be elevated for improving the smile lines. It is indicated in patients with inverted smile line (reverse smile line), which is caused by pulling the corner of the mouth inferiorly. To identify the depressor anguli oris muscle, the patient must frown and the muscle must be simultaneously palpated 1 cm lateral and inferior to the oral

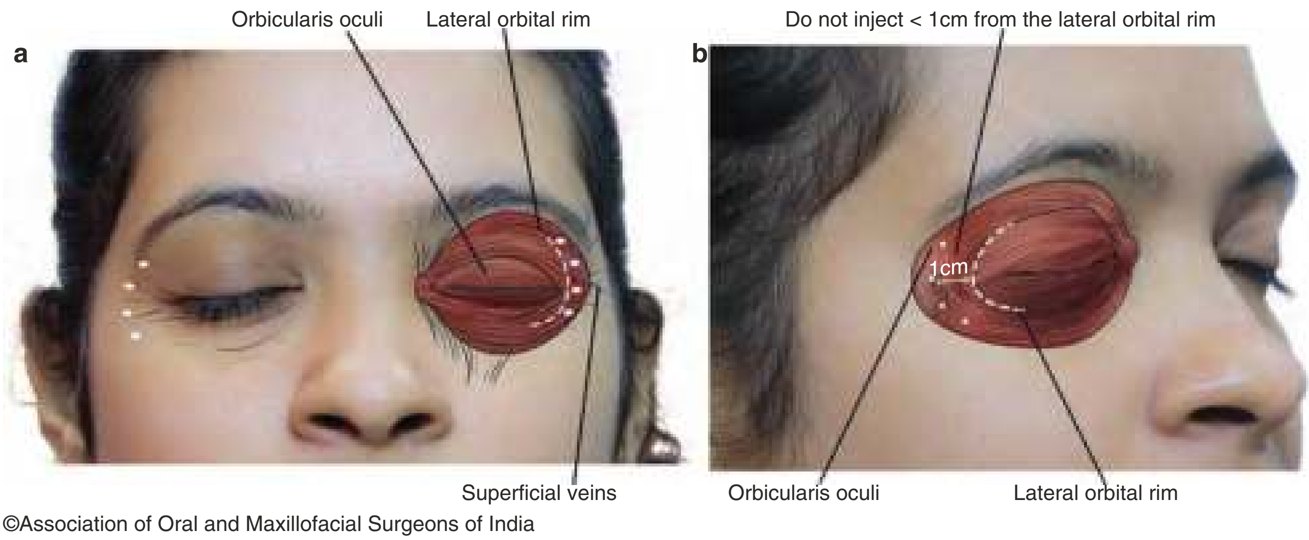

Fig. 33.6 (**a**, **b**) Crow feet wrinkles injection technique

commissure. Inject approximately 2–5 U deeply into the muscle on either side [16].

(e) *Gummy smile or Gingival show correction Injection technique* (Fig. 33.8): In some patients, while smiling, their upper lip is pulled up, which reveals some amount of gingival tissue. If this is >1 cm, it is referred to as a "*Gummy smile or Gingival Show*". The levator labii superioris alaeque nasi elevates the upper lip during smile. These muscles have their origin on the frontal process of the maxilla, and insert into the skin of the lateral aspect of the nose and upper lip. If only one muscle contracts, it results in a 'snarl', and this muscle has been referred to as the "*Elvis*" muscle [16]. Normally, 1–2 U of the Botulinum neurotoxin is injected on each side in the muscle. Care should be taken because this injection can produce elongation of the upper lip.

(f) *Platysmal wrinkles Injection technique* (Fig. 33.9): The platysma forms horizontal lines or wrinkles. Into every horizontal crease, an intradermal injection of 1–2 U may be injected for every 1.0–1.5 cm [16]. There may be several creases, but each treatment session must not use more than 15–20 U. In these areas, careful injections are absolutely essential, as these muscles are cholinergic, and deep injections may affect swallowing. If the injections are placed at deeper levels, or high volumes are used, a weak or diminished swallow may result.

(g) *Masseteric Hypertrophy Injection technique* (Fig. 33.10): The masseter can give masculine characteristics, such as square jawlines and wide mandibular borders. This is enhanced when the muscle hypertrophies, and may not be attractive in women. Bruxism and clenching of teeth can lead to hypertrophy of the masseter muscle, which in turn increases the horizontal width of the mandible [16]. While injecting into the masseter, one finger may be placed along the lower border of the mandible, one finger along the posterior border and one at mandibular angle. This may be done with the patient clenching, as

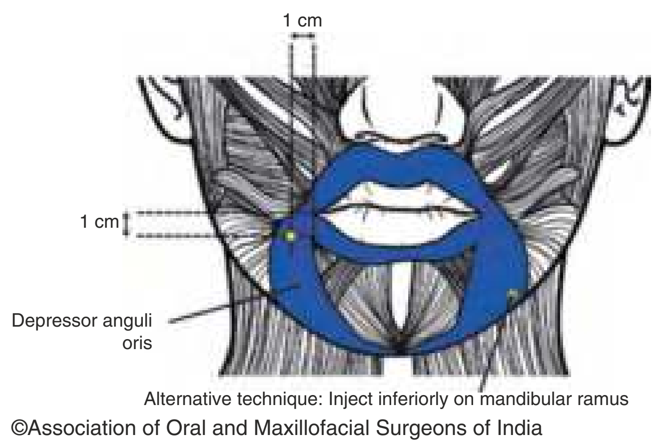

Fig. 33.7 Smile line correction

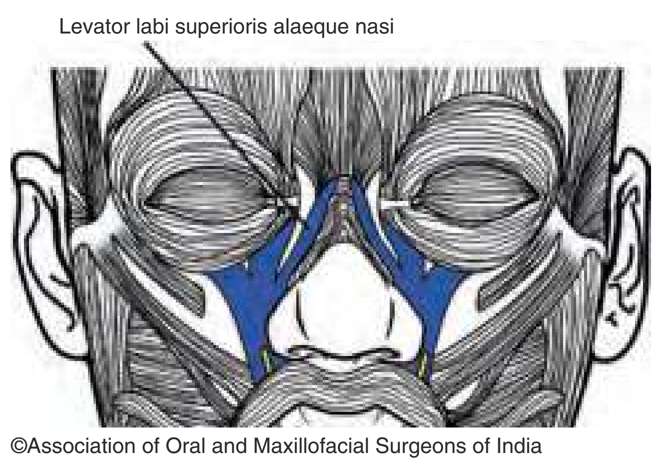

Fig. 33.8 Gummy smile correction

Fig. 33.9 Platysmal banding

this marks the perimeter of the muscle. While injecting bone should be felt by the needle and withdrawn slightly just above the bone and deposit 4–5 U along the marked lines. Depending on the volume of hypertrophy, around 20 U may be injected [16]. Over-injection at the masseter region may result in problems with bite or chewing.

(h) *Frey's Syndrome or Gustatory sweating Injection Technique* (Fig. 33.11): This is a condition in which mild to profuse sweating occurs in the cheek or malar area while eating. A diagnostic test called "*starch-iodine test*" [16] can be performed prior to injection of Botulinum toxin. Povidone iodine is applied over the cheek and corn starch is sprinkled. The patient is advised to eat, to stimulate the salivary gland and left to dry for a few minutes. The corn starch turns black in the area of sweating [16], and a grid is drawn along this area. Once the test is confirmed, usually 30–50 U is injected along the grid as shown. The botulinum toxin blocks acetylcholine, which is the neurotransmitter that stimulates sweating.

33.2.5 Complications and Recommendations While Using Botulinum Toxin

- Apply pressure at the site before and after treatment. Cold packs may also be used.
- The use of small syringes and fine-gauge (30 g) needles can reduce pain and bruising at the injected site.
- Using topical anaesthesia (EMLA—Eutectic Mixture of Local Anaesthesia) reduces pain while injecting.

Fig. 33.10 Masseteric hypertrophy

Fig. 33.11 Frey's Syndrome

- Injections should be symmetrical regarding doses, muscles and areas. This is important for the natural balance of the facial structures and to avoid asymmetries.
- Since the results are expected for 4–6 months, treatments are usually repeated twice a year, for maintenance of the results.
- There are isolated few reports of systemic adverse effects after injections with the use of doses larger than those usually recommended for cosmetic purposes [17].
- The most common injection-related side effects are pain, transient edema at the injected site, erythema, haematomas and ecchymosis [13, 17].
- Common technique-dependent complications include eyelid ptosis, asymmetries and excessive brow elevation.
- In the lower face, complications are related to high doses can cause undesirable paralysis of the musculature, resulting in asymmetric smiling and complications due to the incompetence of the sphincter function of the mouth.
- In the neck, complications can be dysphagia and difficulty in the movements.

33.3 Dermal Fillers

33.3.1 Role of Fillers in Facial Aesthetics

Throughout the past decades, there have been major changes and advancements in the injectable preparations used for soft tissue augmentation. Introduced by Dr. Arnold Klein [1] in the 1980s, for lip augmentation, collagen has progressed to the broader concept of volumising the face and to correct the subcutaneous atrophy due to ageing and fat loss.

Following extensive clinical trials in the late 1970s, the FDA first approved the use of bovine collagen in 1981, which greatly advanced the field of soft-tissue augmentation. Over the past 10 years, several types of facial fillers have been approved in the United States and Europe, and there is a constantly evolving and expanding assortment of the dermal filler materials and devices for soft tissue augmentation [18].

Hyaluronic Acid (HA), which was introduced as a facial filler in 2003, brought about a much needed change from the allergies being reported due to bovine collagen [18]. Hyaluronic Acid is a member of the glycosaminoglycan family and a natural component of human connective tissue. The HA molecule is identical across all species and lacks a protein component, thus it has little to no potential for immunologic reaction in humans. It is composed of repeating disaccharide units, stabilised with cross-linked hydroxyl groups that bind water to create volume. This gives a plumped appearance to the skin. HA in the skin decreases with age and sun exposure, reducing the skin's water-binding capacity and turgor, ultimately leading to skin wrinkling and sagging [19]. HA can absorb up to 1000 times its molecular weight of water, and Hyaluronic Acid fillers volumise the face by replacing body Hyaluronic Acid and restoring hydration [5]. Studies have shown that hyaluronic acid requires less injection volume as compared to bovine collagen for optimal cosmetic results, and HA is also found to be more effective at maintaining the cosmetic correction [20, 21].

The U.S. Food and Drug Administration (FDA) has now approved various types of Hyaluronic acids, bio-stimulatory products like calcium hydroxyapatite and poly-L lactic acid, as well as polymethylmethacrylate as a substitute for fillers.

Fillers are categorised as permanent, semi-permanent and temporary. The majority of injectable fillers are temporary, lasting from several weeks to several months, although some reportedly last 9–12 months. Many of these processes require ongoing treatment to maintain the desired appearance [22].

33.3.2 Classification of Fillers

Based on their duration of action, fillers may be classified as follows:

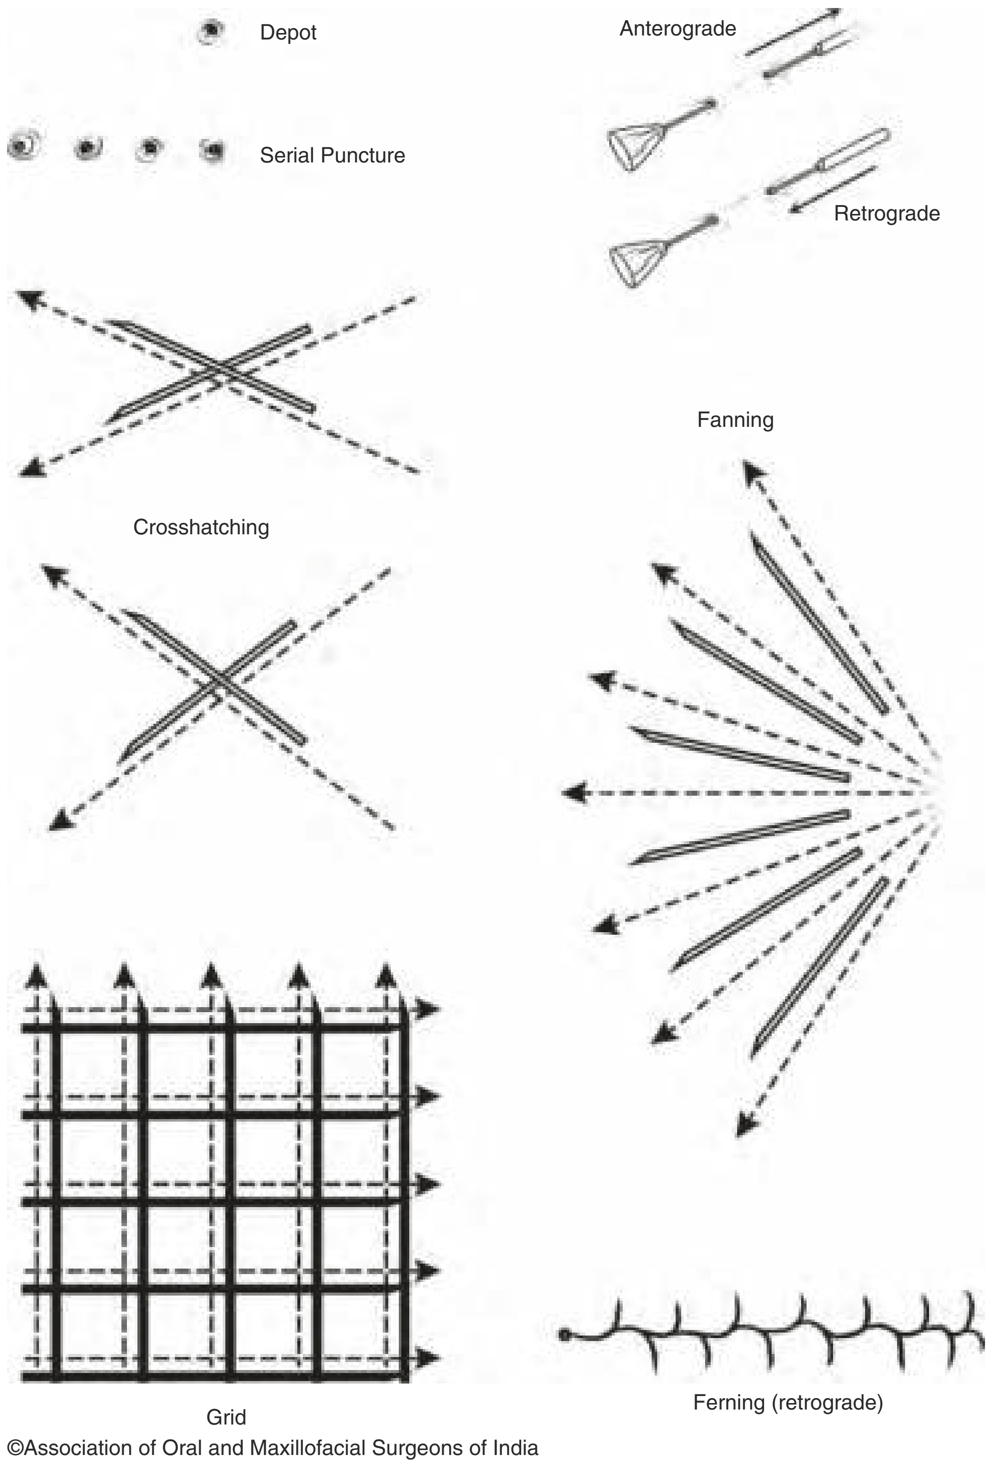
Temporary (3–12 Months) These are mainly used to replace collagen in the skin, which weakens with age and loses its elasticity. Collagen has three main sources—bovine, porcine and human. Bovine collagen is very similar to the human molecule and is widely used. It only has specific differences in the end peptides (telopeptides), which are removed in processing, leaving a core protein similar to that of a humans [23]. Hyaluronic acid is the most commonly used Filler material of this category.

Semi-Permanent (1–5 Years) Calcium hydroxyapatite is one of the commonest semi-permanent fillers. It creates a stable scaffold for soft tissues to grow. Calcium hydroxylapatite may be injected into the deep dermis, where the microspheres are held in place until they are resorbed and collagen deposition occurs. This results in formation of non-scar-tissue type of collagen, which provides volume in the area under treatment [24].

Permanent (>5 Years) These are mostly synthetic implants, which are made of Polymethylmethacrylate (PMMA) microspheres. PMMA microspheres may be mixed with denatured bovine collagen and lidocaine, and suspended in a phosphate-buffered saline solution. Since PMMA is inert, it is well tolerated by the body and does not induce allergic reactions [25, 26].

Preparation of the Patient before Injection of Fillers: The patient's face is washed gently to dry and disinfect the skin. This is done using propanol solution. Since the dermal fillers are very painful while injecting, application of the topical anaesthesia around the area of injection using EMLA (Eutectic Mixture of Local Anaesthesia) for 30–45 min prior or particular branch of Maxillary division or Mandibular division of the trigeminal nerve is anaesthetised using 2% Lignocaine as a local anaesthetic injection.

Fig. 33.12 Various patterns in Injection technique



33.3.3 Dermal Filler Injection Methods (Fig. 33.12)

Hyaluronic acid is available in syringes in a sterile packed container. These have 26–30 gauge needle, with a length of 1–1½ inches.

These are injected at the subdermal planes in various fashion which are mentioned in Box 33.2.

The following is a description of various techniques.

Linear Threading: In this technique, fillers are injected in a needle and thread fashion. The needle is inserted and withdrawn repeatedly along a straight line. It has two types.

1. *Anterograde Injection:* The filler is injected while the needle is being advanced, and the filler is therefore easily tracked in the front of the needle.

Box 33.2 Dermal Filler Injection Methods
- Linear threading,
- Depot injection,
- Fanning method,
- Serial puncture,
- Cross hatching,
- Grid and Ferning

2. *Retrograde Injection:* The filler is not injected simultaneously during needle advancement. Once the needle is slowly withdrawn, the filler is injected.

Depot: In this technique, a small amount of the filler is deposited in the correct plane.

Serial Puncture: In a single wrinkle or fold, multiple closely spaced depot injections are placed.

Fanning: It is done through one point of entry and the needle is rotated like a fan in multiple directions, and the fillers are deposited in a retrograde way. It is important to stop injecting as the needle comes close to the insertion site in order to avoid build-up of fillers at the point of entry.

Cross Hatching: Injecting as multiple linear thread deposited in an X-shaped fashion.

Grid: It is injected as linear threads intersecting perpendicular to each other point of entry.

Ferning: [16] This is similar to retrograde injection. The needle is inserted on either side of the central tract, and the fillers are deposited in a branch-like fashion almost like the branches of a fern.

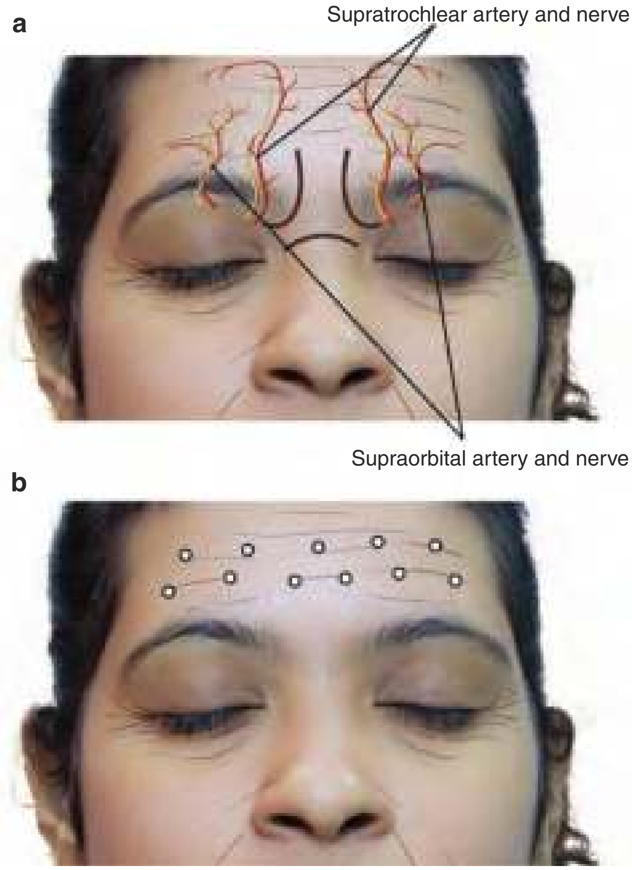


Fig. 33.13 (**a**, **b**) Glabellar & forehead wrinkles

33.3.4 Injection Techniques

(a) *Glabellar and Forehead region* (Fig. 33.13a,b): The Glabellar region is the most prominent site for wrinkling and very well shown even in a mild expression. There are vertical lines of wrinkling, which result from contraction of the corrugator supercilii muscles, and horizontal lines which occur due to contraction of the procerus muscle. Before injecting, the patient should frown the brow and the needle is inserted at the subdermal plane and injected in a linear fashion and it is also deposited deep and parallel to the wrinkle. Small depots or serial puncture fashion of fillers are injected along the line of the wrinkles throughout its entire length. Gentle rub or massaging to be done to distribute the filler uniformly. In the case of bruising, icepacks can be used. Injecting into a vessel must be avoided as this can lead to the formation of emboli.

(b) *Nasolabial Fold* (Fig. 33.14a,b): The nasolabial fold is defined as the groove from corner of the alar base to the margin lateral to the angle of the mouth. The nasolabial groove must never be eliminated completely as this can result in an unaesthetic appearance. Injection may be done using serial puncture, linear threading, cross-hatching, or fanning. Only the medial part of the fold must be augmented, with injections perpendicular to this. This is best done by imagining a tall, thin, triangular deficit in front of the fold that needs to be filled. To prevent bruising, ice and pressure may be applied. Initially, hyaluronic acid swells and may appear as a firm mass on palpation but gradually blends in after the first week.

(c) *Lip Augmentation* (Fig. 33.15): This is one of the most common cosmetic procedures done using Hyaluronic acid filler for augmenting or everting the lips. The areas to be augmented are the outline of the lip, body of the lip or both. There is a potential space in the body of the vermilion, which, if correctly entered, will allow the filler to

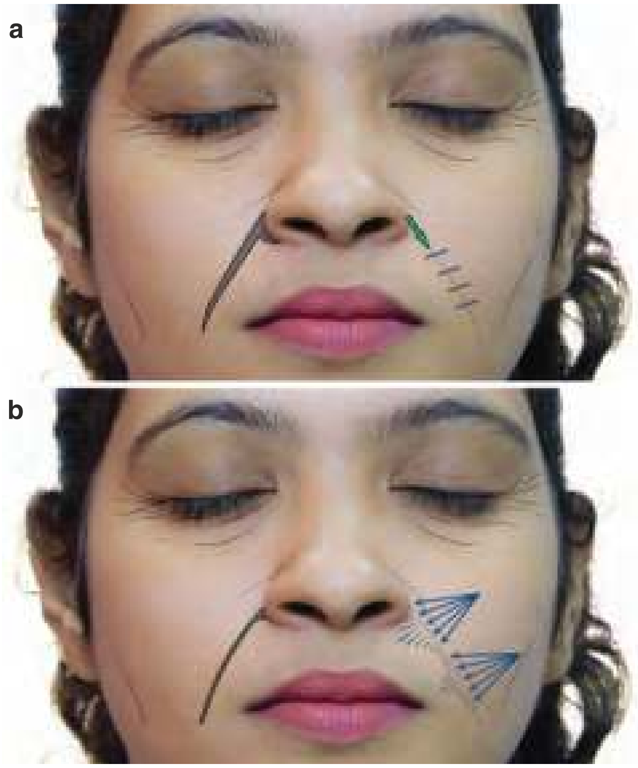

Fig. 33.14 (**a**, **b**) Nasolabial fold injection technique

move within it along the entire lip margin. Dermal fillers injected in the body of the lips can augment, rejuvenate and improve the symmetry of the lips. Philtral columns can get flattened with age. These can be accentuated by injecting along the border of the vermilion and philtral region to give a more prominent philtrum and cupids bow with eversion of the lip. The philtrum may be pinched after injection to accentuate the ridges. Injections are generally placed superficially in to the subcutaneous plane. Massaging or a gentle rub after injection helps to distribute the filler evenly. Injection may be performed in an anterograde fashion, from lateral to medial, and the filler can be tracked along the vermillion.

(d) *Tear Trough Deformity* (Fig. 33.16): Tear Trough is usually referred to as the crease at the medial segment of the inferior orbital region. As ageing occurs, the infraorbital rim becomes more skeletonised and depressed. To correct this sunken appearance, HA may be injected into the semicircular depression under the eyes. Normally a 30-gauge needle, 2.5 cm long, is used to inject in the dermal layer of the lower eyelid to avoid bruising, as this area is highly vascularised. The needle is then inserted upwards at an angle, till it reaches the top of the orbital rim. The finger of the opposite hand may be used to direct the needle by positioning it at this point. The tip of the needle must touch the bone and its precise location must be verified prior to injection. The filler is injected slowly and deeply into this area. Massaging may be done at the injected area to avoid irregularities. If the HA is deposited too deep, a "*Tyndall effect*" [16] may be observed. Hyaluronic Acid can occasionally increase fluid retention around the periocular area, and lead to infraorbital swelling, edema or discolouration in the medial portion of the orbicularis muscle. If this occurs, subcutaneous hyaluronidase injections may lyse the Hyaluronic Acid and reduce the swelling.

(e) *Injection technique to increase the cheek volume* (Fig. 33.17): In some patients, fat loss or volume deficit can cause cheek hollowing. The loss of buccal pad of fat causes wrinkled cheeks, exaggeration of nasolabial folds and jowling of the skin at the lower border of the mandible. The submalar region (below the zygomatic arch) and buccal region (lateral to the nasolabial fold) are areas that need attention. The injection technique should be administered in a grid or fanning pattern. The injections must be administered at the dermal–subcutaneous plane. Massaging after injection can help smoothen irregularities.

33.3.5 Contraindication [22]

Some of the most common conditions to be avoided for fillers include:

- Scarring and collagen/connective tissue disorders
- Diabetes
- Infections—e.g.: Viral Herpes
- Coagulation problems
- Pregnant or Lactating women
- Psychological conditions

33.4 Conclusion

Botulinum Toxin Type A and Hyaluronic acid dermal fillers are very safe and effective under a trained physician or surgeon for therapeutic and cosmetic use. Wrinkles especially those which are located in the face and some asymmetries, mainly caused or worsened by the repeated contraction of facial muscles and ageing process can be effectively treated by these methods.

Proper knowledge of the anatomy of facial muscles and proper techniques are important to achieve predictable results and avoid complications. Informed consent for the procedure must be obtained from the patient after explaining the risks and the outcome, before commencing the treatment. Though Botulinum toxin and dermal Fillers give temporary results, they are safe and very effective in achieving aesthetic outcome.

Case Scenarios

Case 1 (Fig. 33.18a,b,c)

A 43-year-old female complaining of excessive tooth and gingival exposure on smiling. Clinical features (Fig. 33.18a): excessive gingival show on smiling normal lip length and normal size of the tooth. Treatment Plan (Fig. 33.18b1, b2, b3 and b4): locating the levator labii superioris muscle and injecting Botulinum toxin Type A with a dose of 5 U on both the sides. The injection point is located at the junction between lip and the ala of the nose. Post-operative findings (Fig. 33.18c): no gingival show on smiling.

Fig. 33.18 (**a**) Clinical features with excessive Gingival show. (**b1, b2, b3, b4**) Intraoperative. (**c**) Postoperative, absence of Gingival show

Fig. 33.19 (**a**) Clinical feature with forehead wrinkling. (**b1, b2**) Intraoperative. (**c**) Post-operative, absence of Wrinkling

Case 2 (Fig. 33.19a,b,c)

A 47-year-old male, complaining of excessive wrinkling in the forehead on looking upwards and frowning with ageing appearance. Clinical features (Fig. 33.19a): wrinkling and folds found on the forehead on upward starring and frowning. Treatment Plan (Fig. 33.19b1, b2): locating the frontalis muscle and injecting Botulinum toxin Type A with a dose of 5 U on both the sides at 3 different points marked and above 1 cm from the supraorbital margin. The injection point is located midway between supraorbital margin and frontal hairline. Post-operative findings (Fig. 33.19c): absence of wrinkling.

34 Hair Transplantation

Sreedhar Reddy Pothula and B. S. Jayanth

34.1 Introduction

In the past few decades, maxillofacial surgeons have played a pivotal role in enhancing the aesthetic value of the face through many surgical and non-surgical procedures, with hair transplantation being one of the popular choices which has seen an exponential demand in the last decade. Though hair restoration procedures were being performed for many decades ever since Dr. Norman Orentreich in 1959 published them in the annals of the New York Academy of Sciences, there has been many advances to the originally described punch grafting which has become obsolete and has been replaced by the so-called micrografts via the two basic techniques of follicular unit transplantation (FUT) and follicular unit extraction (FUE). The success of the above techniques is in part attributed to the theory of donor dominance which postulates that the hair taken from the donor area of the posterior scalp will continue to grow without getting hit by factors which were responsible for the thinning out of hair in the frontal areas [1].

Apart from hair transplant being a promising procedure for male pattern and female pattern alopecia, it has been applied to other causes of hair loss too; traumatic and burn scars on hair bearing areas, alopecia following surgical procedures (i.e. Craniotomy, rhytidectomy procedures), redo hair transplantation, congenital reasons like cleft lip scenario. Currently the scope for hair transplantation is expanding with the demand from patients who want to strengthen a weak hairline, desire to lower the hairline or fix missing facial hair on the moustache, beard, eyebrow or eyelashes.

As the field of hair transplantation continues to evolve at a breakneck speed with specialists from multiple specialities performing this scientific artistry, it's all the more pertinent that we as maxillofacial surgeons are abreast of the current principles and practice of this hair restorative surgery.

34.2 Surgical Anatomy

An understanding of the surgical anatomy of the scalp is necessary to avoid complications and to optimise your performance for hair transplantation.

Scalp consists of five distinct layers with the most superficial layer being the skin which comprises of epidermal and dermal layers. These layers contain hair follicles, sebaceous and sweat glands with rich vascular supply. The second layer of scalp is made up of connective tissue, which is well vascularised and heavily innervated by sensory nerves. The deepest portion of the hair follicle, bulb and papilla, may extend through the skin into this layer (Fig. 34.1a). Thus, when obtaining donor grafts, effort should be made to incorporate the upper part of dermal layer to obtain the entire hair follicle. The third layer also called galea aponeurotica is a tendinous tissue connecting the two bellies of the occipitalis and frontal muscles. Loose areolar connective tissue is the next layer which contains numerous potential spaces, capable of great distension thus allowing for exceptional mobility of scalp. Unfortunately, these spaces are also capable of potential space for haematoma collection and spread of infections. The deepest layer of the scalp defines the pericranium, which is analogous to periosteum throughout the body.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_34) contains supplementary material, which is available to authorized users.

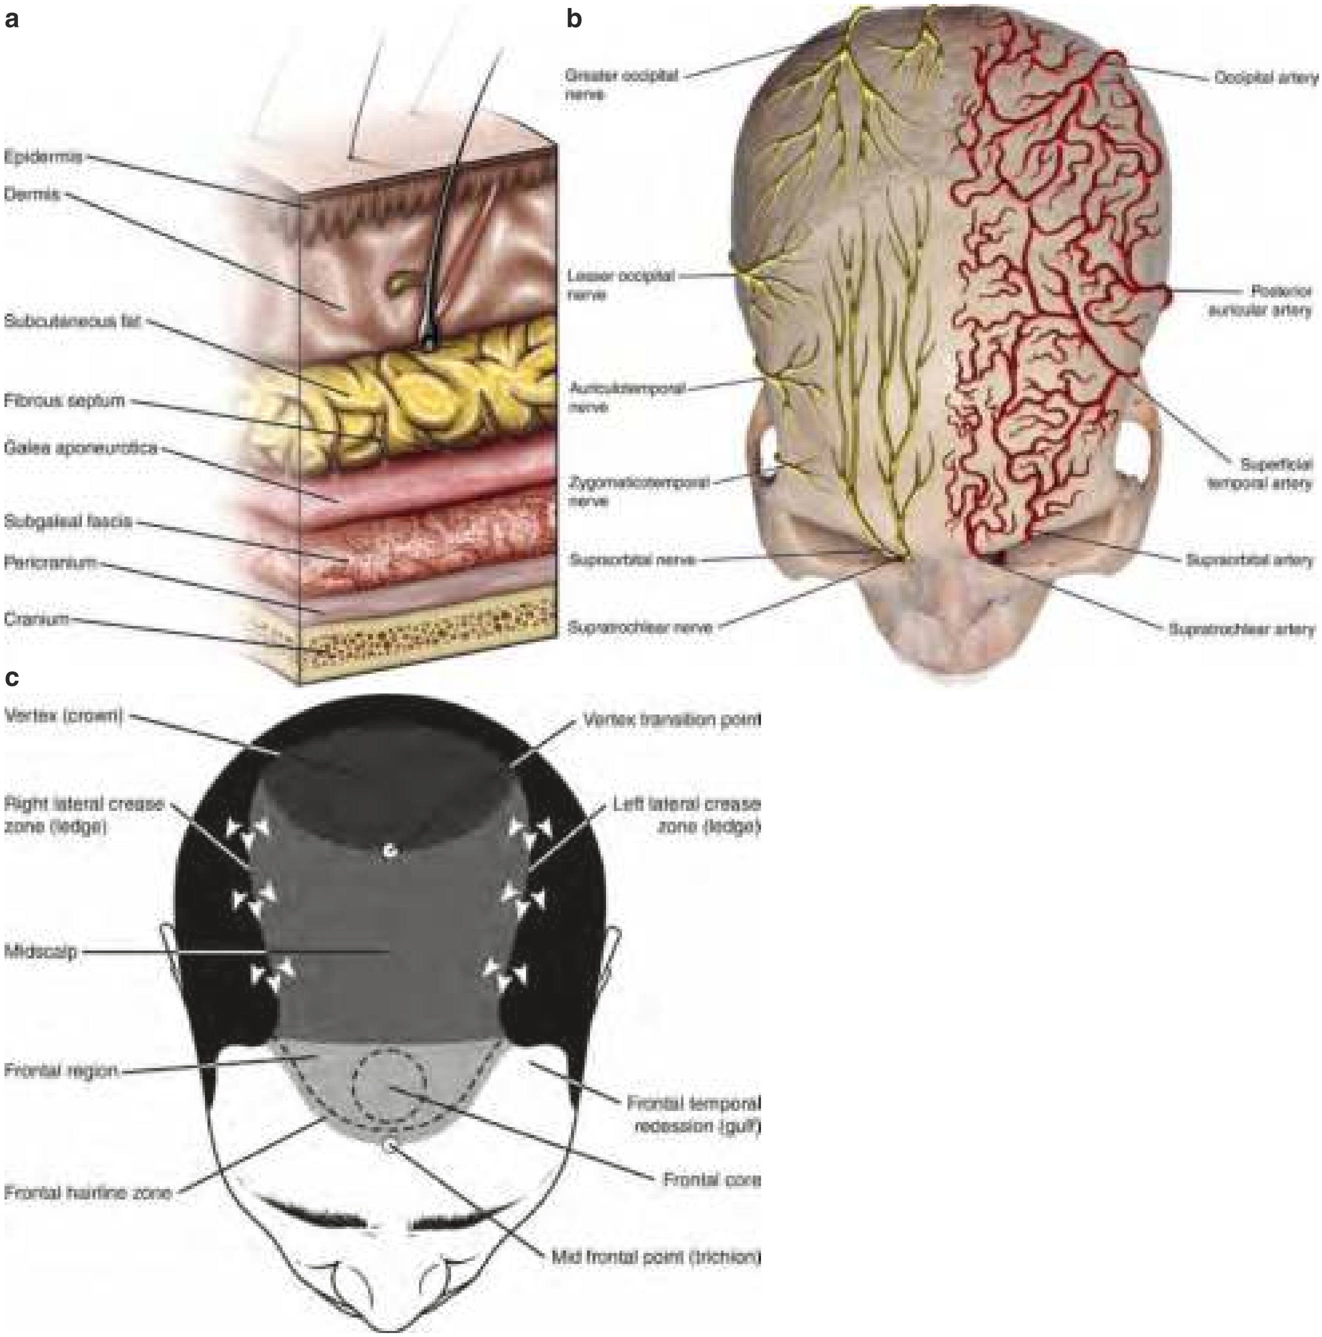

Fig. 34.1 (**a**) Hair follicle extending into dermis; note the layers of the scalp. (**b**) Arteriovenous supply of the scalp with sensory innervation. (**c**) Zones of the scalp

34.2.1 Blood Supply and Sensory Innervation

The arterial supply to the scalp arrives from branches of both external and internal carotid arteries. Branches of the external carotid artery in order from posterior to the anterior include the occipital, posterior auricular and superficial temporal arteries. The supratrochlear and supraorbital arteries are branches of the internal carotid artery. The veins of the scalp follow the same basic network of the arteries and drain into the jugular veins (Fig. 34.1b). All of these vessels freely anastomose in the connective tissue layer of the scalp. Awareness and approximate location of the main branches are very important during the hair transplant surgery not only to avoid haemorrhage or haematoma but also to prevent ischemia to the follicles. Occipital artery which enters the scalp immediately above the external occipital protuberance at the superior nuchal line can easily be injured if depth control is not maintained. If arterial haemorrhage is encountered, electro cautery and suture ligation are adequate to secure homeostasis. Damage to vessels could likely lead to the formation of donor area scar.

Sensory innervation of the scalp arises from all three branches of trigeminal nerve antero-laterally with the forehead getting its supply from the supraorbital and supratrochlear branches of the ophthalmic division, while the anterior temporal scalp is supplied by the maxillary division and the mandibular division goes onto supply the temporoparietal zone of the scalp through its auriculotemporal nerve. The spinal cutaneous nerves of the cervical plexus (c2 and c3) come to supply the area posterior to the auricle via the greater and lesser occipital nerves. These nerves are found in the connective tissue just superior to the galea.

34.2.2 Zones of the Scalp

Typically, the areas of male pattern hair loss are horseshoe shaped and are divided into three zones [2] (Fig. 34.1c)

1. Frontal—extends from the hairline to the mid-scalp and is curvilinear. Has a frontal hairline zone anteriorly with the line being irregular like coastline of the sea with mounds and recessions. The follicles in this zone is mainly single hair follicle for the first two to three rows generally blending into multiple follicular units posteriorly giving rise to the density effect known as shingling. The frontal core zone is a small area in the central aspect of the frontal region which is circular to oval and is very important in framing the face receiving the highest density of grafted hairs.
2. The mid-scalp—is at the top of the head. This horizontal area is bordered on both the sides by the temporal parietal fringes and is sandwiched between the frontal zone anteriorly and the vertex posteriorly.
3. Vertex or crown—the most posterior area being rounded and characterised by whorl arrangement of hair is the toughest area to transplant.

The temporal fringe is the lateral hair zone present on the sides of the scalp anterior to the tragus of the ear and posterior to this is the parietal fringe.

The frontotemporal apex is the area usually devoid of hair at the junction of the lateral frontal hairline and temporal fringe. This coincides with the deepest point of the recession on the forehead and is aligned with the lateral canthus of the eye.

34.2.3 Microanatomy of Hair

Hair consists of a living part under the skin extending into the dermis known as follicle and a non-living keratinised part above the skin, the so-called hair shaft (Fig. 34.2). The shaft has three further layers namely the outer protective cuticle, inner cortex and in certain cases the medulla forms the core, and they mainly help in protection and anchorage of the hair.

The growing structure of the hair is the follicle with the upper part being constant and consists of the top infundibulum at the opening of sebaceous gland and isthmus in the middle where the piloerector muscle comes to insert. The lower part of the follicle known as the bulb is very vital as it's the one involved with regeneration and most of the stem cells are located here. Hence, while implanting holding, the graft above or beside the bulb is vital to ensure sustenance of regenerative potential.

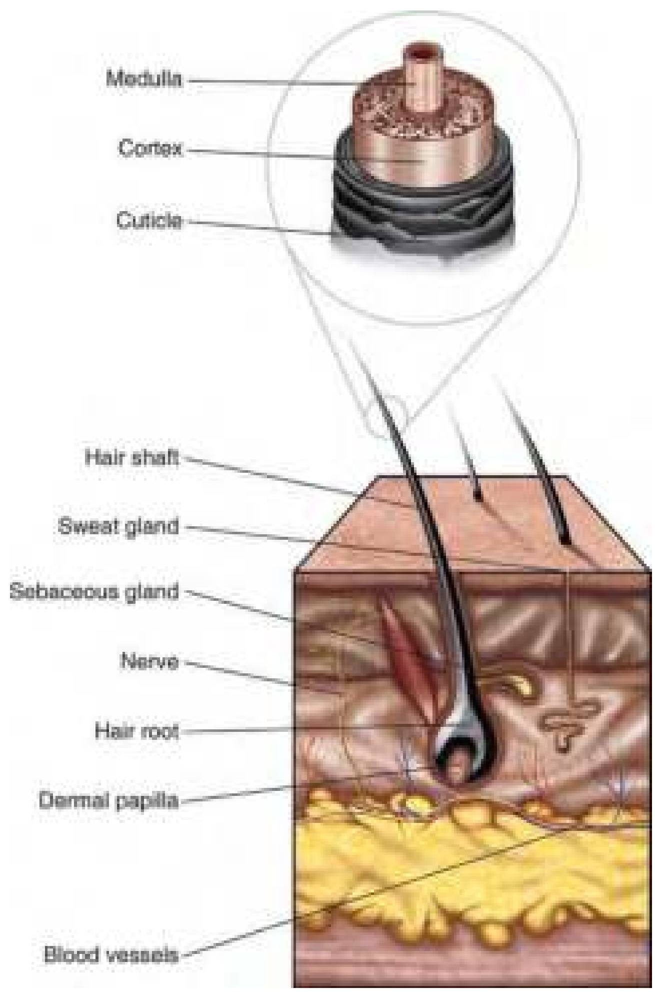

Fig. 34.2 Microanatomy of the hair

34.3 Terminology

The unique language of hair transplant surgeons consist of a few common words to communicate within the speciality [3] (Box 34.1).

Box 34.1 Hair Transplant Surgery: Terminology

Follicular unit graft (FU): The natural Bundle of hair strands consisting of one, two or three hairs woven within a single unit and held by connective tissue elements as the follicle. The graft containing two or three follicular units becomes a multi follicular unit graft.

Micrograft: The follicular unit which has single hair graft within it is referred to as a micrograft, and the same is preferred for frontal hairline implantation.

Minigraft: The follicular unit which has more than a single hair graft and houses four to six hair grafts prior to cutting with microscopes are minigrafts.

Follicular unit density: It's the number of follicular units per cm^2.

Hair density: It's the number of hairs per cm^2.

FUT: The grafts are obtained from the harvested strip through slivering and dissection of individual follicles under magnification.

FUE: The grafts are obtained individually in the donor area one at a time utilising a punch and handheld extractor.

Stick and place implantation: Refers to implantation made immediately as the recipient site slit is made with a needle or blade.

Pre slit implantation: Refers to implantation made after all the recipient site slits are made with a blade or needle.

Coronal slits: Refers to slits oriented along coronal from side to side.

Sagittal slits: Refers to slits oriented along sagittal plane from front to back.

34.4 Growth Cycle and Hair Loss

Hair is cylindrical, outgrowths on the skin made up of keratinous filaments. The normal human scalp contains between 100,000 and 140,000 follicles with hair being arranged in follicular units, small groups of 1–4 hairs each. There are approximately 50,000–60,000 follicular units on the human scalp.

Testosterone is the main regulator of hair growth with the androgens binding to receptors in the dermal papilla influencing the growth. Human hair does not grow constantly and evenly but grows in phases and in cycles which are reproducible. Anagen is the growing phase of hair that accounts for 85% of the hair growth, during which hair grows at 0.5 inch per month for up to 10 cm per year with adequate blood supply providing nutrients and minerals to the hair. This phase lasts for anywhere between 3 and 6 years. As long as this phase persists, the hair stays on the scalp and is genetically determined. Anagen is followed by catagen and the later phase onset signals the end of active hair growth. During this transitional phase which lasts for 1–2 weeks, the production of hair stop and hair follicle start to shrink in size and nearly 2–3% of the hairs are in this phase. Telogen is the final phase of the hair cycle where the aged hair fall out and new ones push themselves out of the skin. This final phase lasts for nearly 3 months with around hundred hairs being shed per day and nearly 10–15% of the hairs are in this phase at any point in time (Fig. 34.3).

People often confuse with hair fall to hair loss. Hair fall is common in every individual. Around 10–20% of total hair will be under shedding process. That hair will grow back in 3 months. On average 80–60 hair strands fall is considered as normal.

Male pattern hair loss or androgenetic alopecia as the word suggests is a result of both androgens and genetic factors which work together causing the clinical effect of baldness [4]. Though there are many reasons for hair loss, androgenetic alopecia is the most common reason and accounts for 95%. Fortunately, it can be treated with hair transplant surgery. The diagnosis of androgenetic alopecia is supported by a family history of hair loss, although a positive history is not always identified. There is a slightly greater incidence of having a positive history on the mother's side but the inheritance of male pattern hair loss can come from either side of the family.

In androgenetic alopecia, there is change of hair from terminal hair to vellus hair. There happens to be a gradual evolution of this pattern, with each subsequent cycle of the new hair being fine and thin leading eventually to various grades of alopecia. It initially starts with the frontal hairline recession and regression, followed by loss of more temporal hair and simultaneous thinning of the vertex hair. Norwood classified approximately 7 different types of male pattern hair loss. Identification of these types is key to an understanding of proper planning of hair transplant surgery.

Testosterone gets converted to dihydrotestosterone (dht) both systemically and in the process of intrafollicular conversion under the influence of the enzyme 5-alpha reductase leading to its binding with androgen receptors of the follicular cells in genetically predisposed men leading to inhibition of protein synthesis by shortening the anagen phase, thereby producing finer hairs with shaft becoming thinner; this stunted hair follicle growth leads to miniaturisation of follicles till they become extinct establishing balding [5].

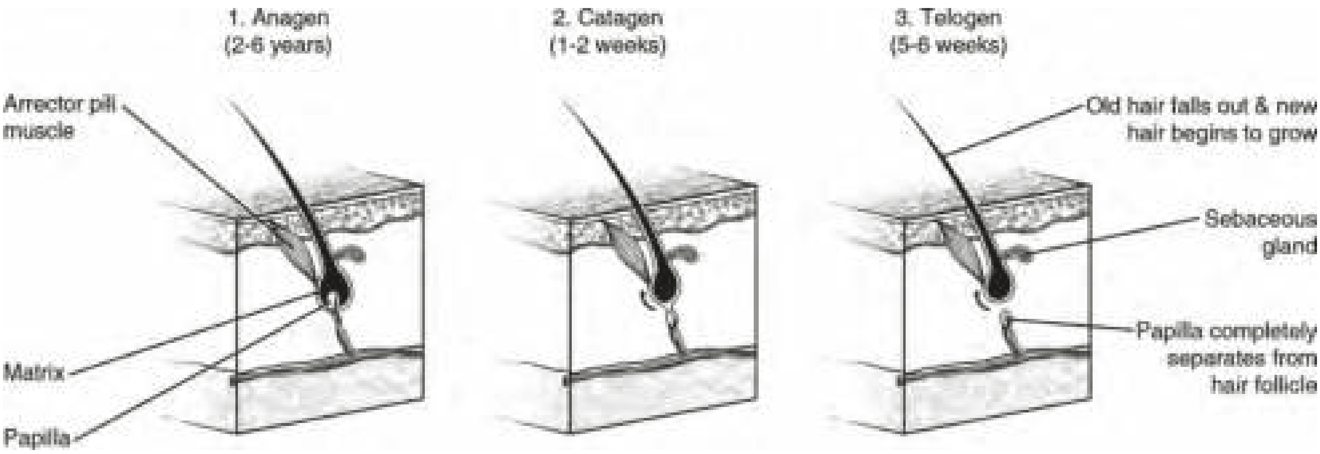

Fig. 34.3 Hair growth cycle

Box 34.2 Basic Requirements for Hair Regrowth

1. Regulating dihydrotestosterone levels in the blood
2. By ensuring normal supply of balanced nutrients to the hair roots
3. Proper blood circulation to carry the nutrients to the roots in the scalp
4. Maintaining good health through general well-being of the individual

Clinical studies have given us an understanding that hair can be grown back if the following four things are ensured (Box 34.2):

Hair loss is not a disease but a condition where anagen or the growth phase reduces and the telogen or fall phase is extended. This forms the basis of hair loss in alopecia conditions other than androgenetic alopecia. The factors leading to hair loss could stem from internal/external factors.

Internal Factors There are many factors which internally lead to deficient states harming the hair growth. A few of them which are relevant today are iron deficiency, calcium deficiency, zinc deficiency, general debility, anaemia, hypothyroidism, deficiency of the fat soluble vitamins, thyroid problems, insulin resistance, metabolic disorders like gout and PCOD, prolonged illness, emotional turmoil following surgery and individuals with seborrheic scalp.

External Factors The lifestyle and environmental factors do influence the hair health and growth cycle. The common causes are smoking including passive smoking, stress, alcohol intake, lack of sleep, crash dieting, fad diets, high-protein diet, exposure to extremes of heat or cold, less intake of fluids, poor scalp hygiene, dust, pollution, fumes and exposure to endocrine disrupting chemicals.

34.5 Classification

The most popular classification of the male pattern hair loss is the Norwood classification system (1975) which is a refined version of the original Hamilton system (1941) [6].

34.5.1 Norwood Classification (Fig. 34.4)

Type 1 presents the normal hairline with minimal recession of the frontotemporal area.
Type 2 patients present a symmetrical and mild recession of the frontotemporal area along with thinning of the hair.
Type 3 patients define balding with minimal or no in the frontal areas and a deep recession.
Type 4 patients present with significant recession and loss of both frontal and vertex hair with a bridge of her between the two still retained.
Type 5 category patients present a progression of the type four category with only thin and narrow bridge of hair between the frontotemporal and the vertex areas.
Type 6 represents the loss of hair that separates the frontal and the posterior vertex areas with further progression in lateral and posterior zones.
Type 7 represents the most severe form of balding with only a band of hair remaining in the low occipital and temporal areas with extensive miniaturisation of the hair.

Basically, in the above classification, the two areas of hair loss—a bitemporal recession and thinning crown gradually enlarge and coalesce until the entire front, top and crown of the scalp are bald.

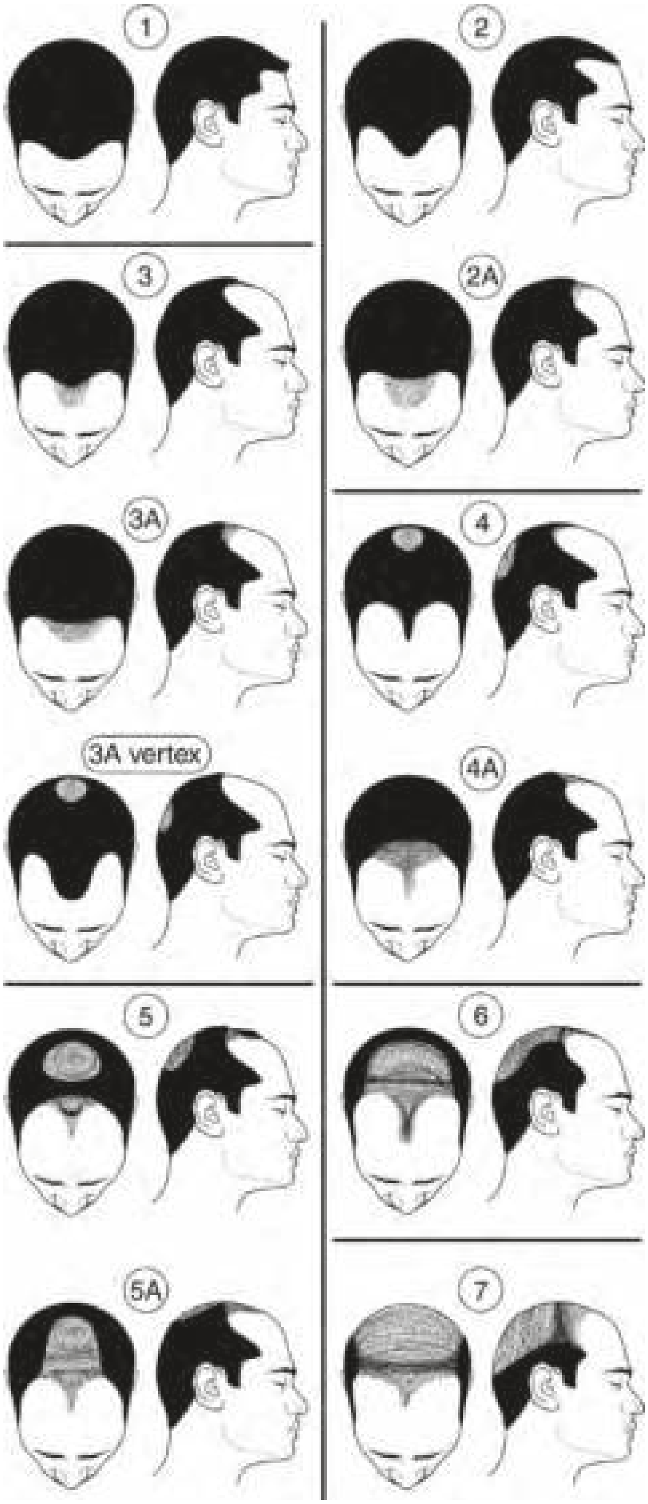

Fig. 34.4 Norwood classification of male pattern alopecia

To regain the crowning glory, medical treatment gives good results up to type 3 patients while hair transplantation is the only choice for patients between types 4 and 6.

Routinely, clinicians come across variations of the classification which fall outside the Norwood classification, they are as follows: Differential use pattern alopecia, diffuse and patent alopecia.

34.5.2 Classification of Hair Loss in Women

The Ludwig classification (1977) uses three stages to describe female pattern genetic hair loss (Fig. 34.5).

Type I (mild), type II (moderate) and type III (extensive). In all three Ludwig stages, there is hair loss on the front and top of the scalp with relative preservation of the frontal hairline. The back and sides may or may not be involved.

In Ludwig type I, there is early thinning that can be easily camouflaged with proper grooming. Type I patients have too little hair loss to consider surgical hair restoration.

Women with type II hair loss have significant widening of the midline part and noticeably decreased volume. Hair transplantation may be indicated if the donor area in the back and sides of the scalp is stable.

In Ludwig type III, there is a thin, see-through look to the top of the scalp. This is often associated with generalised thinning over the entire scalp. Often patients that have progressed to this stage have too little donor hair to make surgical hair restoration worthwhile.

All women experiencing hair loss should have an accurate diagnosis made, preferably by an experienced dermatologist. This is particularly important since the diffuse hair loss that women typically develop, can occasionally be caused by a number of treatable medical conditions. Regardless of the extent or cause of hair loss, only women with stable hair on the back and sides of the scalp are candidates for hair transplantation.

Other infrequent alopecias observed among the patients visiting hair clinics are as follows:

Alopecia areta: it's an autoimmune disorder which starts with small round and punched out areas with no hair. Lesion has very smooth skin and not even a single hair is present in the lesion.

Alopecia totalis: there is total loss of scalp hair.

Alopecia universalis: there is total hair loss in the body including the eyebrows.

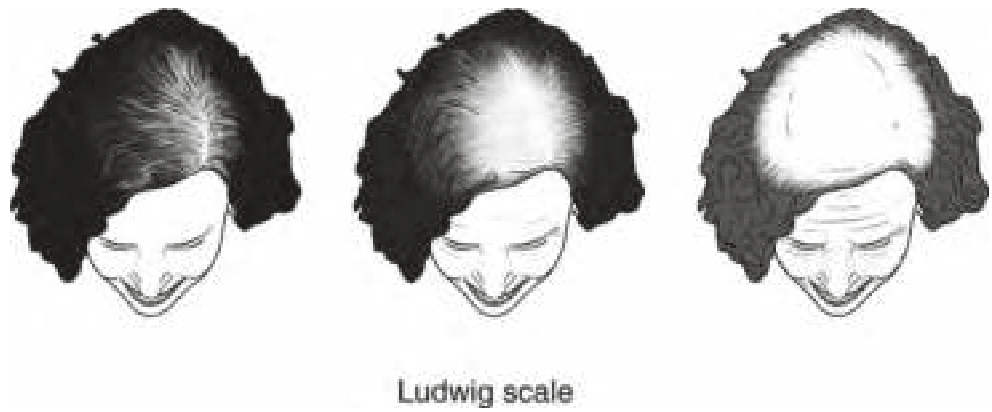

Fig. 34.5 Ludwig classification for hair loss in women.

Turban alopecia: caused due to tight turban usage. It affects frontal and parietal areas mainly and is seen among Sikhs.

Trichotillomania: a psychiatric disorder where the individuals deliberately pull their hair every day leading to hair loss in those areas.

34.6 Medications for Hair Loss

Only 2 drugs have been approved by FDA and have proven their efficacy in the management of hair loss with good success.

34.6.1 Minoxidil

This is a direct hypertrichotic drug, which was initially approved as an antihypertensive agent and was found to have side effect of hypertrichosis. Today, it is available as an over the counter drug with 2% formulation for women and 5–10% formulation for men as topical solution and gel. It improves hair count, weight and growth of hair. Post transplantation too it has been found to decrease the shedding of hair and enhanced the time to onset for hair growth. According to few studies, minoxidil acts as a vasodilator by opening up the potassium channels and thereby enhances the vascularity of the hair bulb which in turn promotes hair growth. However, the exact mechanism is unknown. This topical product needs to be applied to the scalp and not the hair and patients need to be informed about the initial increased shedding of weak hair in the first 4–8 weeks. Further, the patients need to be counselled to apply the product twice a day to maximise the efficacy and to wait for a timeframe of at least 4–5 months prior to seeing the results.

34.6.2 Finasteride

Finasteride is a drug which is used only in men for reversal of miniaturised hair follicles. This drug is a competitive inhibitor of the enzyme 5-alpha reductase which blocks the conversion of male hormone testosterone to dihydrotestosterone, and thereby works on the pathogenesis of androgenetic alopecia. It is to be taken orally once a day daily at 1 mg. Finasteride can cause loss of libido and oligospermia in few individuals. However, this side effect is reversible once the drug is discontinued.

Other medicines like Dutasteride though being a potent inhibitor of 5-alpha reductase is not that popular in the market as it has got adverse effects. Few natural products like saw palmatto can be used in young individuals who refuse to take finasteride.

34.6.3 Cyclical Therapy

It entails giving vitamins with calcium supplements on a single day, followed by iron and mineral combination product on one other day of the week and finally amino acid blend; the three regiments are also advocated that their intake be on alternative days as different nutrients and the daily dosing is avoided. The basis of this therapy is that hair requires nutritional support during their anagen growth phase and also for its maintenance; without nutrients, hair cannot get support and the stimulated hair growth to demonstrate disappointing outcomes. This therapy is the result of pioneering work on the role of nutritional supplements in hair growth.

Platelet-rich plasma (PRP) is an autologous biological modifier which has many concentrated growth factors in it and has demonstrated good results in reducing hair loss and has shown to enhance hair counts. It is prepared in a three-step process where blood is drawn, processed and injected into the scalp. It is injected into the scalp once every fortnight for 4–6 sittings and this can be combined with the standard therapy.

34.7 Clinical Consultation

It is important to begin the consultation by knowing the general health of the patient with a focus on endocrinal conditions affecting hair namely the thyroid disease, any uncontrolled diabetes, polycystic ovarian disease in the case of females and also enquiring specifically about family history of hair loss, past medical management, understanding personal hair care regimen and any past hair transplants done.

The next focus of the clinician during consultations should be on the expectations and motivation levels of the patient trying to drive home the message that it's a progressive condition especially in younger patients who are demanding and want a low hairline. It's important to have a family member during consultation and ensure that they understand that any future hair loss is understood and you are only trying to frame the face. The pattern of the hair loss also needs to be well documented.

The donor site assessment will verify the presence of any white hair, check the elasticity of the scalp, the density of the hair follicles per square centimetre, note the calibre of the hair (thick vs. thin), presence of curly or straight hair, rule out any existing scars and skin pathology including dandruff and infections.

The assessment of the recipient site will focus on the quality and quantity of remaining hair, ascertaining the grade of balding and the pattern of hair loss, previous results of hair transplantation, the skin to hair contrast, direction of the existing hair and existing skin condition. Based on the priorities of the case and having assessed the areas requiring hair transplantation, the number of follicular units required per square centimetre (around $30/cm^2$) is calculated to arrive at the number of follicular units to harvest.

34.8 Concept of Hair Transplantation

Hair transplantation as performed today is basically micro-follicular unit transplantation and few clinicians call it as hair restoration as there are many methods to achieve the results.

In the early days, hair transplant concept started with flap rotation techniques requiring procedures to be performed under general anaesthesia. These invasive techniques did not gain popularity as the results were not satisfying and the procedures left disfigurement in few individuals. Later on during the evolution of techniques, macro and micrografts being 5–6 mm in size were introduced which were harvested with biopsy punches and the resulting grafts were implanted. These plug like grafts being unnatural in appearance gave a classical doll's hair appearance after growth and got phased out with further refinement of hair transplant procedures.

By around 1963, follicular unit transplantation or strip technique was introduced which became a workhorse of hair transplantation until recently and is still considered to be the gold standard method for hair restoration. In the year 2002, Rossman and Bernstein refined the punch method of harvesting the follicles and named it follicular unit extraction which has seen an exponential growth in the recent years and is today the most popular technique of hair transplantation.

The principle behind hair transplantation is quite simple. The hair that grows on the back and sides of the scalp tends to be permanent in most of the individuals. These occipital and parietal hairs are resistant to androgenic alopecia and are used to implant into the frontal or vertex area which will continue to grow as long as occipital hair grow, but in few individuals with advanced grades even these donor hairs can be miniaturised and lost. That's the reason as to why anticipating the future hair loss is most important factor while planning hair transplant procedure.

Hair transplant as a procedure is successful only when hair loss is stabilised, as it will not stop further hair loss. We as surgeons can only relocate and transfer few strong follicles from donor area to recipient area without increasing any new follicle per se. Many young patients who are frustrated by taking medicines over a period of time will seek hair transplant procedure as a remedy, which is an absolutely wrong decision for the clinicians to encourage. It is imperative on the part of the clinician to stabilise any ongoing hair loss before embarking on the hair transplantation, with individuals below the age of 25 years being denied the scope of the procedure.

Hair transplant surgery demands good planning, great surgical skill and good aesthetic sense on the part of the clinician, as hairs grow in specific direction and angulations for the given area of the scalp, and grafts should be placed in a way which should look natural and cover the scalp gaps thus achieving good density.

Most of the patients would like to know if the results are permanent with guaranteed results. Here, it's the astute clinician who should make all efforts to ensure that patient understands the concept of the hair transplant and the future consequences too, rather than simply promising the results.

The basic concept in hair transplant surgery is one of camouflaging technique which makes them look better rather than taking them back to their crowning glory days of their past during their younger days.

Patient should understand that he may still loose hair further and get worse with his genetic predilection to go bald and it's a progressive process. Hair transplant will only help him to maintain hairs which are aesthetically acceptable for his age and few individuals may require future sessions too.

Preparation Prior to Hair Transplantation

Routine blood test consisting of Complete blood count, glycaemic levels, prothrombin time and serology are done for every case. In patients with any underlying medical conditions, further investigations as deemed necessary for the case are done and a medical fitness is obtained from the physician.

All patients are advised to stop topical minoxidil at least a week prior to transplant to avoid bleeding hampering the progress of the case.

Photographs and consent for the procedure are obtained as a part of standard operating procedure for hair transplantation.

Consenting for the procedure should focus on detailed information of the procedure with clarity given on the results that can be obtained explaining the pros and cons of the procedure, their complications and outcomes. Alternative suggestions should also be given including no surgery, use of camouflage techniques and patients being on only medicines. Adequate time should be given to discuss and understand the proposed procedures. Finally, the proposed treatment plan with the fees proposed should be mentioned in the consent along with written preoperative and post-operative instructions.

The treatment plan formulated needs to account for the quantum of hair to be transplanted, the hairline design, the areas of high priority on the scalp, patient commitment and compliance.

34.9 Techniques and Description

34.9.1 Follicular Unit Transplantation (FUT) (Box 34.3) (Video 34.1)

FUT is also called strip method or stitch method. It's a gold standard method in hair transplant procedures till date though it's an old method [7]. The modern-day FUT is mainly harvesting a single strip, though earlier few doctors practised with multiple blades to obtain multiple strips which are obsolete now.

Strip method includes taking or harvesting a strip of the skin layer from the donor area usually from the occipital area of the head below the occipital protuberance and above the nape of the neck in the so-called safe zone for harvesting.

Strip measurements are variable with 30 cm being the maximum length and 1–2 cm width depending on skin laxity of the patient. However, the length and width are variable according to planning arrived at during the consultation with the patient as per the indication of the case. At times we have to limit strip width to 1 cm if the skin laxity is limited. Usually a strip of 30 cm in length and 1.5 cm in width will give around 2000–3000 grafts depending on the hair density of the individual.

Box 34.3 FUT

- Linear scar in donor area.
- Healing time is more in donor area.
- Little post-op discomfort in donor area.
- Difficult in tight scalp, with risk of scarring.
- Can't use in non-scalp hair like beard or body hair.
- Quality of graft is good
- Less time
- No need for shaving entire donor area.
- We can harvest up to 4000 follicular units in a single session.
- Less expensive
- Follicles Transection rate is very less.

34.9.1.1 Assessment of the Donor Hair

Hair transplant outcomes will greatly depend on the donor hair quality and quantity [8]. The important factors that the clinician has to bear in mind are as follows:

1. The number of grafts that are present per square centimetre
   Few individuals have thick density being good or best donors (Fig. 34.6a) while a few have sparse density being poor donors (Fig. 34.6b) with the number of grafts per sq cm varying between 25 and 65 grafts on an average in healthy Indian adults. It further varies from person to person and sometimes from area to area in the same individual. Usually, occipital area has thick density whereas parietal area has less density. Good observation of the grafts in the donor area is most important for the surgeon to achieve good results.
2. Number of follicles present per graft
   This is highly variable with 2, 3 or 4 follicles being present in Indian adults whereas a few have only one or two follicles per graft. The presence of reducing follicles per graft is a sign of the progressive nature of the blading process.
3. Donor skin area
   Few individuals have large donor area as their scalp size is larger while a few individuals have donor bearing area which is smaller (Fig. 34.7a, b). This entity will decide the number of grafts that is available for harvesting.

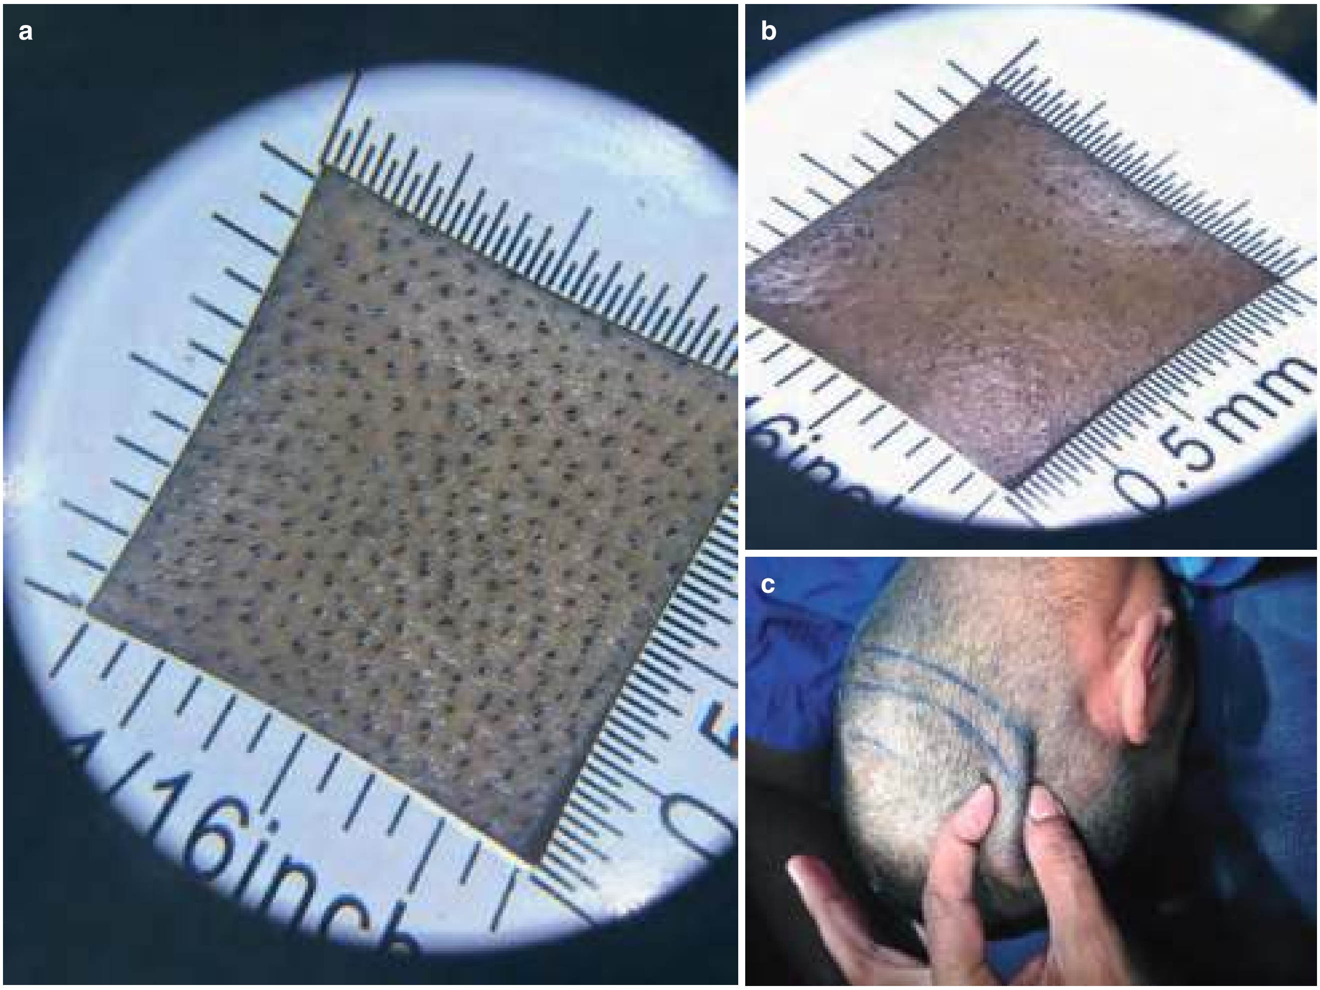

Fig. 34.6 (**a**) Good/best donor area based on hair follicular density. (**b**) Poor donor area based on hair follicular density. (**c**) Donor area skin laxity testing to ascertain the strip width planned for FUT

Fig. 34.7 (**a**) Large head with more surface area at donor zone. (**b**) Small head with lesser surface area at donor zone

4. Shaft diameter
   Individuals with thick shaft diameter will have better density and the outcome of the results is enhanced.
5. Skin laxity (Fig. 34.6c)
   In individuals with better skin laxity, we can harvest more grafts by FUT method by going for wider strips in a single session, whereas the same skin laxity may not have any significance with the FUE method.
   Patients who present with straight hair end up optically having less density because light can pass through hair strands and skin becomes visible especially if the hair is black and is contrasting against a fair skin background. Whereas presence of curly and course hair in an individual with dark complexion can give the illusion of thick density.

34.9.1.2 Donor Site Preparation and Anaesthesia

Trimming is essential in the donor site to harvest the strip and the team member in charge of the preparation can ensure trimming the hair to 3 mm all over the scalp. Few surgeons prefer the procedure without trimming so as to reduce the downtime for the patient's social acceptability. But trimming will ensure better visibility and accessibility to the surgeon while performing the suturing with attention to detail to ensure minimal scarring along the strip harvest. Following the trimming, the next step is to wash the scalp with betadine solution. The clinician should ensure that preoperative photos, consent for the procedure, recording of baseline vitals of the patient and his weight is recorded prior to the preparation of the donor site.

The harvesting of the strip is done with the patient in prone posture following the standards of care with an iv line, monitoring of the vitals with a 3 parameter monitor, and following a dose of prophylactic antibiotic under aseptic conditions. Next, the donor area strip length and width to be harvested are marked out based on the skin laxity tests and depending on the individual's follicular density per square cm.

Once the marking is done, local anaesthesia is administered to the donor area, usually preferring field block in that area. Injecting the local anaesthetic in the lower border of the strip would provide sufficient anaesthesia to the field above.

34.9.1.3 Preparation of Local Anaesthesia

Hair transplant procedure is time taking and lasts around 6–8 h. Lidocaine usually is a very safe anaesthetic with a duration of action lasting between 90 and 120 min and therefore we need to add a long-acting drug-like bupivacaine for hair transplant procedure. Combination of the above would work better for 8–10 h and the overall dosage should not exceed the maximum permissible as per the weight of the individual. The local anaesthetic solution used is typically as follows:

Lidocaine 2% 30 ml + bupivacaine 0.5% 4 ml + ns 60 ml. The above combination gives 64 ml of local anaesthesia, which is of lidocaine 1%.

Tumescence is widely used in hair transplant surgery to raise neurovascular bundles away from the hair follicles which will reduce the trauma to nerves and vessels during the procedure. Another important role for the use of tumescence is in reducing the bleeding during the procedure since scalp bleeds more.

Tumescence solution consists of 500 ml ns + 1 ampule of 1:1000 epinephrine and this is injected into the strip area following the local anaesthesia at least 15 min before the strip harvesting.

34.9.1.4 Instruments for the Strip Procedure

Variscore blade (Fig. 34.8) is useful to have control on the dimensions of the strip and it gives the option to adjust the strip width by adding or reducing the metal spacer plates. Each metal spacer plate comes with thickness of 2 mm and 1 mm and, for example, if we need a strip with width of 1.3 cm, then we need to add 6 plates of 2 mm and 1 plate of 1 mm. The variscore blade has added advantage of depth control while making incision and can accommodate two surgical blades. Usually, for scalp, we can use number 15 surgical blades.

Prior to the incision marking, the strip dimensions are done. Most of the surgeons make straight incision, which may lead to scar. It's always better to follow Langer lines of the skin which ensures less scars with the strip incision looking like a crescent shape with the end tapering off. Strips which are as long as 30 cm (Fig. 34.9) in length run from above one ear to the other ear. It's always recommended to

Fig. 34.8 Variscore blade -popular blade handle for FUT

Fig. 34.9 Strip harvested prior to slivering

Fig. 34.10 Wound margins prepared for trichophytic closure

place the incision at or just below the external occiput area as the follicles here are considered permanent. It is indeed not good to go too low below the external occiput as we may end up in big blood vessels. After the initial indentation of the incision is done with variscore blade, it is later followed up by the use of BP blade number 15 and the incisions are made very carefully to reach up to 3 mm beneath the follicular depth with some amount of subcuticular fat around it, while we ensure that we do not cut the galea. While making the incisions, care is taken to prevent slicing of the follicles at the skin margins and the flap is raised from one end to the other using gentle yet deft strokes with the blade.

Good illumination and haemostasis can help to raise strip with minimal damage to both the follicles and vessels in the vicinity. Damage to the vessels is most common if proper tumescence is not attained and can lead to bigger scar and shock loss of hair in the donor area. Any adventure into the galeal layer can lead to haematoma and chances of spreading infections through emissary veins.

Haemostasis is achieved prior to closure by using bipolar diathermy; the scalp wound is irrigated with normal saline and a double layer closure is performed with vicryl 2.0 (TS 2404, 3/8 circle, cutting edge) for the inside and a prolene 3.0 (nw800, 3/8 circle cutting edge) for the outer skin (Fig. 34.11a, b). The strip that is harvested is preserved in cold saline on a petri dish at 4 °C.

34.9.1.5 Trichophytic Closure

Trichophytic closure (Fig. 34.10) involves trimming of the upper and lower edges of the skin which facilitates the hair to emerge through the scar ensuring that we will give aesthetically acceptable scar to the patient (Fig. 34.12b) Wound closure done without the above clinical manoeuvre leads to poor scar (Fig. 34.12a), which is quite obvious.

Post-operative care of the wound is important. Antiseptic creams are optional if the donor site wound is washed with clean water or ns on a daily basis. In our experience, suture removal is recommended on 11th post-operative day to avoid wound gaping or wound dehiscence.

Fig. 34.12 (**a**) Poor scar resulting from normal wound closure (**b–d**) post operative scar following trichophytic closure

Variable Strip Technique

This will help us to get maximum grafts with less tension along the scar leading to a better scar. Most of the individuals have thick density in the occipital area and lesser density in the parietal area and any misjudgement will lead to poor wide scar in the parietal areas. Here, by using variable dimensions of the strip technique (Fig. 34.13), we can target for more grafts with least possible scar. In this technique, the strip width is more in the occipital area than compared to the parietal area as illustrated in the image below.

Fig. 34.13 Variable dimensions of the strip marked out for harvesting

34.9.1.6 Slivering

Slivering is a process where the strip is sliced into small bits of tissues with rows of hair follicles in them, through meticulous deft handwork akin to the baker slicing the bread loaf into thin slices. It is the first step of the separation of grafts from the strip while avoiding any transection of the graft. Higher magnifications should be used to perform this important step for which a few clinics are using stereoscopic microscopes while the others manage with normal 10× magnification. It should be done simultaneously while the surgeon performs the wound suturing to save the crucial graft holding time of around 6 h.

At the end of this step, we get slivers which are ready for the separation process (Fig. 34.14). The separation process is separating individual grafts from the sliver. For the separation process, we need more trained technicians as it is cumbersome exercise and needs great attention to detail to avoid any form of trauma to the graft being obtained with an obvious fight against time.

For the separation process, we need to use 3× magnification which can be done on a sterilised wooden spatula or an acrylic illuminated sheet.

Wooden spatula would give us good resistance to cut the grafts whereas acrylic sheets will be slippery. Advantage of the acrylic sheet is we can illuminate from below, which is easy for separating the grafts. The separation process is nothing but getting rid of the excess fat around the grafts and making the grafts slender in a pear shape or tear drop shape. Care is to be taken to ensure that we do not denude the roots and little fat is left behind for survival of the graft through plasma imbibition. All skin has to be trimmed and removed from the graft and finally these prepared grafts are preserved in cold normal saline around 4–8 °C temperature.

Fig. 34.14 Slivering and separation of grafts from the strip in FUT

While separating the grafts, we would get single, double, triple follicular unit grafts, and care is exercised to maintain the follicular unit (Figs. 34.15 and 34.17a), as it is natural to ensure better survival. These are segregated further in different bowls and are used up for implanting starting with single units for the frontal hairline and progressing onto multiple follicular units as we go posteriorly in a progressive manner.

34.9.2 Follicular Unit Extraction (FUE) (Box 34.4) (Video 34.2)

In this technique, we extract the individual follicles one graft at a time with the help of small punches. Also known as no stitch and no cut method, it's minimally invasive procedure compared to the FUT. FUE gained popularity in recent years because of its ease of doing and being less invasive with minimal downtime for the patient. Initially, FUE was introduced with manual punches which was more tedious and time consuming limiting the number of grafts that could be done in a session [9]. Current advances with motorised punch have improved the pace and its effectiveness in harvesting more grafts. Though many different motors and punches are available in the market, normal dental micromotor with straight hand piece would suffice to perform FUE (Fig. 34.16a, b).

Punches are made up of either titanium or stainless steel with the diameter of the punch ranging from 0.6 to 1 mm, with 0.9 mm being suitable for Indian scalp. The advent of FUE has expended the scope of harvesting follicles from other sites of the body wherein 0.6 or 0.7 mm punches are useful for beard site and 0.8 or 0.9 mm punches have been suitable for chest hair harvesting, respectively.

Fig. 34.15 Separated follicular units

Box 34.4 FUE

- No linear scar, small round dots in donor area.
- Decreased healing time in donor area.
- No post-op discomfort in donor area.
- Useful for those with risk of donor scarring. Like young pt, very muscular, very tight scalp.
- Useful in Body hair transplant
- Graft quality is not as good as FUT.
- Procedure is time consuming.
- Large sessions required to shave the entire donor area.
- More expensive.
- Follicles transection rate is more

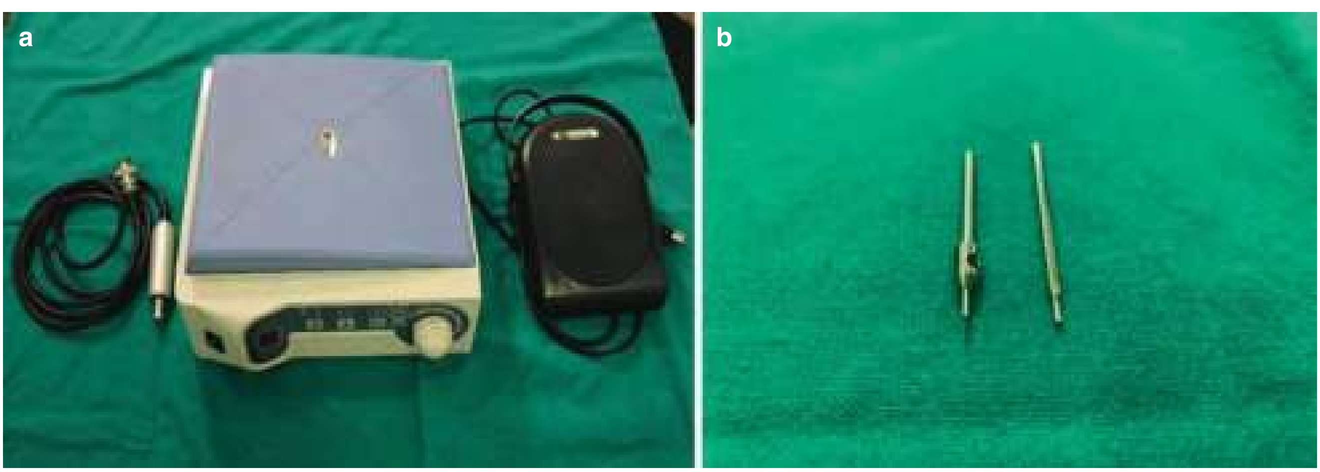

Fig. 34.16 (**a**, **b**) FUE instruments: micromotor, straight handpiece and punches

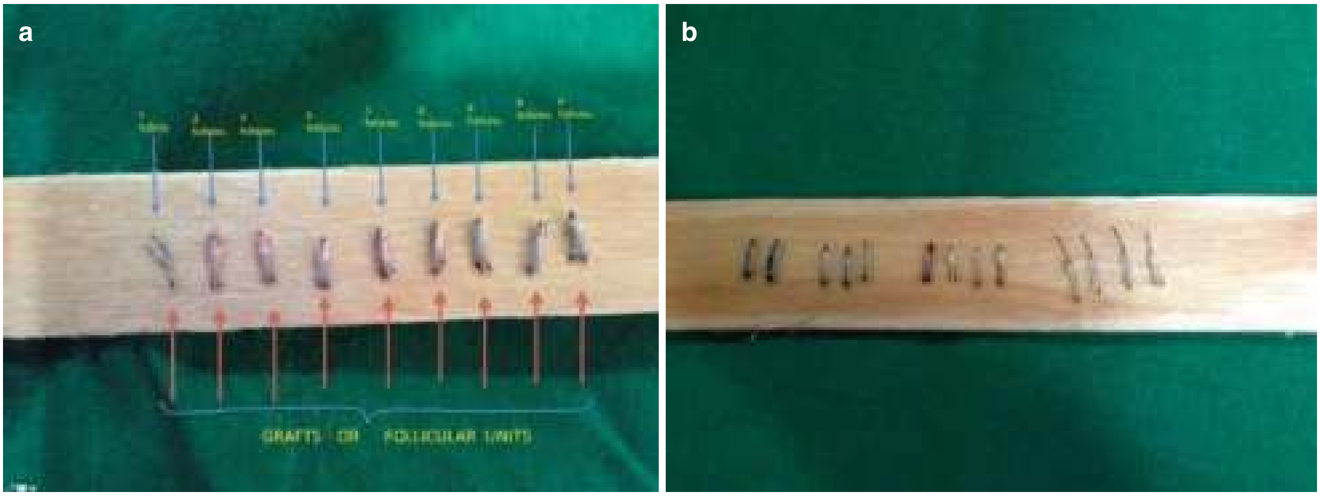

Fig. 34.17 (**a**) Follicular units and their natural arrangements. (**b**) Comparison – FUE grafts on the left which are lean and slender versus FUT grafts on to the right which are bulkier

Punches are available as dull, sharp, serrated and oscillating type. Normal dull or sharp punched would be sufficient to perform FUE. On an average one punch can be used to harvest around 1000–1500 grafts.

This latest motorised technology has made surgeons' job easy and in experienced hands we can harvest around 800–1000 grafts in 1 h, provided patient's skin is favourable.

Being a blind procedure, this is technique sensitive and is associated with a steep learning curve requiring more concentration. It is performed under 3× magnification controlling the punching around the hair graft while maintaining depth and angulation which is very vital to harvesting the grafts. The punch should get down to epidermis and dermis junction not going beyond 4 mm from the skin. Surgeon should always analyse the angle of exit of the hair and be parallel it prior to the punching. Acute angles of the grafts would lead to difficulty in punching and lead to not only bigger punch holes but higher transaction rates. Most of the Indian skin is favourable for FUE procedure because of thicker skin types. The follicles obtained by FUE are comparatively slender and devoid of extra adventitious tissue in comparison to the FUT follicles (Fig. 34.17b).

34.9.2.1 Blades

They can vary in size and shape from being thin sharp blade to having a pointed chisel as in the case of sp90 which is one of the popular blades for pre slit technique. Today, the surgeons have a choice of customising the blade with commercially available tools and can use a square or tapered blade as per their choice.

34.9.2.2 Needles

Standard 19 gauge hypodermic needle is preferred for making the graft recipient sites while the same can be achieved with solid core needles eliminating epidermal implantation.

34.9.2.3 Limitations of Follicular Unit Extraction

FUE has an important role to play in hair transplant because it can reach the areas where strip cannot reach to harvest grafts. When we plan second session, FUT may not be possible in unyielding skin types. In poor candidates where donor areas of the scalp have poor hair quality, FUE can be used to target beard and body hairs. FUE like any other procedure is associated with a few disadvantages like comparatively more GTR (graft transection rate), especially in curly hair types and in these few cases graft yield is abysmally low wherein the surgeon will have to convert the case to strip technique. Follicular splay is another situation where hair roots are placed apart which causes difficult extraction. In case of scattered grafts too, the punch may tend to damage more grafts while harvesting and would not be an ideal situation to continue harvesting with high graft transection.

34.9.2.4 Hairline (Fig. 34.18a, b)

The hairline design and location are the most critical factors in the success of hair transplantation, for which one should understand the concept of facial thirds. Till the age of third decade of life, the anterior hairline at the midline is located at a distance equal to the middle third height of the face from the glabella, adding additional 1 cm in length to it with each passing decade of life to take the hairline upwards and backwards to give a matured look to face considering the progressive nature of hair loss. The frontotemporal apex is the deepest point of the anterior hairline laterally as it merges with the temporal hairline and is located along the lateral canthus of the eye [10].

It is to be borne in mind that the hairline anteriorly is not a straight line but an irregular one having peaks and troughs making it look like a coastline with the front two rows made

Fig. 34.18 (**a**, **b**) Hairline design and natural looks

Fig. 34.19 Recipient site slits

Fig. 34.20 sp 90 blade used for recipient site preparation

up of single follicular units and gradually it progresses to double and triple follicular units to give the density. The central core or frontal tuft area gets the maximum density of hairs implanted to enhance the strength and aesthetic value of the hairline thus created.

34.9.2.5 The Recipient Sites Preparation and Implantation

Recipient sites are prepared (Fig. 34.19) to receive the grafts by making slits in the skin with either 19 gauge hypodermic needles or sp 90 blades (Fig. 34.20) or other microblades which are of 1–1.1 mm in width. This step could be done prior to implantation for all the grafts (pre-slit method) or individually for each graft while simultaneously implanting it (stick and place method).

Slits made with blades tend to give more natural looks when compared to needle implantation (Table 34.1). As a prerequisite to facilitate implantation, the site needs to be trimmed short while the remaining hairs guide us in the direction and angulation of the implantation. Proper tumescence will allow us to expand scalp so that we can place more grafts in the given area while also reducing any damage to the neurovascular bundle and enhances visibility.

The slits are performed in the area with proper direction (converging forwards), depth (follicular length for the given patient) and angulation (15° in the front −45° as we approach the crown part of the scalp).

Once the slits are done, implantation is done by using jeweller's forceps (Fig. 34.21), which are pressure graded. This is also called 2 forceps technique as one forcep is used to locate the slit while the other one is used to implant the graft into the slit. The grafts are to be held above the bulb or beside it where the dermal fat is held.

Implantation of 3000 grafts by forceps would need around 3–3.5 h approximately (Fig. 34.22a).

34.9.2.6 Implanters

Few surgeons use implanters (Fig. 34.22b) which can hold the graft in it and all you have to do is to eject them into the site at the desired direction and angulation. Technicians will preload the graft into the implanter. Implanter can be used with pre slits or without pre slits made in the scalp. However, implanters tend to create a circular slit which may lead to pitting kind of scars at the base of the graft after growth. They need extra hands for the procedure and come at an extra cost too.

Table 34.1 Advantages and disadvantages of blade versus needle for slit creation

	Blades	Needle
Distribution	Uniform	Variable
Bleeding	More	Less
Direction and angulation control	Better	Possible in few trained hands
Time taken	Less	More
Aesthetic appearance	More likely	Less likely
Healing	Without marks	Leaves pitting/embossed scars

34.9.3 Combi Technique (Fig. 34.23)

This is a combination of FUT and FUE in a single session. Combi technique is recommended when we need more grafts as in anything over and above 3500 follicles in a single session. In this technique, the strip is first harvested

Fig. 34.21 Jeweller's forceps used for implantation

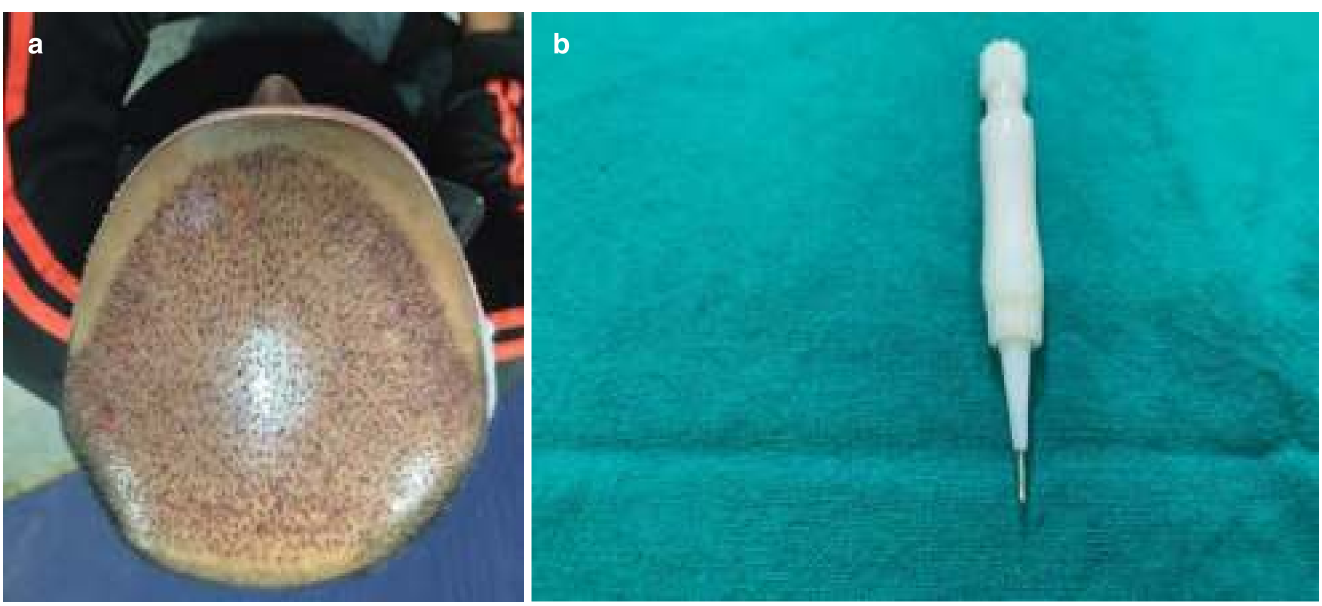

Fig. 34.22 (**a**) Immediate view of a case post implantation. (**b**) Implanters used for implantation

and then the FUE is performed above and below the strips in the same sitting before implanting. Advantages of this procedure are that the surgeon can reduce the strip length and still can obtain more grafts thereby reducing the strip length and the resulting scar. However, it requires an experienced surgeon and well-trained team to execute the procedure.

Fig. 34.23 Combi technique post-operative view

34.10 Post-operative Care

Immediately after the procedure, the heaviness, numbness or tightness may be there for a few hours. There is also some swelling on the forehead and temple area due to the tumescence and surgical insult and the resulting swelling is normal. Patients are allowed to sleep on the back or on the sides but are not allowed to sleep on their tummy as otherwise the swelling tends to gravitate onto face and eyes. Patients should be asked to massage the forehead from the middle to the sides for 5 min every hour for first few days. Rarely some patients may feel momentary dizziness especially while standing up from the lying down position on the procedure table.

There is some oozing of blood-stained fluid from grafted site as well as in donor area (both in case of strip or FUE). Bending forward of the neck can stretch the stitches and can initiate some more oozing from the stitches therefore keeping the chin up is recommended.

Patients are restricted to perform any contact sports/gymming for a period of 12 days and should avoid swimming for up to 3 weeks. They should also not get to field work under the sun for first 3 weeks. Patients who ride a bike are allowed to wear a helmet after a period of 4 weeks. Topical minoxidil can be restarted in the transplanted site after a waiting period of about 15 days post-operatively. Patients are also forbidden from riding a bike or driving in an open vehicle for up to 2 weeks.

After the procedure, antibiotics and analgesics are provided for 5 days. The donor and recipient sites may or may not be bandaged. If bandaging is preferred, a non-adhering betadine pad is placed over the operative sites with several layers of flattened gauze sponges over them to hold the betadine pad in place as the scalp is wrapped with clean bandage using to two to three 4-inch gauze rolls. Crepe bandage can

Fig. 34.24 (**a**–**d**) Outcome following hair transplantation

be used over it. The dressing is removed the following morning, and the scalp and each graft are clean meticulously by gently dabbing with a cotton swab with normal saline. Patients are advised to sprinkle or spray normal saline over the grafts every 3–4 h for 8–10 days. Suture removal is performed on 11th day and is not applicable for FUE. Initially for 10 days the grafted area should be washed without rubbing the grafts. Whereas after the above period, grafted area can be washed and patients can rub the grafts. Most of the grafts will be shed by 12–20 days which is a common phenomenon, one need not to worry about it falling off.

Regrowth and Results (Fig. 34.24a–d)
Summary of events following a hair transplant.

Immediate after a hair transplant, there will be mild blood excretion and oozing.

1st day scabs (nothing but dried blood) will form and continue forming for the next few days.

After 4 to 10 days you will notice itching. This is normal, but do not scratch or pick on the transplanted areas.

After 10 days your scalp will be cleared of all scabs.

After 11–20 days your new implanted hair will shed. Now your new follicles are in its dormant (sleeping) stage. It's time to watch and wait.

Pt must be aware that a lag phage exists before hair growth is initiated. After approximately 4 months, the telogen phase to the implanted grafts ends and anagen begins. Complete growth can be seen only after 8 months and hair continue to grow until 12–14 months.

34.11 Complications

Able professionals should manage any adverse outcomes by minimising the damage and help achieve the desired outcomes with low morbidity. Fortunately, today the follicular unit hair transplantation is a safe procedure with low rates of complication when performed with care [11].

34.11.1 Complications in Preoperative Phase

Overexpectations of the patients are the major cause of complications and arise due to hasty or incomplete consultation and is better addressed with more than one consultation to assimilate the requisite information with the help of informative brochures, websites and discussions with the clinician to arrive at realistic outcomes especially in the younger patients who happen to be unclear and lack maturity for comprehending the results; in such cases, it's better to keep them on medical line of treatment till they become practical in accepting the results. Any individual with body dysmorphic disorder and Norwood vii patients where you would not make much difference would count as poor patient selection by the clinician. In case of ongoing hair loss, the clinicians should not be tempted to promise full coverage or high density influenced by the advent of current medicines as the patients may change their minds and stop the intake of medicines over a long period of time, eventually resulting in inappropriate placement pattern and lack of donor site for harvesting. Clinicians should not be further influenced by the patients' demand for low unaesthetic hairline, or be drawn into performing mega sessions arising out of patients' demand and be careful in choosing the donor material in the middle of the back and sides of the permanent fringe avoiding any slanted scars or scars visible in scanty donor hair bearing areas.

34.11.2 Complications in Surgical Phase

1. Pain:
   Patients who are counselled appropriately and are provided with a relaxing ambience generally experience minimal discomfort. In-depth local anaesthesia achieved through precise nerve blocks and ring blocks administered with a long-acting drug-like sensorcaine and taking help of vibrating devices while injecting the solution slowly will go a long way in enhancing the comfort levels. Anxiolytics should be prescribed by the clinicians to patients who are apprehensive about the procedure.
2. Bleeding and popping:
   Optimising the health of the patient prior to the surgery results in blood pressures being within normal limits. Adequate tumescence consisting of saline and epinephrine has to be injected below the dermis to allow the surgical field to be lifted away from the bleed vessels and then the clinician has started the procedure after 15 min will have minimal bleeding. Too much of tumescent in the recipient site can be a cause of popping, though clinician cannot eliminate popping as pre slit technique can minimise the issue.
3. Bad hair direction:
   Clinicians should plan appropriately to maintain the direction and exit angle of the hair that mimics the natural growth. Keeping the grafts with a few millimetres of hair will allow the clinician to ascertain the angle during implantation.
4. Hiccups:
   Due to the irritation of the aberrant branch of the vagus nerve, patients can have hiccups through the procedure.
5. Poor graft quality:
   A good team leader will constantly supervise to ensure proper handling of the follicles, which will minimise trauma to the follicle resulting from transaction, manipulation, desiccation, oxygen starvation and crushing of the graft [12].

34.11.3 Post Surgical Complications

1. Donor site effluvium:
   Hair in the growth phase can fall rapidly post transplantation due to temporary lack of oxygen during surgery resulting in loss of hair variably along to suture line when significant blood vessels are cut. Any such hair loss will be noticeable around the third week postoperatively and leads to embarrassment to the surgeon. If the donor area can be raised above the blood vessels with good volume of tumescence, the above complication is rarely encountered.
2. Infection:
   This is a very rare complication seen today given the standard asepsis precautions followed and is rarely encountered where the patients are not given adequate post-operative instructions especially in cases of tight donor area closure and in patients with compromised immunity.
3. Dehiscence:
   A poor surgical technique associated with bad suturing, harvesting wide strips, performing tight closures or resulting infections and necrosis can lead to dehiscence.
4. Dysesthesias:
   Today it's no longer a complication thanks to adequate use of tumescence which will lift the hair follicles above the neurovascular bundles.
5. Scars:
   This unavoidable outcome can be prevented by following the basic principles of surgery with accurate approximation, closure without tension, by using double layered closure, trichophytic technique and avoiding resolvable suture for closing the skin. Donor scars also occur due to improper donor assessment prior to the surgery. Skin laxity test will help us to evaluate the skin laxity so that we can limit the strip width. At times we may need to consider variable width dimension to reduce the tension in the wound, usually where occipital area skin laxity is more and parietal area skin laxity is less. So we can consider more width at occipital area and less width at parietal area. If skin has less laxity, we can consider FUE.
   Any hypertrophic scar can be managed with steroid or injection and later implanting hairs with FUE.
6. Forehead swelling and ecchymosis:
   Based on the laxity of the skin in the frontal area and the trauma induced by the slit making process, swelling occurring at 3–4 days post hair transplantation can be mitigated by including some steroids in the la solution, applying pressure bandage and some digital massage across the forehead.

Fig. 34.25 Folliculitis post hair transplantation

7. Surgical effluvium:
   This is similar to the donor site effluvium which results in the anagen hairs going into telogen phase and falling out around the second or third post-operative week and regrowing with the grafts. Preoperative use of minoxidil solution tried 1 month prior to the procedure is recommended to prevent the above complication.
8. Cysts, pustules, pimples and folliculitis: (Fig. 34.25)
   The above sequelae following hair transplantation can be avoided by preventing deep implantation of grafts, transacting hair during site creation and piggybacking of one follicle up on another. Most of them do settle down with time; however, acne like therapy can be offered to resolve the lesions faster.
9. Pitting and tenting:
   It's very important to avoid the above complication in the frontal hairline which could otherwise be unacceptable and are easily preventable by avoiding deep placement of the grafts as in the case of pitting and too superficial placement of the grafts as in the case of tenting.

10. Poor growth:
    This can be attributed to poor handling of the grafts resulting in physical and biological trauma to the grafts associated with dehydration of the follicle, crushing of the follicle during implantation, thermal insult and prolonged holding time outside the body.

The incidence of complications may be reduced by avoiding mistakes by the team in general (Box 34.5) and those related to the technique, specifically graft survival (Box 34.6).

Box 34.5 Frequently Made Mistakes Made by Team

- Too much cross talk between team members annoying the patient.
- Members do not address patient by name.
- Grafts prepared either too chubby or skinny.
- Too many single grafts prepared.
- Photography not taken properly.
- Consent not taken properly.
- Grafts allowed to dry.
- Not interested in routine work.

Box 34.6 Factors Affecting Graft Survival

- Proper donor tumescence
- Temperature of holding solution
- Dehydration of follicle
- Crush injury of follicle
- Transection of follicle
- Adequate dermis and fat around follicle
- Smoking
- Biological modifiers

34.12 Current Advances

Futuristic developments in the field of hair transplant need to focus on the current lacunae in the procedure and revolves around the availability of limited donor supply and the duration of the procedure.

Low-level laser light therapy has been approved by FDA as a device to stimulate the hair growth in the 650–800 nm spectrum. Home-use scalp brush or helmets with laser technology are available which use the pain-free technology to stimulate epidermal stem cells in the hair follicle to move the follicles into anagen phase.

Automation of the FUE process with the use of robotics has shown to reduce the follicular transaction rates and improve the harvest speed, resolving the issue of skills possessed by practitioners. Artas and neo-graft are devices which have glamorised the field by involving robotic technology, but the running expenses and need to create sites and manually implant follicles need to be solved in the coming days.

If hair can be cultured from the scalp biopsy, then the patient would not need to donate hair by going through a painful procedure, by cloning hair we can create unlimited supply of follicles and avoid ration of hair. Current state-of-the-art research promises that the technology would get transferred from bench side to the bedside in a few years from now.

34.13 Role of a Maxillofacial Surgeon

A maxillofacial surgeon makes a good hair transplant surgeon as they are well trained in surgical anatomy of the head and neck with a detailed knowledge of flap design and through in-depth working knowledge of the local anaesthesia management. They have a great aesthetic sense with artistic hands and are well versed with cephalometric analysis which comes handy in judging facial proportions and hairline placements, further most of them are very well adapted to handling the rotary handpiece from their formative training. Maxillofacial surgeons are well trained exclusively in head and neck surgery for 3 years and are competent at managing wounds and infections, thus justifying their qualifications to perform hair transplantation alongside plastic surgeons and dermatologists.

34.14 Conclusion

Surgeons who deal with aesthetic surgeries on the face need to have a good range of skills to deal with all aspects of beauty which are defined by the individual elements. The most important of them all being framing of the face like a photo frame with hair transplantation which will allow us to focus our vision on the finer elements of the facial beauty be it the nose, lips, eyes, teeth, jawline or a good smile. If surgeons follow the principles of hair transplantation surgery, they will create patients with high degree of satisfaction using the micrografts of FUE or FUT procedure. This sophisticated form of art will bring a sense of gratification to oral and maxillofacial surgeons by embracing it as a tool along with all other tools at his disposal.

34.15 Case Scenarios

Case Scenario 1 (Fig. 34.26)

Figure 34.26: male pattern baldness—Norwood classification 4.

Treatment: FUT method with 2850 plus microfollicular grafts transplanted.

Case Scenario 2 (Fig. 34.27)

Figure 34.27: male pattern baldness class 5.

Treatment: 4000 follicular units transplantation done through Combi technique involving both FUT and FUE in the same session.

Fig. 34.26 (**a**–**f**) Case scenario 1

Fig. 34.27 (**a**–**d**) Case scenario 2

35 Ear Reconstruction

Paritkumar Ladani

35.1 Introduction

The human ear is a vital and distinctive feature of the face, and therefore, its deformity confers a significant impact on self-esteem and mental development in affected patients. Microtia is the commonest congenital ear malformation. The management of ear malformations can be challenging, because of its complex 3D structure. To achieve proper reconstructive results, it is first essential to understand the basic anatomy and architecture of the ear [1]. Materials used for reconstruction of the ear include autogenous cartilage, alloplasts like silicone, Medpor, and osseointegrated materials. Surgical reconstruction of the ear with autogenous grafts is a unique marriage of science and art [2]. Good results depend not only on surgical skill but also on conforming to the basics of plastic surgical principles and tissue transfer. The gold standard for external ear reconstruction even today is the use of autogenous cartilage frameworks.

35.2 Incidence and Etiology

The incidence of microtia is around 1 in 10,000 live births. It appears to be more frequent at higher altitudes, especially above 2000 m, due to the low oxygen levels. The condition is 2.5 times more common in boys than in girls and more commonly affects the right ear. Unilateral cases are four times as common as bilateral ones. Aural atresia is found with microtia in 75% of cases. Microtia usually occurs if there in an abnormality in the embryologic development of the six auricular hillocks. These develop at 4–12 weeks of gestation. Microtia may be associated with other birth defects. The exact cause behind the abnormal embryologic development remains unknown. However, certain teratogens like isotretinoin and thalidomide have also been implicated in this [3].

Microtia may occur in association with other malformations, including facial nerve weakness, cardiac defects, urogenital defects, hemifacial macrosomia, and spine defects. It has also been associated with syndromes like Goldenhar syndrome and Treacher-Collins syndrome [4].

35.3 Surgical Anatomy

It is crucial to understand the external auricular anatomy and architecture before proceeding with reconstruction (Fig. 35.1a). The ear has certain definite structural elements. The overall outline of the ear is oval shaped and is slightly flattened posteroinferiorly. A distinct line can be made out that defines the helical rim, arising from its root and ending at the crus helicis. Another line forms the concha, which consists of the tragus and antitragus. The fossa triangularis is the final defining structure that defines the ear (Fig. 35.1b). A complete understanding of these structures allows the microtia surgeon to use these basic components to reconstruct the complex three-dimensional structure.

When viewed in the horizontal plane, the ear is divided into three parts. The superior portion starts at the top of the helical rim and ends at the helical root at the superior border of the concha cymba. The midportion starts at the upper border of the concha cymba and ends at the upper aspect of the antitragus. The lowest portion extends from the tip of the lobule to the superior border of the antitragus. The length of the ear is defined as the distance between the highest point (supra-aurale) and the lowest point (subaurale). This may vary between patients in accordance with the differences in the shape of the patient's face and their lobule characteristics. For instance, the ear lengths vary from 55 mm to 65 mm, with a

Fig. 35.2 Relation of ear to nose and facial plane

mean of 62.4 mm in males and a mean of 58.4 mm in females. The width is approximately 55% of the ear length and is around 35.5 mm in males and 33.4 mm in females. The protrusion of the ear, also called the auriculocephalic angle, ranges from 15° to 20°. This is the angle between the mastoid skin and the posterior surface of the auricle. Again, this may show variation between patients. However, this angle should remain the same in both the normal and the reconstructed ears [3]. The angle between the vertical axis of the face and the longitudinal axis of the ear is referred to as the ear inclination. It must be measured with the patient oriented to the Frankfort horizontal position. This is around 24° with the face, but is 32° in relation to the nasal dorsum (Fig. 35.2).

35.4 Classification

There are four grades of microtia, depending on the severity. These are as follows:

Grade 1: The ear has anatomically normal characteristics, but may be slightly smaller than normal. An external auditory canal is usually present, but may demonstrate atresia.

Grade 2: The size of the ear is than in grade 1, and it may be less developed. Although a part of the helix may be formed, the triangular fossa, scaphae, and antihelix are under-developed. Atresia of the external auditory canal may or may not be an associated feature.

Grade 3 or classic: This is the commonest grade seen and usually consists of a vertical remnant of skin. There is a superior component that contains the malformed cartilage, and an inferior component that forms the displaced earlobe. This grade is almost always associated with atresia.

Grade 4 or anotia: The outer ear structure is completely absent, and atresia is always present.

There is another simplified classification, in which microtia is divided into the lobular type (ear remnant and lobule

Fig. 35.3 (**a**) Lobule-type and (**b**) conchal-type microtia

are present) or conchal type (presence of concha, external canal, and tragus with lobule) (Fig. 35.3).

35.5 Evaluation and Management

The management of a child with microtia should ideally be discussed with parents shortly after birth, to reduce parenteral stress and offer them reassurance. The audiologic testing should be performed before discharge. In cases of unilateral microtia, treatment is not urgent because the other side will have normal hearing. Treatment can be thoughtfully planned after consulting with relevant specialists. However, in bilateral cases, brainstem auditory-evoked response testing must be performed as soon as possible so that the child can be fitted with a bone-conduction headband. The microtia surgeon can discuss about all the possible option with the family, including observation, autologous costal cartilage, alloplasts, and prosthetics. Each method of management has a different timing, and therefore, all optins must be discussed at an early stage. In addition, the microtia surgeon must also coordinate ear reconstruction with auditory management, so that the timing of the hearing correction may be optimized [4].

35.6 Timing

Timing of repair is governed by both physical growth and psychological consideration. The ears reach much of their mature size by age 7. Generally, by the age of 6, cartilage is sufficiently developed to provide an optimal primary framework. However, the older the child, the more cartilage is available for reconstruction. On the other hand, waiting for cartilage growth must be weighed against the psychological and social effects of the missing ear on the child. Studies show that psychological effects usually manifest only around the age of 7–10. However, by age 6, most children are aware of the problem and want to get it corrected [3]. The timing can also depend on the method of reconstruction chosen. The Brent method, which requires less cartilage, may be performed as early as 6–7 years of age. On the other hand, the Nagata method can be done only after 10 years of age, when the chest measures at least 60 cm at the xiphisternum. This is because it needs larger amounts of cartilage [1].

35.7 History

Tanzer et al. first established the technique for total auricular reconstruction. The technique was modified by Brent, who utilized more defined surgical techniques such as fabrication of the framework and reconstruction of the tragus using composite chondrocutaneous grafts. These techniques were three stages and four stages, respectively. Nagata and Park outlined techniques that involved just one or two stages for ear reconstruction [5]. Allolastic implants were tried since the 1960s. Initially, silicone implants were used, but these were associated with complications such as implant failure following minor trauma or abrasions. In 1993, Wellisz reintroduced the prefabricated alloplastic implant for microtia reconstruction. This was constructed from PHDPE [6].

35.8 Principle and Planning (Video 35.1)

The Microtia surgeon should begin with proper planning and achievable goals for successful auricular reconstruction. It is important to discuss the details of surgical procedure and limitation of surgical repair with the family during preoperative consultation. The surgeon must prepare the family for multiple stages, long preoperative and postoperative care, and complications. The reconstructed ear will possess some deficits as compared to the normal ear and will be less flexible and elastic. The reconstructed ear can also be prone to complications, including hematoma, poor healing, infection, or skin breakdown. These complications can compromise the definition and contour of the reconstructed ear [3].

If the patient has coexisting anomalies, such as clefts, early surgery must be done first to correct these. For instance, in cases of Treacher Collins syndrome and other first and second branchial arch defects (craniofacial microsomia, Goldenhar's syndrome, etc.), the bone reconstruction must be achieved first, with scars peripheral to the proposed ear [7].

The precise positioning and dimensions of the reconstructed framework will define the end result of the surgery. The reconstruction must be symmetrical to the contralateral ear in the unilateral case. In bilateral cases, the parent's ear is used as a reference. Visual examination may not be reliable, and it is essential to make exact measurements, after properly positioning the patient. For an ideal position, the superior extent of the ear must be placed parallel to the Frankfort's horizontal plane, at the level of the lateral brow (Fig. 35.4). The root of the helix may be positioned at the level of the subnasale, approximately one ear-length behind the lateral brow. Measurements must be taken carefully, particularly from the lower one-third of the face, in cases of facial asymmetry (seen in about 88% of patients with microtia). The asymmetries can range from mild differences in gonial position to full-blown hemifacial macrosomia and can lead to inaccuracies in measurement [3].

The final outcome also depends on the skin quality around the ear area. If the skin is scarred, natural expansion cannot take place, and the final ear may have a poor definition. In such cases, supplemental tissue in the form of flaps (e.g., temporoparietal fascia flap) may be considered to augment the supple skin envelope. In general, skin elasticity varies for each individual, and this can influence the final definition of the ear [8]. In cases of tight skin, a lower-profile 3D framework (1 mm) may be created, to avoid strain on the skin.

35.9 Simulation Training

The surgeon must obtain enough training in plastic and reconstructive surgery, including skills such as gentle flap dissection, delicate wound closures, and skin grafting, to achieve optimal outcomes. In addition, surgeons must be familiar with precise carving that is required for forming the 3D framework for the ear. Potato, carrot, or pumpkin can be used to learn and perfect the art of sculpting a framework [8]. Silicone dental impression material provides a convenient replica of costal cartilage, as it has the same consistency and texture. An exact replica of the rib cartilage and a precise template of the ear will allow the simulation to mimic the clinical situation. Creating the framework can be done using wood carving instruments. These techniques aid the novice surgeon in improving their results during the actual surgery [9].

Fig. 35.4 Future position and size of ear

35.10 Template

Preoperative photographs should be obtained, and measurements of the normal ear must be obtained when the patient is awake. The surgical template is prepared from radiograph film using normal ear as a guide. In the beginning, an outline of the helical rim, lobule, antitragus, tragus, and conchal bowl is created from the opposing ear as the first template [3]. This template needs to be reversed to plan the ipsilateral ear. Another mirror image template is created based on the first one, which is smaller in dimension. This would allow for the extra thickness following insertion of cartilage under the skin (Fig. 35.5). The inferior pole on the framework is created much smaller in size, to accommodate the transposition of the earlobe. If the patient does not have usable earlobe tissue, this can be carved into the lower end of the framework. A second template is created, this time minus the helical rim. This template is used as a guide for creating the base of the framework from the sixth and seventh ribs, after which the rim of the helix can be added. The templates must be chemically sterilized prior to intraoperative use. A third template, made along with the first, has markings at the lateral canthus of the eye and commissure of the mouth. This allows ideal framework positioning and orientation. The distances marked on the template must be verified by measuring the distance between the lateral canthus and the root of the helix [3].

Fig. 35.5 Final surgical template of ear made from x-ray film

35.11 Auricular Reconstruction Using Autologous Rib Cartilage

35.11.1 Harvesting Rib Cartilage

For harvesting the rib cartilage, an incision, 4–5 cm long, is placed obliquely on the ipsilateral side, at the level of the synchondrosis of the sixth and seventh ribs [10]. The incision is carried down through the muscle, to expose the costal cartilages. It is safer to harvest the cartilage without perichondrium because leaving the perichondrium behind offers one more layer of protection to pleura. The perichondrium also allows for the regeneration of the cartilage/bone matrix. Removing perichondrium can not only offer less protection but also lead to significant depressive chest deformities [8]. After harvesting is complete, intercostal nerve blocks may be administered. Closure of the muscle and deep fascial layers is done, and a large piece of cartilage may be banked in a subcutaneous pocket for the second stage [10]. Smaller cartilage pieces may be diced and placed inside the sutured perichondrial pocket, where it can aid in cartilage regeneration (Fig. 35.6).

35.11.2 Framework

The supporting framework is a living sculpture that serves as the foundation for the repair. Rather than carving the framework to exactly mimic auricular cartilage, the surgeon must make allowances for the abnormal skin coverage that is present. These limitations include skin-volume shortage and greater skin thickness, both of which produce excess skin tension. To prevent the flattening of the ear's rim that this tension might cause, one must carve a somewhat thicker and more substantial helix. This exaggeration of the cartilaginous framework will compensate for the thickness of the overlying skin. The 3D framework must be at least 9.5–10.0 mm high in the case of primary reconstruction and further augmented by 1.0–2.0 mm for secondary reconstruction [8].

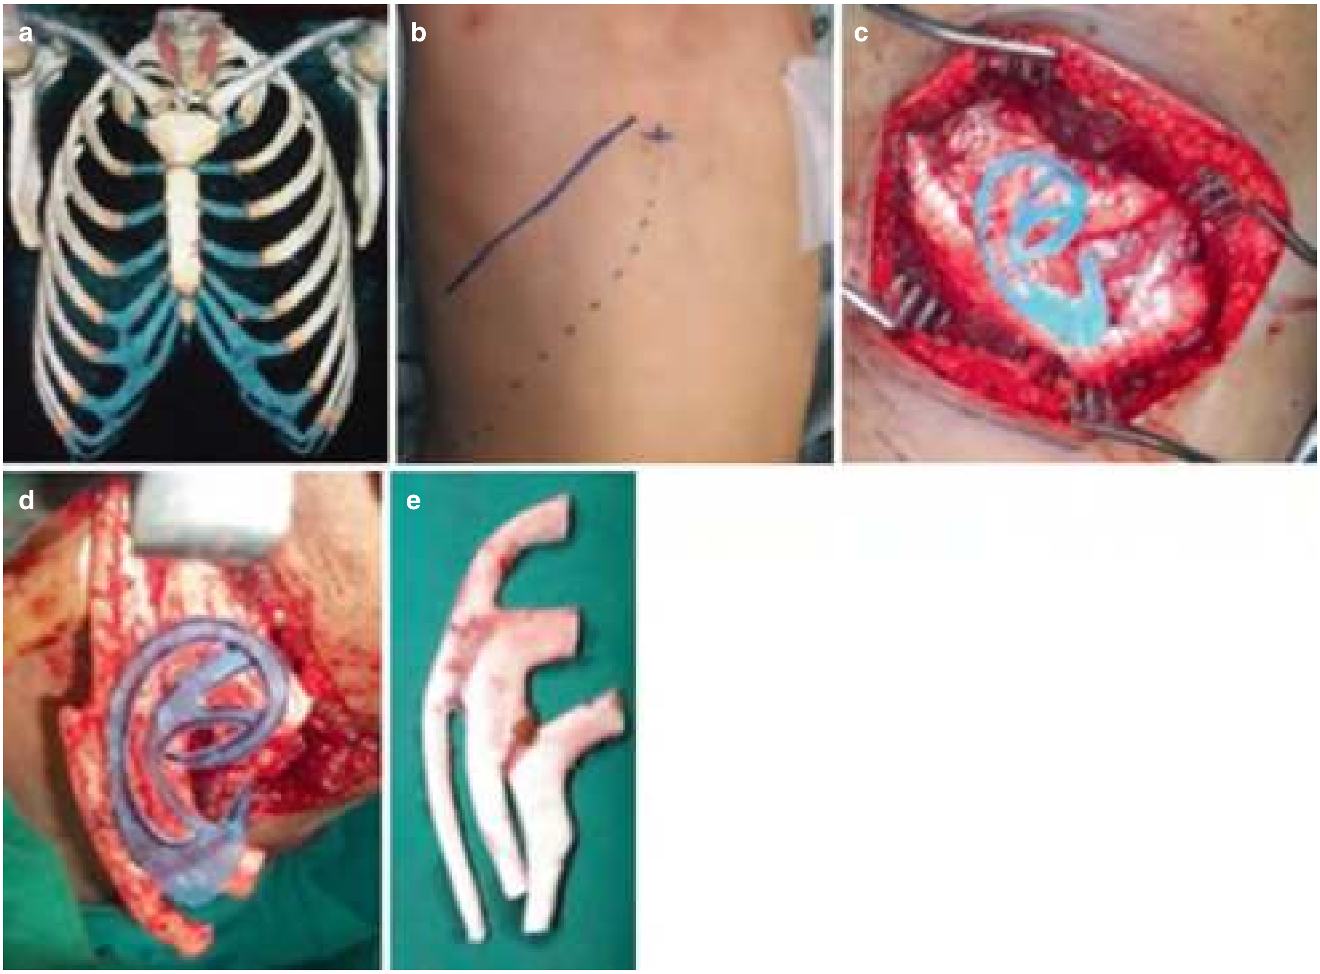

Fig. 35.6 (**a**) 3D CT scan of Rib cage. (**b**) Incision for cartilage harvest. (**c**) Exposure of rib cartilage. (**d**) Template used to harvest cartilage. (**e**) Harvested cartilage

The cartilaginous framework is constructed from the synchondrosis of the sixth and seventh ribs (Fig. 35.7b, c, d). Cartilage wedges from these ribs are used to create the helical sulcus and the triangular fossa. The helix itself is formed from the eighth rib because it is longer. If additional length is required, the ninth rib can also be harvested (Fig. 35.7e) [10]. While carving the helix, it must be ensured that superior portion is higher than the inferior portion. The part of the helix that will be continuous with the lobule must be trimmed at the lower end, until it is long enough to receive the lobule attachment. The constructed helix is then affixed to the basal cartilage. On doing this, an outward inclination of 10–15° is maintained, at the middle one-third of the ear. The entire length of the lower part of the basal cartilage, at the outer end, is trimmed [5]. The floating rib cartilage that is used to create the helix must be thinned on its outer convex surface. This causes the cartilage to warp in a favorable direction and creates an acute angle that resembles the helix. This cartilage is then fastened to the body of the framework with 5-0 Stainless steel suture. The thickest parts of the remaining segments of cartilage are used to create the rest of the auricle, namely, the antihelix and antitragus-tragus complex, which surround the conchal bowl (Fig. 35.7f). The highest point of the antihelix is the middle, and this slowly tapers down to the helix. The superior and inferior crura are created, at the slope toward the lowest portion of the base frame. Enough space must be secured between the upper helix and superior and inferior crura, in order to accommodate the skin envelope. Otherwise, an effect of continuity between 2 crura and helix is created, which is undesirable [8]. The components of the framework are then assembled and secured together using 5-0 stainless steel wires. To achieve a snug fit, a small incision is placed in the cartilage and the wire is pulled gently toward the incision without burying it [10]. The position of the antihelix within the antitragus must be high, and trimming must be done at a lower level toward the superior and the inferior crura. In order to augment the antihelix, cartilage may be added in a vertical manner near the conchal area.

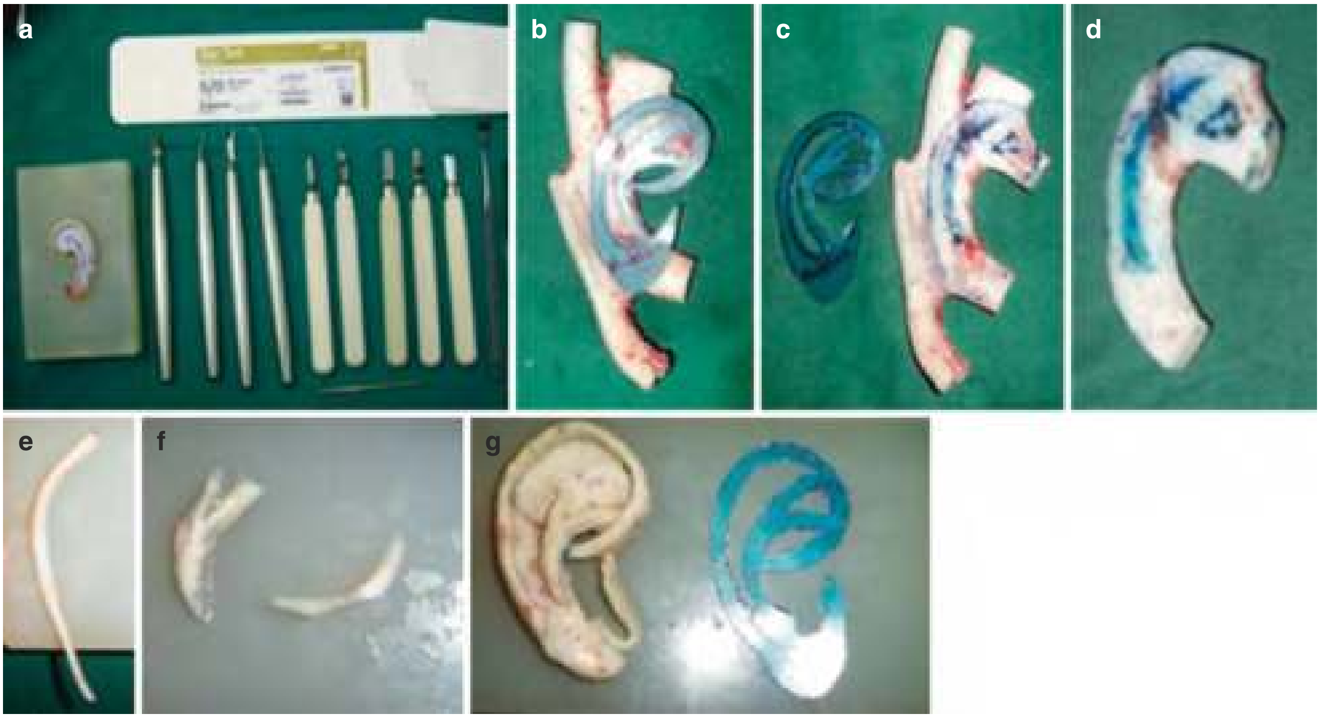

Fig. 35.7 (**a**) Armamentarium for carving, (**b**–**d**) preparation of base of the cartilaginous framework from the synchondrosis of the sixth and seventh ribs, (**e**) helix prepared from eighth rib cartilage, (**f**) antihelix and tragus, and (**g**) Final framework

This gives an effect of deepening of the concha. The antihelix is also trimmed in the region of the scaphoid fossa, so that it develops a slight inclination that resembles the natural convolution. Finally, the surfaces of the entire framework must be tapered smoothly tapered, and block-like corners must be removed, to ensure that the covering skin fits on smoothly (Fig. 35.7g). Throughout the process, isotonic saline solution is used to irrigate the cartilaginous framework. This helps preserve chondrocytes. The use of rotary and power tools must be avoided to prevent chondrocyte damage [7].

35.11.3 Skin Pocket

A pocket must be created within the skin in a meticulous fashion. This will provide proper vascular covering to receive the framework. As per the level of the lobular remnant, the level of the incision line for rotating the lobule may be determined. A small part of the lobular remnant is transposed posteriorly and separated from the microtic remnant. Then, the lobule is dissected and rotated to create a pocket that will accommodate the caudal end of the cartilage framework. This causes the lobule to be brought down and results in a smooth interface between the lobule and the framework. Creation of the skin pocket preserves the subdermal vascular plexus. The amount of dissection (at least 2 cm beyond the outline) must be wide enough to allow proper draping of the skin flaps over the framework with minimal tension. Any cartilage, if present in the vestigial remnant, is removed. Meticulous hemostasis must be achieved [5]. An incision is placed at the posteroinferior border of the vestigial remnant, and the cartilaginous framework is placed in the subcutaneous pocket. The tail end of the framework is inserted into the lobule first, followed by suturing of the outer incision. In order to let the skin adhere to the framework, two polyethylene drains with multiple perforators must be inserted beneath the framework. These are secured to the skin using 5/0 nylon sutures. A syringe (50-cc) may be connected to the drain. After final suturing of the subcutaneous pocket, the skin flap is approximated, and the piston of the syringe may be fixed in activated position using two wooden tongue depressors (Fig. 35.8) [5]. If skin blanching is noticed at this stage, the pocket must either be enlarged or the framework must be inserted at a lower position. The use of pressure dressings must be avoided as these can compromise the vascular supply. The entire reconstructed ear must be layered in petrolatum gauze, which must be placed loosely and left in place for 3 days [3]. The syringe with the activated piston may be changed frequently in the postoperative perio, ensuring that proper tension is maintained. The drains may be removed on the fourth or fifth postoperative, provided that the volume of fluid drained is less than 1-cc. Petrolatum gauze may be left in place until suture removal, on the sixth postoperative day [5].

Fig. 35.8 (**a**) Before activation of suction and (**b**) after activation of suction

35.11.4 Second Stage

The second stage of surgery involves elevating the auricle from the head, which creates the auriculocephalic angle. This procedure should ideally be performed 6–9 months following the first stage. In the conventional method, the incision lies several millimeters away from the margin, and reconstructed ear is gently lifted from the base. Care must be taken to preserve connective tissue on the undersurface of the ear, as well as on the bony floor. The posterior part of the auricle and the skin defect overlying the mastoid are grafted with skin. Since the ear lacks skeletal support, it contacts the mastoid skin and is not elevated. This creates a narrow space, which may be difficult for the patient to clean [8].

In the Nagata technique, the second stage is more complex than the conventional one. This involves the following steps: (1) separation of the auricle from the mastoid, (2) The banked subcutaneous rib cartilage or an alloplast is used to create a wedge-shaped block, which is placed underneath the auricle, (3) A temporoparietal fascia (TPF) flap is then harvested to cover the posterior part of the auricle, and (4) A split skin graft harvested from the scalp to cover the fascial flap. Scalp skin is preferred as it has better color match as compared to groin skin (Figs. 35.9 and 35.10) [8].

35.11.5 Complications

- During the harvest of Rib Cartilage

The two commonest complications at this stage are pneumothorax and atelectasis. If detected intraoperatively, pneumothorax can be easily treated and may not require chest tube placement. Positive pressure ventilation is used after irrigating the wound to see if there is any leak. If there is no leak, the wound is closed in layers. If a leak is seen, it indicates the presence of pneumothorax. In this case, a red rubber catheter is inserted into the pleural opening to which a syringe is attached to this to evacuate residual air. Following this, the chest may be closed and an intraoperative chest radiograph is asked for to rule out residual pneumothorax. If this is absent, the wound may be closed, the catheter may be removed and follow-up may be done with serial films [3]. Atelectasis is best prevented by frank preoperative preparation of the patient and vigorous postoperative respiratory therapy.

- Skin Flap Necrosis

The first 10 postoperative days are critical to check for any skin flap necrosis. It is essential to achieve a balance between the thickness of the skin flap and the size of the pocket with the contouring of the cartilage framework. To prevent skin necrosis, it is advisable to minimize or completely avoid the use of epinephrine in the flap. The status of vascular supply can be tested by placing the framework in the pocket, activating the suction drain, and observing any for blanching along the rim of the helix. If blanching is present (indicating vascular compromise), the size of the pocket may be enlarged until blanching disappears. If needed, the skin supply may be increased by placing a tissue expander 2 months prior to insertion of the framework and skin adhesion [1]. If skin necrosis is observed, it must be attended to immediately, as it can cause infection of the underlying cartilage

Fig. 35.9 Ear reconstruction in hemifacial microsomia associated with microtia. (**a**) Preop and (**b**) Postop

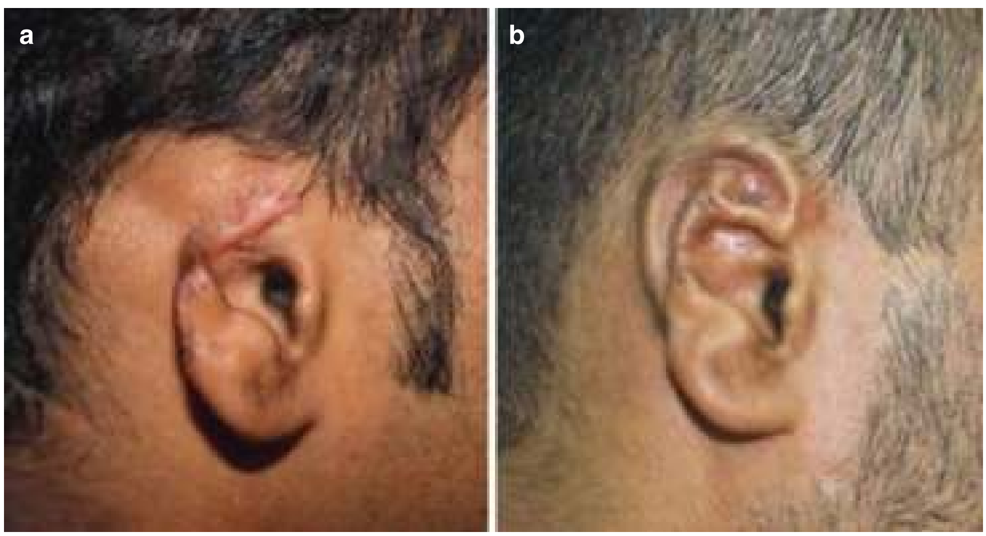

Fig. 35.10 Ear reconstruction after traumatic amputation of upper half of ear. (**a**) Preop and (**a**) Post op

and framework resorption. The damage can be minimized by covering with a local skin flap or fascial flap (Fig. 35.11).

- Infection

This is uncommon in the autologous reconstruction. If it occurs, along with appropriate systemic antibiotics, vigorous irrigation of the surgical site must be done.

- Cartilage Resorption

If there is either ischemia or infection, there are chances that the cartilaginous framework can get resorbed or deformed. This can also occur if the skin envelope is too tight, especially at the hairline border. To avoid this, dissection of the skin pocket around the hairline must be done carefully. Any tight fibrous band that exists along the hairline must be released.

- Wire Extrusion

If any wires extrude from the framework, they can easily be removed at the outpatient facility. It is necessary that the wire must be removed as soon as extrusion is noticed, and the patient/family must be educated accordingly. Otherwise, there are chances that the exposed wires can cause resorption of cartilage around the wire.

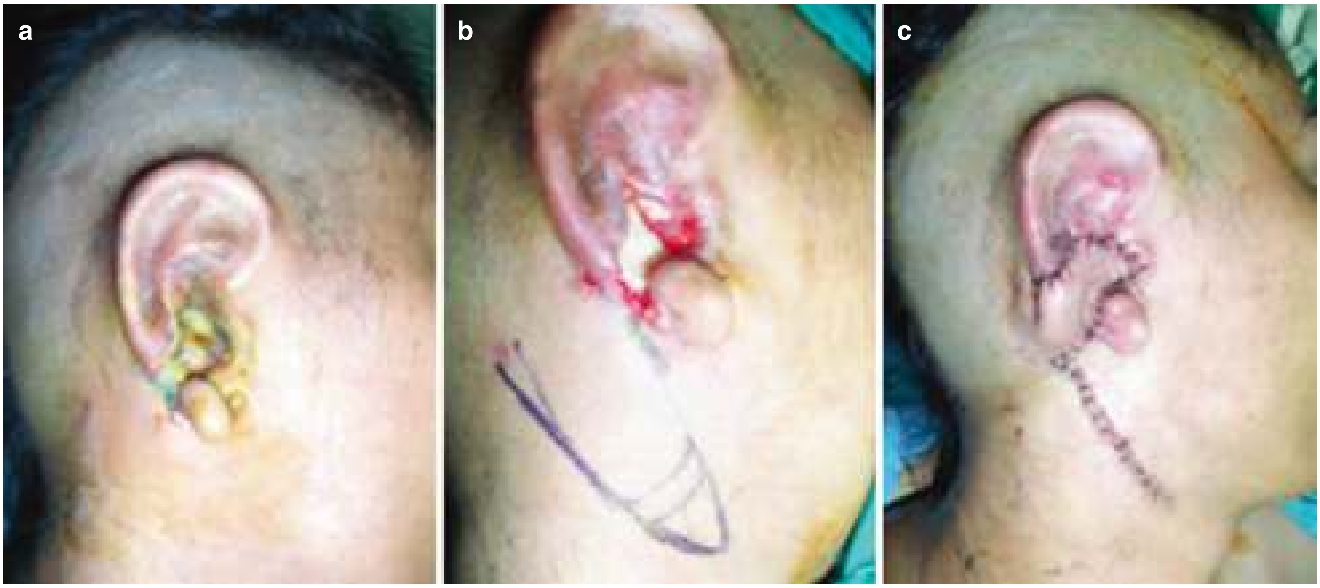

Fig. 35.11 (**a**) Necrosis of skin at near suture line, (**b**) debridement and marking for local flap, and (**c**) flap in situ

35.12 Auricular Reconstruction Using Alloplast

The material used for creating framework has been a subject of debate and research. Autologous costal cartilage is still the most preferred material in microtia repair. However, some surgeons consider using alloplasts because of the following advantages.

1. Donor site morbidity is avoided,
2. Reconstruction can be done at a younger age,
3. Reduction in the number of interventions,
4. More predictable outcome,
5. The structural limitations associated with the use of autologous rib may be avoided
6. The ability to tailor reconstruction to individual patient needs (such as low hairline and bilateral malformations) [11].

The ideal alloplast for auricular reconstruction should have the following features: cost-effectiveness, ability to be implanted safely, ability to resist infection, and capability to undergo customization to resemble the contralateral normal ear. To date, more than 40 different materials have been used for creating the auricular framework. These include ivory, nylon, wire mesh, and silicone. Silicone was thought to show good results since it could mimic the flexibility and form of the native ear cartilage. However, it had a high rejection rate, especially when placed under thin skin flaps. pHDPE (Fig. 35.12) is a modestly flexible, robust enough to withstand microtrauma, and easily shapable and allows soft tissue ingrowth. This permits it to be protected against extrusion and infection. It also allows targeted drug delivery to the implant [11].

35.12.1 Technique

It is crucial to assess the age of patient, dimension of contralateral ear in the case of unilateral microtia, and the dimensions of their gender-matched parent's ear preoperatively for achieving equal dimensions between the normal ear and the reconstructed pHDPE ear. The ear created must be adult sized as the alloplast does not increase in size.

The vascular Doppler is used for marking superficial temporal artery. The incision is given in the postauricular area few millimeters behind the new helical rim of the microtic ear to approach TPF flap. Incision is extended in a curvilinear fashion over the TPF flap to improve the exposure and also helps to harvest the distal flap of recommended length. Other approaches may be used, including an Y incision (Fig. 35.13a), which extends superiorly from the mastoid area, and the Z incision, (Fig. 35.13b) which exposes the TPF. These approaches also allow better access to the fascia.

Fig. 35.12 Porous high-density polyethylene (PHDPE) framework for auricular reconstruction

However, they increase the risk of alopecia at the incision lines and at the apex of a triangular flap.

An anteriorly based skin flap of minimum thickness is elevated meticulously, and microtic cartilage is excised. Usually, the inferior portion of the flap is attached initially to the lobular remnant. If this is malpositioned, this skin flap may be removed and used as a free graft to improve skin coverage. A TPF flap, based inferiorly, of approximately 10.5 by 13.0 cm is raised off the deep temporal fascia and periosteum beneath, superior to the level of the temporal line. The base of the flap is made wide (around 6 cm) to include additional vascular supply (branches of the occipital artery, postauricular artery, and the mastoid emissary vein), and the base of the flap is made wide, around 6 cm. The flap must be made as robust as possible, and loose areolar tissue on the deep surface of the TPF must be included in it. This tissue, which lies deep to the skin graft, allows the skin to slide over the underlying tissue. This resists surface trauma and implant exposure. The pHDPE framework is then sculpted, fused, and matched to contralateral ear. Prior to implant placement, two flat suction drains are inserted through the skin of the mastoid. One drain lies deep to the pHDPE, while the second lies in the posterior part of the donor site on the scalp. The implant is placed over the mastoid area and covered with the TPF flap after checking its anatomic orientation, projection, and axis. The flap is made to wrap tightly around the implant by the negative pressure generated by the first drain. The second drain functions to remove any serous exudate from the donor site. The skin flap, which is based anteriorly, is draped over the TPF. It may also be removed and used as a free skin graft. Sometimes, the skin at the ipsilateral mastoid may not be sufficient to cover the surface of the reconstructed ear entirely. In such cases, a full-thickness skin graft may be harvested from the opposing side postauricular region. A graft taken from this region would provide the best color and texture match. To cover the back of the ear, a larger skin graft may be required, which can be harvested from the inguinal region. After activating the drains, the ear may be coated with a layer of antibiotic cream and the concave regions may be dressed with gauze. The entire ear is then covered in a customized cast made of silicone. This cast prevents seroma, hematoma, or shearing trauma, which may compromise the viability of the skin graft. This cast should not be under pressure. A pressure dressing to prevent seromas can be applied over the donor site. All suction drains may be removed following extubation [11].

35.12.2 Complications

The complications of this procedure may be minor, such as a simple wound infection, or major, such as total flap necrosis with exposure of the Medpor framework beneath. In case the implant is exposed or infected, removal may rarely be required. Late complications include traumatic excoriations to the re-constructed ear, which should be managed with good wound toileting or with local skin flaps if required.

35.13 Prosthetic Ear

Certain traumatic, congenital, or surgical defects may benefit from auricular prostheses. The choice between surgical and prosthetic reconstruction is controversial, particularly for patients. The ideal age for prosthetic treatment is the same as the age for surgical reconstruction, namely, between 6 and 9 years. The child must be capable of caring for the prosthesis. In cases of unsuccessful surgical outcome, the prosthetic ear is one of the options. Prosthetic ear is a suitable option for the ear defects caused by trauma and disease in adult populations.

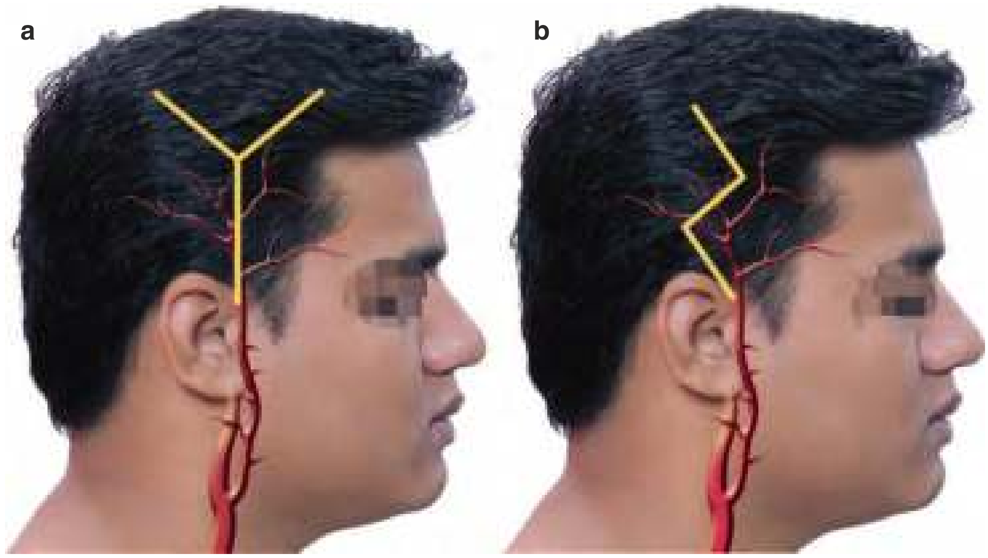

Fig. 35.13 Approach for temporoparietal flap. (**a**) Y shape Incision. (**b**) Large Z incision

35.13.1 Retention of the Prosthesis

Tissue adhesives are used conventionally for ear prosthesis retention because of their low cost and quick results. Tissue adhesive is an old method and causes skin reaction. It is difficult to wear and take off adhesive while bathing and swimming. Osseointegrated implant is superior option for retention, and because of nature sense of prosthesis, ease of use, long lifetime and retention during daily activities, it is accepted by patients. An implant-retained prosthesis is preferred when there is hair on the surface of the defect or when the patient has excessively oily and perspiring skin. The prosthesis may be attached to the implant screws using precision attachments or magnets. Osseointegrated implants are contraindicated during radiation therapy, as the bone is demineralized and prone to hard tissue vasculitis, fibrosis, persistent infections, reduced tissue perfusion, and oxygenation. Osseointegration in such patients is difficult, but may be attained with hyperbaric oxygen treatment [12].

35.13.2 Prosthetic Technique

Impressions are made of both the defect and contralateral normal ear. Usually, rubber silicone material is used and plaster models are prepared. The plaster models of contralateral side are used as a reference to sculpt the framework. This is done using wax or clay. Next, a negative mold is obtained when the wax is removed, leaving behind a void. Medical-grade silicone usually of clear shade is mixed with pigments to create the skin colors of the individual patient. This silicone is packed into the void and cured. After removal from the mold, the texture and the color of the skin can be reproduced to match the contralateral side and adjacent skin [12].

35.14 Future

Regardless of the method used, ear reconstruction cannot provide an appearance that equals auricular prostheses. Future techniques must focus on emerging tissue engineering technologies that can create bone, cartilage, skin, and blood vessels. This can provide a novel direction for the treatment of patients with microtia. The creation of a natural ear using cultured chondrocytes on a prefabricated cartilaginous framework is an area of active research, but still holds some challenge [1]. Creating functional and durable tissue through tissue engineering can remove the need for donor sites and revolutionize reconstructive surgery.

35.15 Conclusion

The human ear is a unique structure that is difficult to replicate owing to its complex cartilaginous structure and thin overlying skin. The ultimate goal of total ear reconstruction should be creation of an auricle that closely matches the normal ear in appearance. Several surgical techniques are available for ear reconstruction. Since microtia is a rare condition, cases are limited, but at the same time, only a high case volume can improve success rates. The learning curve is long and might be at the expense of the patient. Although this learning curve is unavoidable, it is imperative to curtail its steepness. Prior to embarking on ear reconstruction, surgeons must be familiar with the principles and techniques involved. It is important to remember that repetition helps us master the technique.

Disclosure Authors have no financial conflicts to disclose.

35.16 Case Scenarios

Case 1 (Fig. 35.14a–g)

24 year-old male with Unilateral Left side Grade 3 or Lobule type microtia. On audiometry testing, hearing was normal with conductive hearing on left side. External auditory meatus is absent. He was planned for auricular reconstruction using autologous costal cartilage. Costal cartilage was harvested from ipsilateral side. Synchondrotic junction and floating rib were harvested from the seventh, eighth, and ninth rib. Framework was prepared as shown in photo (b). Tragal component is added in framework. Skin pocket was prepared, and lobule was transposed posteriorly. Framework was inserted in pocket, and suction was applied for close adaptation of skin to framework. Stage II surgery was done after 1 year. Ear was elevated, and cartilage graft was placed for support. Graft was covered with temporoparietal fascia flap and skin grafting done. 6 months postop shows symmetric projection of both ears.

Fig. 35.14 (**a**) Preop, (**b**) Framework, (**c**) Postop, (**d**) 3 months postop, (**e**) and (**f**) Comparison between normal and reconstructed ear after elevation of ear, and (**g**) Projection of reconstructed ear

Case 2 (Fig. 35.15a–f)

21 year-old male with Unilateral Left side Grade 4 or Anotia. On audiometry testing, hearing was normal with conductive hearing on left side. He was planned for auricular reconstruction using autologous costal cartilage. Costal cartilage was harvested from ipsilateral side. Synchondrotic junction and floating rib were harvested from seventh, eighth, and ninth rib. Simple Framework was prepared as shown in photo (b). Skin pocket was prepared using Z-plasty incision. Framework was inserted in pocket, and suction was applied for close adaptation of skin to framework. Stage II surgery was done after 1 year. Ear was elevated, and cartilage graft was placed for support. Graft was covered with temporoparietal fascia flap and skin grafting done. 8 months postop shows symmetric projection of both ears.

Fig. 35.15 (**a**) Preop, (**b**) Framework, (**c**) Postop, (**d**) 3 months postop, (**e**) and (**f**) Comparison between normal and reconstructed ear after elevation of ear

Management of Facial Scars

36

Velupillai Ilankovan and Anna Sayan

36.1 Introduction

When the body sustains injury, the process of wound healing will commence. Scar formation is a part of wound healing. These are described as primary, secondary and tertiary intention processes [1]. In primary, there is close approximation of the wound edges, and in the secondary, the edges could not be approximated. The wound is left open, and the defect is slowly filled with connective tissue. In the tertiary, however, there is infection or contamination and there is a delay until the offending items are removed. This is followed by primary intention healing.

An ideal scar is a thin line or lines in parallel to the relaxed skin tension lines (RSTLs) described by Borges [2]. This should have a natural contour, colour and no distortion of the surrounding structures.

The scar particularly the facial is not aesthetically pleasing and can cause psychological distress to patients, resulting in poor body image, reduced self-esteem, generally loss of confidence and at times certain social stigma.

Prevention of an unsightly scar is primarily important requirement to any Surgeons but particularly important to Facial Plastics and Aesthetic Surgeons.

The origin of the word scar comes from Greek termed "iskharo" and in French "eschori" and interestingly was first used in the English language in the fourteenth century.

The primary aim in the management of scar is to produce an invisible line.

Less than ideal scars demonstrate features that are highlighted in Box 36.1.

Multiple causes can play a role in unsightly scar formation. Non-clear wound edges cannot give an aesthetically pleasing outcome. Nutritional status, co-morbidities such as diabetes, previously radiotherapy field and habits such as smoking have a detrimental effect in wound healing and thus imperfect scars. The most important factor is also the surgical competence of the operator.

Box 36.1 Characteristics of less than ideal scars

- wide
- raised
- depressed
- pigmented
- hypo-pigmented
- and erythematous
- may transect natural creases, folds and junctions

36.2 Pathophysiology

The pathophysiology of wound healing and scar formation is very complicated [3].

The wound healing is characterised by four separate but overlapping phases (Box 36.2).

Haemostasis and inflammation occur during the first 4–6 days. During the first few minutes after surgery, there are vascular contraction and formation of fibrin clot. The ruptured cell membranes result in the release of inflammatory factors in order to cause vasoconstriction, which will last for 5–10 min, and then the vessel dilatation starts. This process can take up to 20 min. The vessel dilatation is caused by histamine, which, in turns, allows inflammatory cells to arrive at the wound site. The platelets also adhere to the site of injury. Subsequently, the coagulation cascade will be activated. The structure of the clot will be a fibrin protein network filled with platelets and its contents. The main inflammatory mediators released by the platelets are the prostaglandins, leukotrienes, interleukins, growth factors and cytokines. During the inflammatory phase, there is also the arrival of neutrophils, macrophages and lymphocytes. The main function of the neutrophils is the removal

Box 36.3 Hypertrophic scar vs Keloid

Hypertrophic scar	Keloid
do not grow beyond the boundaries of the original wound	grow horizontally and outgrowing wound boundaries
occur when there are skin wounds of any aetiology	can arise from small injuries such as piercing of ears
Not genetic	genetic
Not related to any race	More in dark skinned
Equal sex predilection	More in females

of the invading materials such as the microbes and products from the cell death. The macrophages are, however, responsible for inducing and clearing dying cells, which will result in improvement of inflammation. The apoptotic cells are cleaned by the macrophages, and the reparative stage begins. During this stage, there is migration of the epithelial cells usually after 48 hours and this process continues until the tenth day. Fibroblasts promote collagen synthesis. The epidermis is thickened in layers, and the collagen fibres promote dermal strength. The collagen deposition takes 2–3 weeks, and at this time, the remodelling phase begins. The collagen fibres will become rearranged during this period, and the cross-linked will be aligned along the tension lines. Largely, the maturation phase can take up to a year or longer depending on the type and site of wound. Therefore, the inflammatory process plays a major role in scar formation with the resultant fibroblast proliferation migration and differentiation.

The formal scar can be made better by using scar and scar reducing agents such as non-steroidal anti-inflammatory drugs (NSAIDs), minocycline and gene therapy. The main recognised scar reducing agents are transforming growth factor (TGF), TGF beta 3, COX-2 inhibitors and angiotensin receptor blockers [4]. The TGF beta modulating agents are still undergoing phase 2 trials in order to find out ideal scar modulating topical or intralesional agents.

Microfat grafting [5] is a technique with great potential in scar management where fat can be used intralesionally using a small 0.7 mm diameter cannula. It has been shown to be even more effective in placing fat in deep dermal layer of the skin using a 23-gauge needle in a treatment called sharp needle intradermal fat (SNIF) grafting. However, the work carried out by Tonnard et al. [6] in emulsifying the fat filtered until a liquid suspension was obtained, called Nanofat, which is injected using a 27-gauge needle, which conveys excellent outcome.

The ideal scar is an invisible line. There was increased interest in the recent past on intrauterine surgery to improve craniofacial clefts with some success and large failures. The extrauterine scars can present as stretched to depressed, hypertrophic or at times keloid. The stretched and depressed scars are as a result of inadequate primary intention management. The differences between a hypertrophic scar and keloid scar are highlighted in Box 36.3.

36.3 Scar Management

36.3.1 General Principles

Scar management includes prevention, pre-injury treatments during the healing period and definitive treatment once the scar is established.

It is essential to take accurate history about any previous scar formation. If it is known, extra precautions should be taken, patients should be alerted and incisions along the susceptible sites should be omitted.

For example, when doing blepharoplasty with a history of previous hypertrophic scar, we should avoid a subciliary incision and the treatment should be carried out via a transconjunctival approach. Avoidance of treatment should be practised, for example, a patient who had keloid on previous ear-piercing episodes.

Limiting skin stretching during wound healing, facilitating appropriate wound resting and preventive exercises in certain sites such as chest and suprapubic areas are observed. Atkinson et al. [7] reported a randomised control trial of the effect of tape fixation and the prevention of hypertrophic scars post-caesarean section with significant scar reduction.

Therefore, scar reduction therapies are classified into:

- topical,
- intralesional,
- radiation and
- scar revision with Z plasty, local flaps and skin grafts.

The latest progress in scar management includes treatment with lasers to reduce angiogenesis, subcision and intradermal fillers. The emulsified fat (NanoFat) with stromal vascular fraction (SVF) and plasma rich protein (PRP) usage is the current trend in the non-surgical outcome of scar management.

- *Radiation*
- *Emulsified fat for scar rejuvenation*

36.3.2 Non-surgical Remedies

The non-surgical modalities of scar management are highlighted in Box 36.4, and the description of each is as follows:

- *Steroid*

Triamcinolone is the mostly used steroid for scars. The mode of action when used as an intralesional therapy is in inhibition of the inflammatory mediators, inhibition of fibroblast proliferation, collagen synthesis and inhibition of TGF—BETA 1 and BETA 2—and enhancement of collagen degradation and collagenase action in keratinocytes [8].

The published reports, however, give varying outcomes with dose-dependent side effects such as hypopigmentation, telangiectasia and dermal atrophy [9]. There is an encouraging outcome, however, in combination therapy when the dosage is reduced.

- *5FU*

The suggested mode of action is an inhibition of fibroblast proliferation and TGF-BETA 1-induced collagen synthesis [10]. Anecdotal results are positive; however, trials lack adequate controls. Nonetheless, the effect is encouraging in combination therapy with steroid and pulse dye lasers. Much work is required in controlled studies.

- *Bleomycin*

It is an antibiotic and has been used intralesionally in vascular malformation with good outcome [11].

The mode of action is in reduction of collagen synthesis and increased destruction of collagen by inhibiting Lysyl Oxidase such as TGF-B1 [12]. Much work is needed in its definitive usage.

- *Lasers*

Lasers target three chromophores such as water, melanin and haemoglobin. Laser-induced tissue hypoxia results in the breakdown of disulphide bonds of the collagen fibrils. Pulse Dye Laser (PDL), KTP laser and Nd YAG lasers have affinity to haemoglobin, leading to collagen necrosis, and results in reduction of proliferation of fibroblast and deposition of collagen type 3. Ablative lasers remove the scar layer by layer with minimal thermal injury [13].

- *Dermabrasion*

This technique is still used in treating irregular scars such as ice pick scars of acne. The aim is to abrade up to the reticular dermis, allowing epithelialisation to take place. This treatment causes erythema for a long time, and the symmetrical outcome is not guaranteed.

Microdermabrasion is an advancement where there is high-speed pressurised aspiration-compression system. The benefit is that it minimises deep thermal injury [14].

Carbon Dioxide (CO_2) and Erbium laser resurfacing supersedes microdermabrasion with minimal thermal damage. Laser resurfacing acts in a different way compared to the vascular lasers. The vascular laser action is as a non-ablative principle, whereas CO_2 and Erbium cause ablation.

Vascular lasers decrease the prominence by destroying the blood vessels and stimulating collagen remodelling, thus softening the scar, whereas the ablative lasers such as CO_2 and Erbium ablate or vaporise the excessive tissues. CO_2 can induce more collagen remodellation and promote wound contraction [15].

The vascular lasers are used in hypertrophic and keloid scars. CO_2 and Erbium are useful in stretched, asymmetric and irregular scars. There is a restriction as it is not effective in all skin types as resurfacing can result in excessive pigmentation in dark, Asian and African skins.

- *Subcision*

It is a technique where depressed scars are elevated, and the controlled trauma can aid in formation of new connective tissue. This is carried out by custom-made subcision knives or 20 gauge needles. It can be combined with autologous fat injection to the subcised areas filling in the space and simultaneous laser resurfacing [16].

- *Fillers*

Synthetic Hyaluronic acid, calcium hydroxylapatite and bovine collagen are used in aesthetic surgery for voluminisation. They can be used in treating depressed scars. However, these agents cannot be used in a larger quantity as they will cause subcutaneous nodules and inflammation, and in bovine collagen, there is 3% incidence of allergic history. There is also a need for repeat injection. Autologous fat has taken over as a material of choice for filling in scar management.

- *Silicone gel sheets*

These sheets are used prophylactically in known patients for bad scars as well as therapeutically. However, the outcome for hypertrophic scars is still questionable and inconclusive.

It appears that controlled studies have shown significant beneficial outcome in scar volume when the silicone sheets are used or not used in mirror image wounds. A Cochrane review of 13 trials involving 559 patients, however, concludes weak evidence in preventing hypertrophic scars in susceptible patients [17].

The mechanism of action is in producing hydration to the scars by occlusion.

- *Pressure therapy*

It is a perceived therapy that there is positive evidence in the literature. The largest randomised trial showed no significant difference in scar reduction with pressure therapy when compared to the controlled group [18].

- *Cryotherapy*

A large uncontrolled study of 135 patients with 166 keloids demonstrated 79.5% response rate with 80% reduction in scar volume. However, the results are not reproducible. This treatment causes atrophic, depressed scars with residual hypopigmentation [19].

Therefore, the usage of cryotherapy particularly on the face should be discouraged as a modality.

- *Radiation*

It is an effective adjuvant to surgical excision particularly to keloid. The effect is caused by inhibition of proliferation

Fig. 36.1 (**a**) Keloid Scar right ear lobule. (**b**) Post-operative photograph following scar excision and one dose of radiotherapy

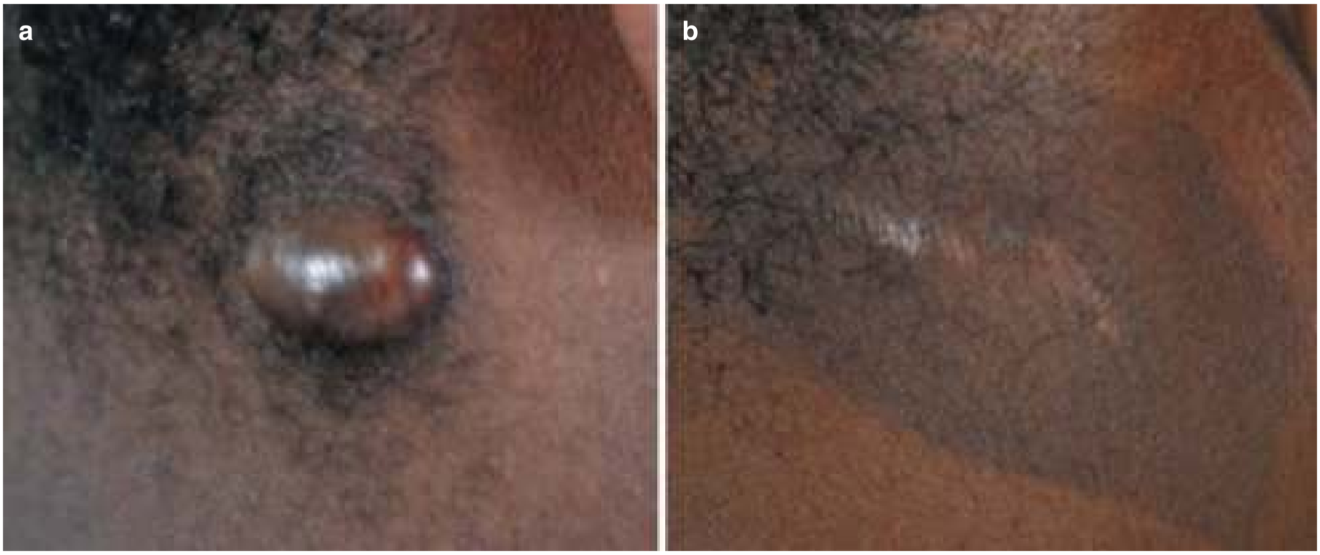

Fig. 36.2 (**a**) Keloid Scar post-auricular region. (**b**) Post-operative photograph following scar excision and one dose of radiotherapy

of fibroblasts and neo-vascular blood formation, resulting in decreased collagen production [20].

The highest cure rate is described in a single dose within 24 hours after surgical excision; however, further studies are needed to evaluate the dosage and to obtain optimum results (Figs. 36.1 and 36.2).

- *Emulsified fat for scar rejuvenation*

The fat tissue is accepted not only as a simple layer of insulation and as a storage for energy but also as a complex endocrine organ, which is intrinsically involved in metabolism and immunomodulatory activities and can provide multi-source resources for stem cells and other undifferentiated cell population, which is essential for regeneration.

In addition to the adipocytes in the fat tissue, there are other cell groups that are functionally very important such as stromal vascular fraction (SVF) and cell-assisted lipotransfer (CAL). The SVF of adipose tissue is a rich source of epithelial progenitor cells, T cells, B cells and adipose tissue macrophages [21]. Separation of SVF is a time-consuming and expensive process requiring collagenase treatment and centrifugation. The recent clinical results obtained with Nanofat grafting where the cells are emulsified show greater value than the components of SVF used separately.

In Nanografting, a 23 gauge needle is used as a sharp needle for subdermal fat injection technique (SNIF) followed by a 27 gauge needle to superficial layers. In order to do this, the fat should be emulsified and takes the name, thus, Nanofat [6].

This now emerges to the forefront in regenerative medicine due to its ability to differentiate into a variety of different cells of cell lineage and the anti-apoptotic, anti-inflammatory, pro-angiogenic immunomodulators and anti-scarring properties.

Nanofat has shown to improve the aesthetics of hypertrophic and keloid scars by improving the texture of the scars in addition to improving the symptoms of pain and itching [22].

Fat is used in voluminisation initially as foundation micrograft just above the periosteum. The second layer is subdermal graft followed by subcision and lastly Nanofat injection using SNIF technique with 23-gauge needle followed by superficial needle injection using 27-gauge needle. This process is to treat depressed scars. Intralesional Nanofat injection improves hypertrophic and keloid scars. This can be combined with other modalities such as laser resurfacing.

36.4 Surgical Scar Management

36.4.1 Basic Principles

As described above, an ideal scar should be an imperceptible line parallel to RSTL. The only exception is scar along the lower lid due to the possibility of ectropion, if incisions are made in parallel to RSTL.

The aim of scar revision is to re-orientate the scar to follow the RSTLs and correction of adjacent structure distortion.

Patient understanding, nutrition, expectation and the psychological stability are paramount factors to implement preoperatively prior to any scar revision exercises particularly in burn scars. The timing of the revision is also important as the remodelling may take up to 12 months.

Nutritional status and the medical history are important pre-operative considerations. It has been described with certain evidence that the use of vitamins A, C and E and zinc have beneficial effects and, at the same time, some herbal supplements such as arnica, garlic, ginseng and saw palmetto can impair wound healing [22]. Systemic conditions such as diabetes and immunosuppression can adversely affect wound healing. Smoking has proven to cause perilous effect on healing and wound repair.

Vitamin E refers to a group of ten lipid soluble compounds that include both Tocotrienols and Tocopherols as a fat soluble antioxidant; it stops the production of reactive oxygen species formed when fat undergoes oxidation [23]. It has been identified that alpha-tocopherol, the most biologically active form of vitamin E, has anti-inflammatory effects by decreasing plasma C-reactive protein (CRP) levels and release of pro-inflammatory cytokines. The CRP, a downstream marker of inflammation in addition to being a risk marker for cardiovascular disease, could contribute to atherosclerosis. Alpha-Tocopherol has been shown to decrease CRP level in patients and has a positive effect in scar reduction. Topical vitamin E application has been practised in managing scar 10 days post-suture removal. Anecdotally, in the last 25 years, good scar outcome has been observed.

36.4.2 Surgical Technique

In most circumstances, incisions should be made parallel to the skin surface. A number 11 or 15 blade is ideal. Tissue handling must be atraumatic. The skin flaps should be held with non-toothed forceps, and the tooth forceps should only be used to handle tissues subdermally. Undermining and constant hydration of edges are essential. In stretched scars, preservation of the dermis by de-epithelialisation will provide extra support in correcting the depression. Haemostasis should be achieved using a bipolar diathermy again minimising thermal injury to the surrounding areas.

Suturing is done in layers. In areas where supportive tension is required, resorbable round body needle sutures are useful. Depending on the site and the extent of the scar, short- or long-term resorbable sutures could be selected. With deep suturing as much as possible, the knot should be buried with skin approximation to achieve 'eversion'. Simple-interrupted sutures are preferable in a majority of areas; however, subcutaneous running sutures could be used where only gentle approximation is needed.

1. *Z plasty* (Fig. 36.3)

This is a common technique used in scar revision to either change the direction of the scar or lengthen the scar. Contracted scars can be corrected by plating multiple simultaneous Z plasties.

The Z plasty is created by using the original scar as a central portion, and triangular flaps are raised. Multiple variations are in Z plasty. In the classical Z plasty, all the limbs are of equal length and the angle between the flaps is 60°. The scar will lengthen by 75%. A 30° angle will lengthen by 25%, and 45° will lengthen by 50%. Multiple Z plasties are useful in long scars, which can be divided into separate segments, and the angles are contoured or modified depending on the sites.

2. *W plasty* (Fig. 36.4)

This technique is used to irregularise scars so that dimensions of the scar are not perceived by the naked eye. A series of consecutive triangles are made. It is mirror image on the opposite side. The arm length should be around 5 mm, and the angle in-between the flap should be maximum 90°. One side of the triangle should be in parallel to our RSTL. The

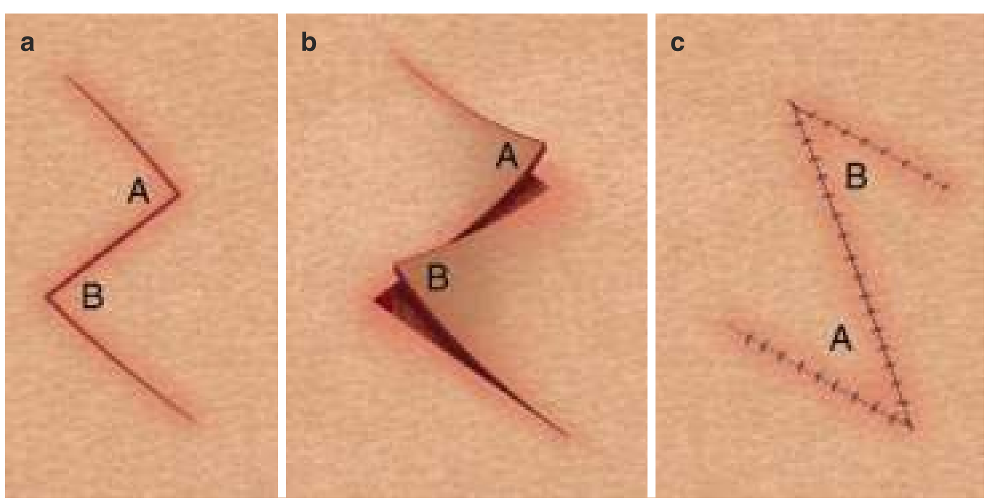

Fig. 36.3 Z plasty (**a**) scar revision. (**b**) triangular flaps raised. (**c**) interposition of triangular flaps

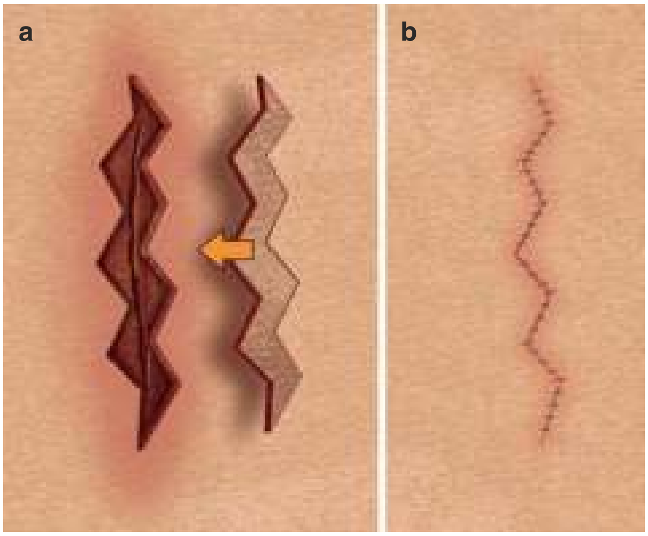

Fig. 36.4 W plasty— (**a**) scar revision. (**b**) post-operative

triangle are excised, undermined and closed with interdigitation. This technique is very useful in correcting unsightly hairline scars such as revision of face lift.

3. *Geometric broken line closure (GBLC)*

This is another technique to minimise the perception of a long scar. Here, random geometric designs are planned with corresponding mirror images. The length of the limbs should be 3–6 mm and at the angle near to 90°, and a W plasty could be done at the end of the design.

4. *V-Y and Y-V advancement*

V-Y scar correction (Fig. 36.5a–c) is utilised when there is an indication on scar lengthening in contracted scars with 'trap door deformity'. In contrast, Y-V technique is utilised where the scar is shortened, removing the 'Y 'extension (Fig. 36.6a–c).

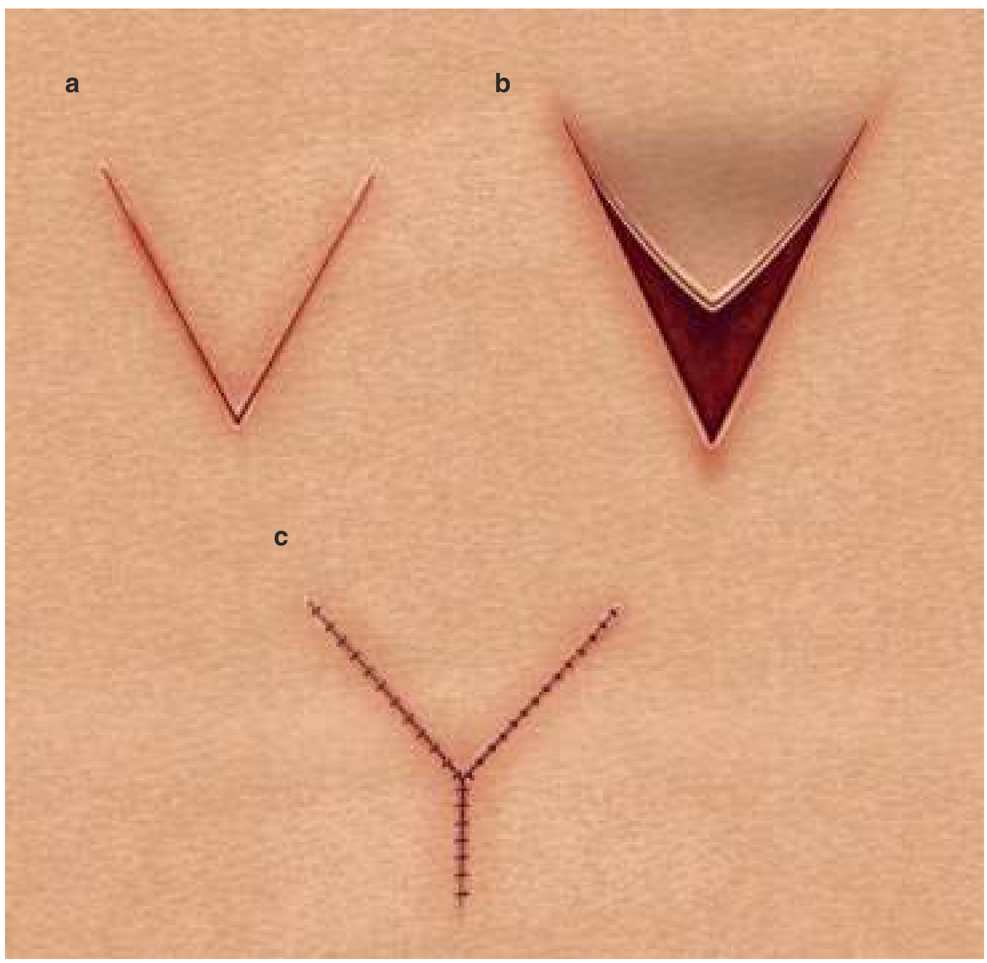

Fig. 36.5 V-Y scar lengthening correction. (**a**) V incision. (**b**) Triangular flaps raised. (**c**) Y closure

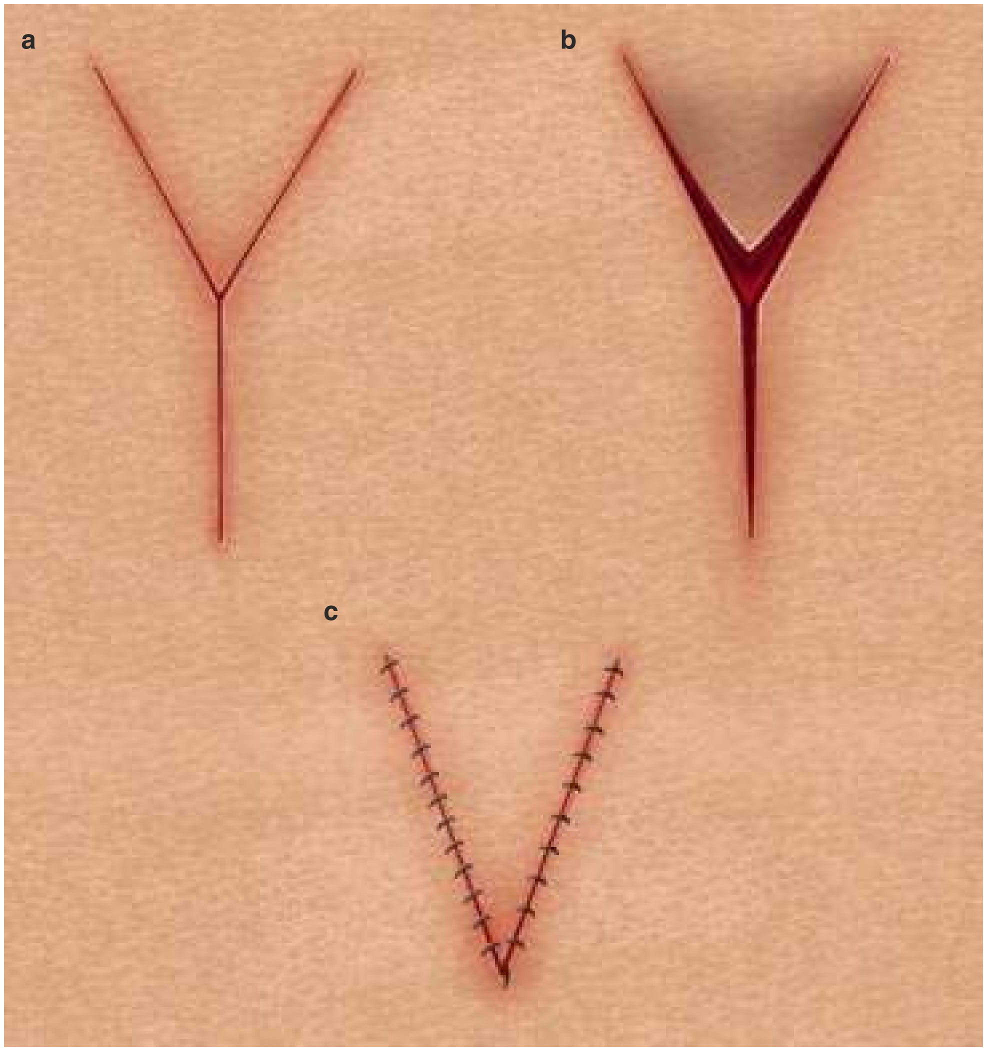

Fig. 36.6 Y-V scar shortening correction. (**a**) Y incision. (**b**) Triangular flaps raised. (**c**) V closure

Flaps can be used to revise large scars. "Doggy ear" and "trap door deformities"could be improved by excising the excess. For passive scar settlement, selective bulking and simultaneous multiple 'Z' and 'W' plasties are useful adjuncts.

Clinical tip
When repairing wounds in patients who are prone to develop hypertrophic scars, deep sutures should be placed using round bodied needles. The suture removal is delayed by an extra 3–4 days. Applying steri strips after removal of the sutures adds extra support, and this should be incorporated to achieve the best result.

Prophylactic intralesional steroids in patients prone to hypertrophic scars should be considered. Obliteration of the dead space by appropriate sutures or pressure dressings with or without drains should be considered to prevent haematoma formation. If not, haematoma on its own will spoil the good work of scar revision.

36.5 Future

Extrauterine scarless surgery is not possible. Therefore, careful patient factor and scar characteristics should be studied to prevent unsightly scar formation and to correct perceptible scars.

General health and optimising comorbidities are important requirements to achieve good scars. Both non-surgical and surgical options should be available in the armamentarium to the Surgeon.

Nanofat has very positive potential in scar management. The research on gene therapy using adenovirus as a mediator to deliver dermal fibroblast is encouraging [24].

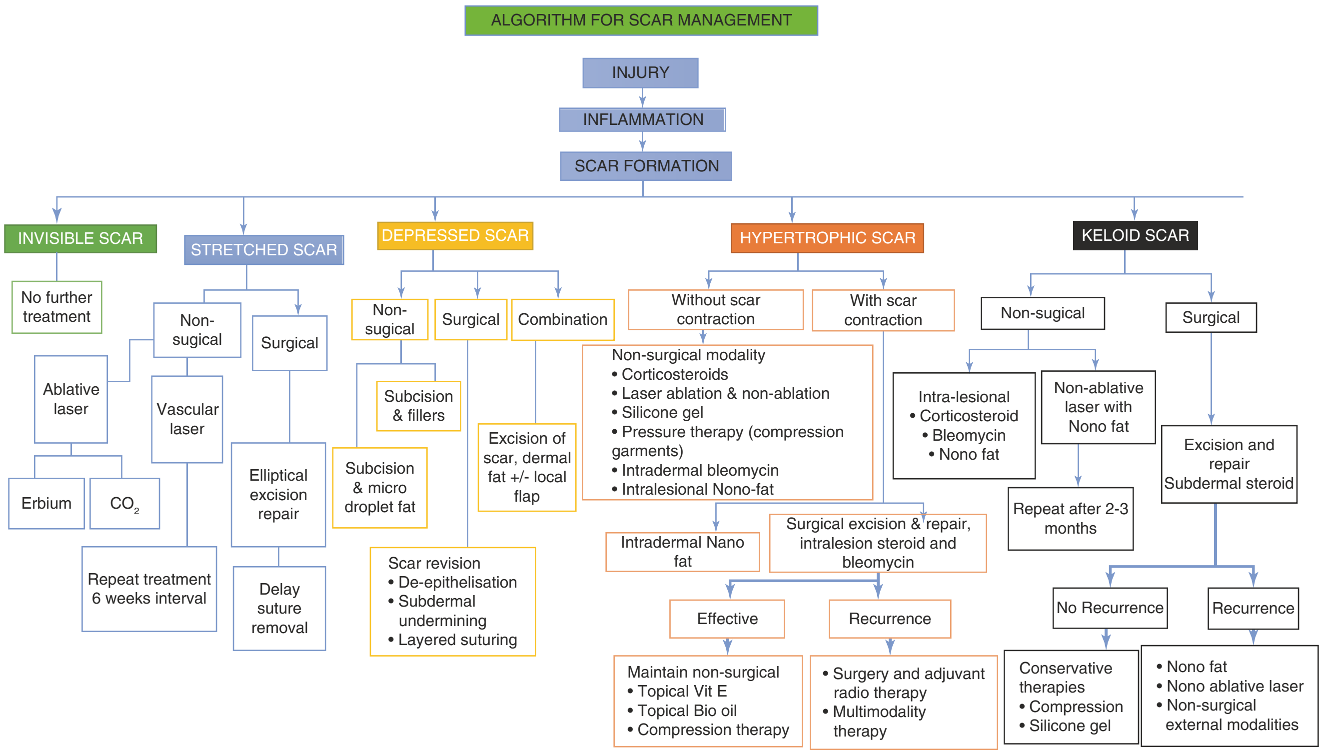

Fig. 36.7 Algorithm for scar management

Although inflammatory response is traditionally believed to be a key event for wound healing in adult skin, studies of foetal wound healing suggest that a high level of inflammation might prevent good scar formation rather than enhancing the wound healing process. Therefore, further studies are needed to confirm if really inflammation is necessary for wound healing in adult skin. However, at present, we need to follow the inflammatory process and available evidence of therapeutic modulators of scar formation.

Furthermore, it is paramount to consider that there are clinical, histological, biochemical and molecular differences between hypertrophic and keloid scars. There is marked difference in the proliferative and apoptotic cell deaths between the scars, resulting in variable response of different treatments. This should be taken into account in treatment planning process.

It is also essential to avoid excessive movements that can stretch the wound and for avoidance of the scar to direct mechanical forces such as friction and scratching and particularly earlobe wounds, to minimise the contact with pillows and wound hygiene.

Not least the patient's involvement plays a vital role in the management of scars. Variable scales in the literature exist for reliable and reproducible scar management, for both the observer, i.e. surgeon, and the patient. The observer opinion is always influenced by vascularisation, thickness and pigmentation. The patient opinion, on the other hand, is influenced by action of itching sensation and thickness of the scar. Out of the available assessment scales, the patient and observer scar management described by Draaigers L et al. is an informative tool in documentation of the progress in the management of scar, which should be addressed [25].

In summary, a surgeon should have an algorithm to follow on how to manage scars in normal patients as well as patients who are prone for hypertrophic and keloid scars (Fig. 36.7).

36.6 Conclusion

Scar formation is a part of wound healing process. Facial scars can be aesthetically detrimental and affect social stigma. As facial surgeons, we need to achieve ideal scars with natural contour, colour and limited distortion. It is paramount to remember that scar management includes prevention, treatments during the healing period and definitive management once the scar has been established. We have, in this chapter, included all the different available treatments separating them into non-surgical remedies and surgical techniques. The algorithm, in this chapter, allows a very easy review process for surgeons who manage stretched,

Fig. 36.8 (**a**) Pre-operative. (**b**) Post-“microfat grafting” and laser resurfacing

depressed, hypertrophic and keloid scars.DisclosureAuthors have no financial conflicts to disclose.

36.7 Case Scenarios

Case Scenario 1 (Fig. 36.1)

A 27-year-old female patient of Asian ethnicity had an extra ear piercing to the right earlobe. Within 4 months, she started to develop a very painful hard lump at the pierced site. Within the following 6 weeks, it developed into an irregular mass involving the whole of the earlobe.

Her medical history was unremarkable, and she was not on any medication.

On examination (Fig. 36.1a), there was an unsightly thick lumpy scar along the right earlobe. A diagnosis of keloid was made.

Under a local anaesthetic, the keloid scar was excised and the earlobe was reconstructed. The next post-operative day she underwent single dose of radiotherapy (10 Gy) as an outpatient.

On review, 6 months post-treatment (Fig. 36.1b), she had no recurrence and on palpation, the skin was soft and non-tender.

Case Scenario 2 (Fig. 36.8)

A 48-year-old Caucasian patient who had a considerable amount of sun exposure presented with an unhappy peri-oral aesthetics (Fig. 36.8a).

Her medical history was unremarkable, and she was not on any medication.

In one examination, she had loss of volume along the peri-oral site mainly along the upper lip. The vermillion border had lost its definition. She had multiple small vertical subdermal lines, which were crossing the vermillion border. She also had epidermal thinning.

A diagnosis of aging of the peri-oral area, particularly upper lip, was made. She, in fact, had epidermal thinning, subdermal scaring and loss of inter- and intramuscular fat.

She underwent “microfat” grafting to restore the volume, subdermal “emulsified fat” to restore the subdermal structure and an “erbium laser resurfacing” (fluence 500 mJ, mode: SP, spot 3 mm, frequency 20 Hz).

The post-operative appearance 4 months later (Fig. 36.8b) showed excellent volume restoration, much improvement in the subdermal scaring, better vermillion definition and a new regenerative skin.

This combination technique is very useful in burn scar management.

37 Surgical Facelift

Velupillai Ilankovan and Tian Ee Seah

37.1 Introduction

An ancient Chinese proverb "岁月不饶人" observed that "no one is spared from the ravages of ageing". A combination of age, gravity, physiologic contraction of facial muscles and solar (sun) and chemical (smoking) insults results in intrinsic and extrinsic changes to the skeleton, muscles and skin [1]. Preservation of one's youthful looks has been a goal of humans regardless of cultures and ethnicities. The search for this elixir of youth was found unexpectedly in the hands of cosmetic surgeons. Even with the recent advent of skin peels, botulinum toxin injections, lasers and injectable filler injections, the century-old facelift still possesses the most dramatic improvement to the moderate to severe ageing lower face when done well.

Facelift or rhytidectomy as its name suggests is a procedure to partially eliminate folds, creases and wrinkles (rhytids) caused by gravity and degeneration. In effect, the creation of two large cervicofacial flaps, which, after suspension and trimming, produces an overall tightening of the skin and the fascial envelope of the face and neck, results in restored anatomical structure. Facelift can help to negate some of these gravitational problems and produce some intrinsic improvement.

37.2 Historical Perspective

Historically, rhytidectomy was limited to skin elliptical excisions and tightening. The German surgeon, Eugen Höllander, first described being persuaded by his patient to remove excessive skin in the temporal, preauricular and postauricular regions in 1901. With cosmetic surgery frowned upon in those times, he did not report his surgery immediately but only recounted retrospectively that the iatrogenic wounds when approximated resulted in some tightening in 1912 [2]. The initial reports of rhytidectomy were dominated by a slew of American surgeons such as Cantrell (1902), Miller (1907) and German surgeons, Lexer (1906) and Joseph (1912) [3]. The French surgeon Passot wrote an important paper "La chirugie esthétique des rides du visage" in 1919 where he illustrated strategically placed forehead, malar, cheek and submental elliptical incisions to tighten the face for aesthetic purposes, thus heralding the concept of short scar rhytidectomy (Fig. 37.1).

Fig. 37.1 Illustration showing Passot's principles on facelift through elliptical excisions

However, with limited undermining, wounds were closed under tension, resulting in unsightly scarring. To circumvent this problem, skin flap only procedures during which only the skin was raised, undermined for a short distance and tightened were introduced (Bames 1927) [4].

The results of skin flap only facelift were short term with limited correction of the ageing face, forcing surgeons to search for better alternatives. In 1974, Tord Skoog, a Swedish surgeon, revolutionized facelift concepts by describing the dissection, elevation and tightening of the superficial fascia of the face in addition to removing excess skin. He expounded the importance of retro-positioning the "buccal fascia" and the platysma for better results. The importance of this technique was later cemented when the superficial fascia of the face was clarified as the "superficial muscular aponeurotic system" (SMAS) by Mitz and Peyronie in a landmark paper in 1976 [5]. Manipulation of the SMAS layer in a superior or supero-lateral vector became an important part of modern facelift. Soon, a flurry of papers on the modifications to facelift procedures concentrated on the management of the SMAS.

Treatment of the SMAS layer could be broadly categorized into three methods. They were plication, elevation, imbrication and SMASectomy [6]. The most conservative of these methods was plication of the SMAS layer, as it did not actually involve dissecting the SMAS layer but instead used sutures to fold the SMAS and achieve a tightening effect [7]. More aggressive management of the SMAS included imbrication, which involved the elevation and repositioning of the SMAS in a superior or superolateral vector [8]. In standard SMAS elevation, the SMAS was dissected, lifted off the parotid fascia and secured to the underlying zygomatic soft tissues or the deep temporal fascia (Fig. 37.2).

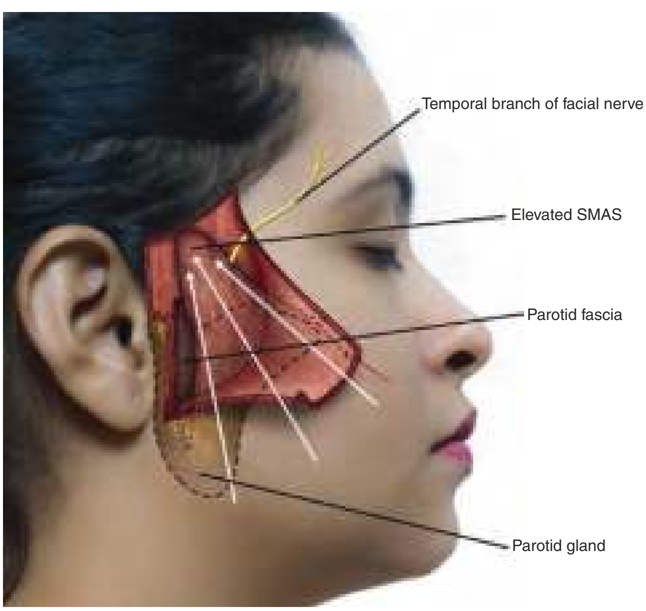

Fig. 37.2 SMAS imbrication

Fig. 37.3 SMASectomy. 1–2 cm of the SMAS is excised superficial to the anterior border of the parotid

SMASectomy was later described [9]. This required excision of approximately 1–2 cm strip of the SMAS, superficial to the underlying parotid fascia, and then tightening were carried out by suturing the opposing two cut SMAS margins [6] (Fig. 37.3).

It soon became obvious to the surgeons that skin excision and SMAS manipulation were only effective in treating the lower face but not as effective in treating midface ageing. In particular, the nasolabial fold proved to be a stubborn adversary. The spotlight turned towards the high density, retaining ligaments such as the zygomatic retaining ligaments, which prevent effective rejuvenation of the midface using the aforementioned procedures.

The deep plane facelift was described by Hamra to include the malar fat pad [10]. In this, the dissection and elevation of the SMAS layer were carried out further to release the zygomatic retaining ligaments so that more traction could be obtained from the midface. The orbicularis oculi and later septal reset were included to improve midface aesthetics, and the term composite facelift was coined by Hamra [11].

As the facelift landscape progressed, efforts turned almost full circle towards smaller incisions. Comparisons of different published facelifts were unable to reveal an optimal technique [12] although complications were significant higher in extensive SMAS procedures.

Attention turned towards having minimal excision, limited dissection and SMASectomy with imbrication, and in 2001, Saylon and later Fulton et al. described the S-lift [13]. In this technique, the preauricular skin was excised in a predetermined S-shape followed by purse-string plication of the mobile SMAS using a U-shaped purse string suture and an O-shaped purse string suture. Both sutures were anchored into the periosteum of the zygoma.

Tonard et al. later introduced the minimal access cranial suspension (MACS) as a modification to the S-lift [14] (Fig. 37.4).

In this procedure, he described suspending the sagging SMAS tissues with cranially directed purse string sutures via limited incisions that extend from the sideburn to the inferior helical attachment. Four main differences lie between the "S" lift and the 'MACS' lift. First, the S-Lift pre-empted the amount of excess skin and excised it via an S-shaped incision. The MAC lift redraped the excessive skin and removed it according to the margin. The second difference lies between point of anchorage as the 'S-lift' anchored to the periosteum of the zygoma, while the 'MACS lift' anchors to the superficial layer of the deep temporal fascia. Third, during the S-lift, SMASectomy and imbrication were carried out, while during the MACS lift, only plication was performed. Fourth, besides the two O and U-shaped sutures, the MACS lift utilizes a third vertical suspension suture that suspended the malar fat pad, thus reducing the depth of the nasolabial fold. This area is accessed by extending the temporal hairline incision, and Tonard and Verpaele called this the extended MACS lift.

Fig. 37.4 MACS Lift

37.3 Anatomy of Ageing Face

Some of the gravitational changes include lateral brow ptosis, tear trough, malar palpebral groove, SOOF descent, malar fat descent, deepening of the nasolabial groove, buccal fat pad herniation, marionette lines, jowls, loss of neck definition, submental fat and excess skin [1].

With ageing, a combination of gravitational forces, laxity of the skin due to loss of elasticity, decreased dermal thickness and loss of dermal appendages results in ptotic, hanging skin.

The mid cheek's fat is divided into three compartments [15] (Fig. 37.5). It is thinnest at the lid-cheek segment and is thickest in the nasolabial region. The malar fat is also moderately thick although not as thick as the nasolabial region.

Accumulation of fat in the cervical region results in loss of neck definition and submental fat.

Superficial fat and deep fat are separated by SMAS layer. The superficial fat is separated into five compartments, namely, the nasolabial, medial cheek, middle cheek,

Fig. 37.5 Cheek fat is divided into three compartments. They are lid-cheek segment (Orange), Malar segment (red) and nasolabial region (yellow). (Figure adapted and redrawn from Aesthetic Plastic Surgery 2009, Chapter 6 by Mendelson BC)

lateral temporoparietal and inferior orbital fat. Deep fat is divided into the deep medial fat and suborbicularis oculi fat (SOOF) [16].

The superficial musculoaponeurotic system (SMAS) is a fibrous sheath, which was described in a classical paper by Mitz and Peyronie [5] in 1976, and starts from the galea superiorly. Superolaterally, it is continuous with the superficial temporal fascia also known as the temporoparietal fascia. In the central upper face, deep into the superficial fat, the SMAS layer is invested by the muscles of facial expression, derived from the embryonic second branchial arch: frontalis, orbicularis oculi, corrugator supercilii, depressor supercilii and the procerus. In the middle third, the SMAS is invested by the nasalis muscles, zygomaticus major, minor, levator labii superioris alaeque nasi and levator labii superioris. Laterally, the SMAS is superficial to the parotid fascia and extends inferiorly to include the platysma muscles. Inferomedial, the SMAS is invested by the orbicularis oris, risorius, depressor anguli oris, depressor labii inferioris and mentalis and is continuous with the platysma.

With the exception of the levator anguli oris and mentalis, the facial nerve travels deep into the SMAS layer and innervates the muscles of facial expression, making dissection above the SMAS during facelift safe [16].

An analogy of the retaining ligaments is that they are rooted in a tree into the periosteum and deep fascial thickening, and as it approaches the SMAS, it divides into numerous branches and inserts into the dermis called retinacular cutis [15] (Fig. 37.6).

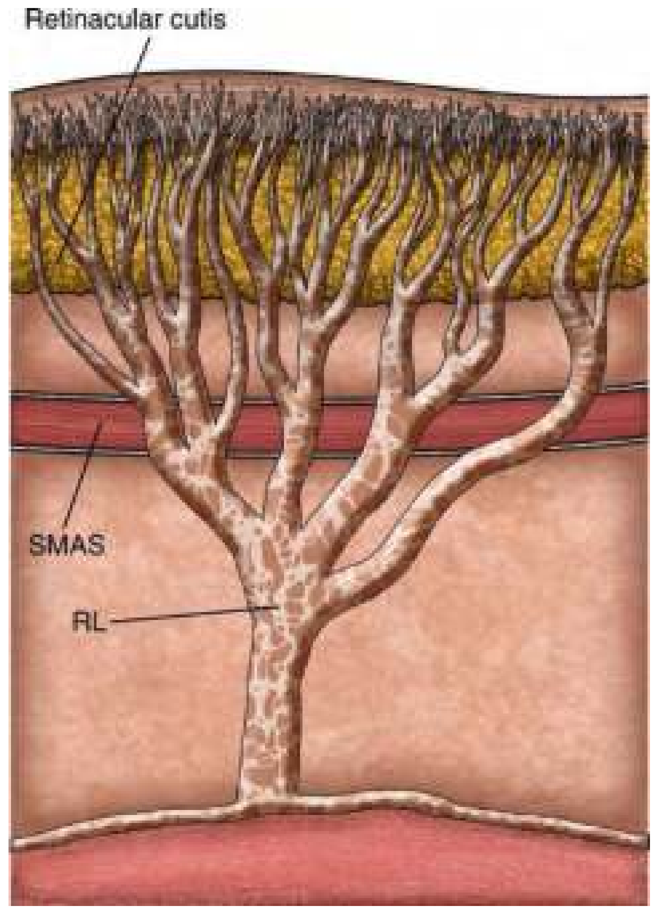

Fig. 37.6 Retaining ligaments (RLs) insert into the subcutaneous layer as retinacular cutis. It is likened to a tree by Mendelson BC [15]. (Figure adapted and redrawn from Aesthetic Plastic Surgery 2009, Chapter 6 by Mendelson BC)

Stuzin [17] and Furnas et al. [18] described the retaining ligaments [17]. The partitioning of separate fascial spaces and compartments is caused by these retaining ligaments, which are classified into osteocutaneous and fasciocutaneous retaining ligaments.

Osteocutaneous retaining ligaments originate from the periosteum and include the zygomatic and mandibular cutaneous ligaments. Stout zygomatic retaining ligaments originate from the inferior border of the zygomatic arch towards the junction between the arch and the body and insert into the dermis of the skin as fibrous septa. It is posterior to the zygomaticus major muscle, approximately 3 mm in width, 0.5 mm in thickness and 4.5 cm anterior to the tragus [18]. Loss of support results in malar fat descent.

The mandibular ligament originates from the periosteum 10 mm above the mandibular border, extends along the anterior one third of the mandibular body and inserts into the dermis [19] (Fig. 37.7). It coincides with the anterior margin of the jowl.

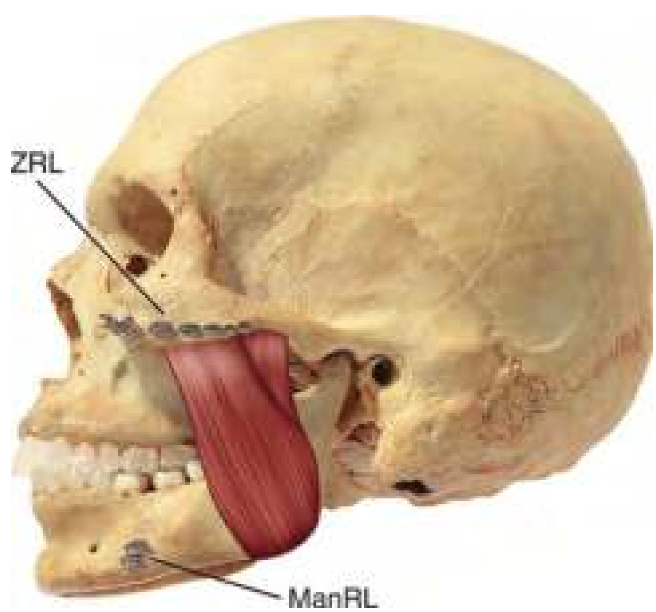

Fig. 37.7 Osteocutaneous ligaments comprising the zygomatic retaining ligaments (ZRLs) and the mandibular retaining ligaments (MRLs)

Fasciocutaneous retaining ligaments include the masseteric and parotid cutaneous ligaments also known as the platysma auricular ligament ~~and~~ coalesce between the superficial and deep fascia of the face [1].

Masseteric ligaments originate from the parotidomasseteric cutaneous ligaments, and. loss of support results in

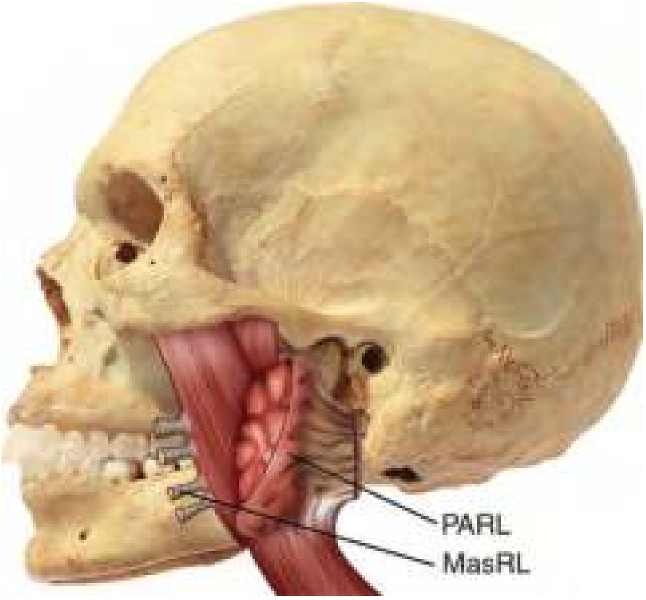

Fig. 37.8 Fasciocutaneous retaining ligaments comprising the masseteric retaining ligaments (MasRLs) and the parotid cutaneous ligaments also known as platysma auricular retaining ligaments (PARLs)

facial jowling. Parotid cutaneous ligaments are formed by the posterior border of the platysma, which had receded into fascial condensation. It is fused with the parotid fascia, is attached to the overlying skin and provides firm anchorage between the platysma and the dermis in the inferior auricular region (Fig. 37.8).

37.4 Standard Facelift

Surgery can be carried out either under general anaesthesia or under local anaesthetic with or without sedation.

Local anaesthesia comprising Lidocaine 2% with adrenaline 1:80,000 is infiltrated in the zygomaticofacial region, infraorbital, mental, greater auricular (Fig. 37.9) and the lesser occipital nerves.

Tumescent solution reconstituted with 1 L of saline, 50 mL of 1% lidocaine, 1 mL of adrenaline 1:1000 and 6 mL of 8.4% Sodium Bicarbonate is then injected subcutaneously after stab incisions are placed in the temporal, preauricular, postauricular and submental regions. Approximately 300 mL of tumescent solution in all is injected.

In both approaches, infiltration of Tumescent solution in a subcutaneous plane is essential to carry out atraumatic dissection. In our practice, 95% of standard facelift are carried out with simultaneous neck lift, as we feel it would be impossible to mobilize the attenuated soft tissue to achieve symmetry and an unoperated look of the midface without bringing attention to the neck aesthetics.

Fig. 37.9 Greater auricular nerve block

37.4.1 Incision

The incision lines are divided into four sections: temporal, preauricular, postauricular and scalp extension. The temporal component is either into the hairline or just at the hairline/sideburn border. The latter has the advantage of not moving the sideburn position; however, it would give a telltale sign of a visible scar. In the former approach, the sideburn area may get lifted into the temporal area and the scar will be hidden. This position should be made in conjunction with discussion with the patient, and suitability of the incision should be selected.

The preauricular marking could be a pre-tragal, intra-tragal or post-tragal. The latter can distort the tragal projection, and the pre-tragal will give a visible scar. We prefer an intra-tragal approach and obtain the tragal projection by placing a subcutaneous anchor suture before the final closure in order to maintain the natural concavity and simultaneously achieve an invisible scar (Figs. 37.10 and 37.11).

The postauricular incision should be a few millimetres into the postauricular area from the sulcus so that postoperatively the scar will settle down comfortably into the sulcus. The scalp extension is carried out by multiple W or Z plasty type incisions in a trichophytic fashion to minimize hair loss and to have an invisible scar (Fig. 37.12).

A 2.5 cm curvilinear incision parallel to the mandibular contour is the submental incision to the neck lift section in order to expose the anterior border of the platysma and the platysmal dissection.

37.4.2 Dissection

The submental flap dissection is carried out at first to expose the platysma muscle as much as possible (Fig. 37.13).

Fig. 37.10 Temporal to preauricular incision (red). Occipital or scalp extension (broken line)

Fig. 37.11 Hairline to tragal incision (red). Occipital or scalp extension (broken line)

Fig. 37.12 Illustration showing the postauricular and occipital or scalp extension

Fig. 37.13 Dissection is in the supraplatysma plane

Next, the scalp and postauricular dissection is carried out. The anterior border of the sternocleidomastoid muscle and posterior border of the platysma are exposed, and a cavity of the neck is connected anteriorly and posteriorly (Fig. 37.14). The next step is to focus on the temporal and preauricular dissection. In the temporal, the deep part of deep temporal fascia is exposed, which we use as an anchor point to the SMAS suturing (Fig. 37.15). The preauricular dissection will expose the zygomatic ligaments, lateral end of the orbicularis oculi and the anterior border of the parotid–masseteric fascia with careful attention towards the buccal branch of the facial nerve (Fig. 37.16).

The preauricular, neck and postauricular dissection should now be in one cavity.

Fig. 37.14 The postauricular flap is then connected to the cervical flap and the submental region made previously

Fig. 37.15 Deep layer of the deep temporal fascia exposed

Fig. 37.16 After the deep temporal fascia is exposed, dissection is carried out in a different plane subcutaneously to raise a skin flap

37.4.3 SMAS and Platysmal Elevation and Plication

SMAS elevation and management are carried out in various forms. We elevate the SMAS in an inverted L fashion (Fig. 37.17) starting at the preauricular plane, and the superior limit is at the lateral end of the zygomatic arch. The anterior dissection passes to the parotid-masseteric fascia (Fig. 37.18). The inferior dissection is to join the subplatys-

Fig. 37.17 An inverted L shape incision (blue lines) is made on the SMAS stopping short of the parotid fascia. The shorter limb is just below the zygomatic arch, while the longer limb is in the preauricular region

Fig. 37.18 Cut SMAS peeled anteriorly to show underlying parotid. Facial nerve exits the parotid deep into the SMAS. Deep into these are the masseter muscles followed by the buccinator muscles with horizontal muscle striations

mal plane at the angle of the jaw with consideration to avoid damage to the two or three cervical branches. In our practice, the elevated SMAS is anchored in a superior direction to the deep part of the deep temporal fascia (Fig. 37.19).

Our platysma dissection and plication are in four steps. The anterior border of the platysma is sutured in the midline [20] (Fig. 37.20). In some patients with short neck, the platysmal suturing needs to be hitched to the body of the hyloid bone. In some patients, a release of the inferior border of the platysma muscle at this area could also be considered. Then,

Fig. 37.19 The cut SMAS is then advanced superiorly and sutured to the deep temporal fascia with 3/0 Polygluconate (Maxon, Tyco Health UK Ltd., Gosport PO130AS, UK) (blue line)

Fig. 37.20 The medial edges of the platysma are sutured to each other at the midline in a corset manner

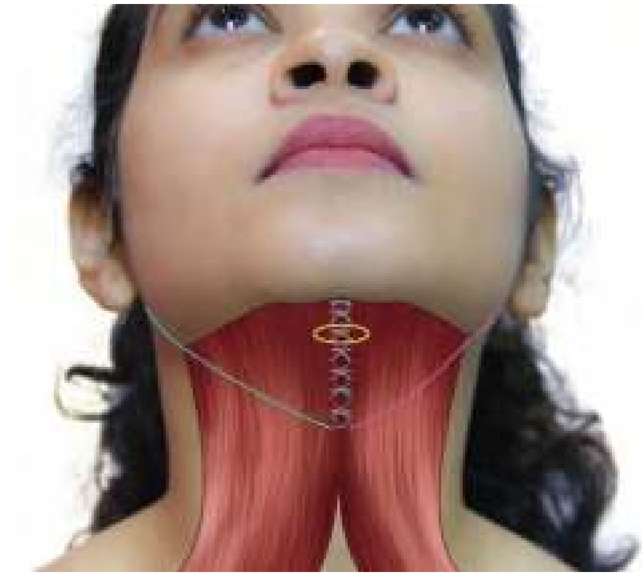

Fig. 37.21 A submental incision is made (white outline). Corset sutures are done twice, and the suture is plicated to the mastoid fascia on both sides

the lateral border of the platysma muscle is sutured to the anterior border of the sternocleidomastoid muscle. The third step is in platysmal plication is placing a cinch suture, which is placed joining the two anterior borders of the muscles in the midline and, after catching the platysma muscle in two or three areas, hitched the sternocleidomastoid muscle and the final anchor into the mastoid periosteum (Fig. 37.21). Depending on the neck anatomy, we sometimes place a second cinch suture about 5–6 mm below the first to avoid bulging of the submandibular gland.

37.4.4 Closure

Meticulous haemostasis is done with bipolar electrocautery throughout the procedure. The cervicofacial flaps are draped over the margins in a superolateral vector with much emphasis on the superior than the lateral direction (Fig. 37.22). Final anchoring is done with two key sutures that are placed along the helical attachment and the superior aspect of the postauricular incision. Cuts are made on the excess skin, perpendicular to the flap margin, stopping just short of it (Fig. 37.23). This allows the margins to be visualized when trimming the excess skin. If a tragal incision was made, the skin can be thinned and trimmed to mimic tragal shape and skin during closure at the tragus. Dog ears are preferably removed at the apex rather than in the ear lobe region. The ear lobe is then replaced 15° posterior to the vertical position to reduce the telltale signs of facelift procedures. Layered repaired is then carried out in the final closure.

Fig. 37.22 Excess skin is draped in a superolateral vector over the margins and excised

Fig. 37.23 Cuts are made perpendicular to the flap margin stopping short of the margins and then excised accordingly

37.4.5 Support Dressings

There are different ways of providing this final exercise. We apply antibiotic topical ointment followed by non-sticky dressing to the pre- and postauricular area and an adjustable Velcro band. In the literature, however, various pressure dressings are applied.

37.5 Post-operative Management

Velcro bands are removed on a daily fashion. Wounds are cleaned followed by topical ointment and reapplication of the Velcro band.

The medications are taken on a prescribed fashion.

The patient is placed on antibiotics and painkillers for a week. Sleeping is done with the head elevated by 2–3 pillows. The patient is seen on the day after the surgery to ensure that there is no haematoma. If drains are placed, they are removed during this time.

Facial bandages are placed between 2 and 5 days. Sutures are removed 7–10 days later. The wounds are kept moist with antibiotic ointment such as Tetracycline 3% or Mupirocin ointment 2% (Figs. 37.24a, b and 37.25a, b).

37.6 Complications and Management

Post-operative complications of facelifts include post-operative haematoma, skin necrosis, sensory and motor disturbances, obvious scarring, seroma, alopecia, auricular deformity and dyspigmentation [21]. Detailed informed consent should be obtained from patients prior to the surgery.

37.6.1 Haematoma

A thorough medical history is needed prior to surgery. Antiplatelet medications such as Aspirin, Clopidogrel, Dipyridamole and powerful anticoagulation drugs such as warfarin will have to be stopped after consultation with the patient's prescribing physicians. Patients on herbal or traditional Chinese medications such as ginkgo biloba and Cordyceps will also need to be stopped before surgery.

Haematoma formation is by far the most common complication with some papers reporting up to 15% [21]. Expanding haematoma usually happens in the first 24 hours and must be evacuated. Smaller haematoma can be aspirated, and pressure bandage is placed for pressure haemostasis. Meticulous haemostasis with bipolar diathermy is mandatory for facelift procedures. The flap and the underlying bed should be scrutinized for bleeding spots with a good head light or fibre optic light attached to a retractor. Brisk bleeding from larger vessels should be ligated. Adjunctive measures including fibrin glue [22, 23] and platelet gel and facelift bandages have been explored.

Large haematoma are a cause for concern and need to be evacuated. They can cause problems in healing including skin ischaemia.

Fig. 37.24 (**a**) Pre-operative profile view showing excess loose skin, jowling, submental fat and deep nasolabial fold. (**b**) Post-operative profile view after facelift and platysma plication. Excessive skin had been resected, jowls had been corrected and there was improved cervicomental definition

37.6.2 Skin Ischaemia and Necrosis

Ischaemic changes and flap necrosis can occur due to circulatory disturbances. This can happen when the flap is too thin or had underwent extensive undermining and exuberant cautery, closed under excessive tension or compromised by excessively tight bandage compression. The incidence ranges between 1.1 and 3% [24]. Venous congestion or arterial obstruction can result in skin ischaemia and necrosis. Large unevacuated haematoma separates the flap off the underlying bed during which perfusion is only by the vessels supplying the flap. This causes the areas furthest away from the perfusing vessels to be at risk of ischaemia.

Necrosis of the skin is more common in the postauricular than the preauricular region.

Application of nitroglycerin paste may help to encourage vasodilation when done in the early stages [25]. Conservative treatment to allow healing via secondary intention followed by laser, excision of the scar with repair via rotation flaps can be carried out at a later stage.

Fig. 37.25 (a) Pre-operative profile view showing excess skin, slight jowling, submental fat and severe loss of neck definition. (**b**) Post-operative profile view after facelift and platysma plication

37.6.3 Obvious Scarring

Scarring can occur when the wounds are closed under excessive tension or if the incisions are placed at an inappropriate position due to poor design. Skin slough and necrosis of the flap can lead to severe scarring. Patients who are more prone to hypertrophic scarring or keloids should be warned. Wound tension can develop and cause scarring if there is excessive removal of skin or if undermining of the flap is inadequate.

Treatment of scarring includes conservative treatment with antibiotic ointment such as Tetracycline cream 3% or Bactroban cream. This is followed by steroid injections such as triamcinolone acetate, application of silicone sheet or gel dressing. As the scar improves and stabilizes, it can be lasered, excised and revised.

37.6.4 Sensory Disturbances

Sensory disturbances occur invariably due to the dissection and separation of the facial planes during the facelift procedure, but this usually occurs temporarily and resolves in 1 year.

The most common sensory disturbance occurs to the great auricular nerve. The greater auricular nerve crosses the sternocleidomastoid muscle at approximately 6.5 cm inferior to the external auditory meatus and travels superiorly to supply the postauricular region.

Injury to this nerve can be temporary or permanent due to dissection over the postauricular, mastoid region and to a lesser extent in the cervical region. This results in numbness of the ear lobe and postauricular area.

Other forms of numbness can be found in preauricular region.

37.6.5 Motor Nerve Disturbances

Keeping away from the planes that the facial nerve travels in is the safest method to avoid motor nerve problems. The facial nerve branches course through the parotid gland and exits the parotid gland to travel deep to the SMAS layer before innervating the muscles of facial expression. Care should be taken when dissecting beyond the parotid or when dissecting deep into the SMAS layer.

Facial nerve injury ranges from 0.4 to 2.6% [21]. The most common motor nerve damage is the marginal mandibular nerve followed by the temporal nerve and then the buccal branch. Neuropraxia from exuberant retraction, cautery heat and compression can result in temporary or permanent loss of the motor function. The marginal mandibular branch courses in the superficial layer of the deep cervical fascia, deep into the platysmal layer, and may be damaged when dissecting in this region. The temporal branch of the facial nerve courses just deep to the superficial temporal fascia and travels 0.5 cm anterior to the tragus and then obliquely to 1.5 cm above the lateral edge of the eyebrows.

37.6.6 Ear Lobe Irregularities

"Pixie or elf-like" ear is a stigma of facelift. The ear lobe should be repositioned in a tensionless fashion, and the ear lobe should be placed 15° posterior to the vertical axis of the pinna [6]. Over resection of the flap at the base of the auricle as well as failure to place subcutaneous stay sutures on the facial flap at the ear base can result in the ear being pulled inferiorly.

Pixie ears can be revised by releasing the base of the auricle and creating a new ear lobe.

37.7 Conclusion

The facelift remains the single most powerful method in facial rejuvenation for the moderate to advanced ageing face. It has developed from small elliptical incisions and closure to full facelift with simultaneous neck lift. A variety of techniques have been described contributing to its evolution including SMAS layer management, standard facelifts, composite facelifts, platysmal plication and smaller flaps such as the MACS lift and S-lifts. The standard face and simultaneous neck lift can treat most of the problems of the mid and lower face as well as the neck. An intimate understanding of the anatomy of the face, appropriate choice of the facelift design and meticulous execution are paramount in giving the patient an ideal outcome while avoiding the possible complications.

Disclosure Authors have no financial conflicts to disclose.

37.8 Case Scenarios

Case Scenario 1 (Fig. 37.26)

A 67-year-old Caucasian lady presented with unhappy aesthetics of her face. She had had a considerable amount of sun exposure over the years. Her medical history was unremarkable.

Clinical features:

On examination she had multiple minor and major wrinkles on her face. On examination of the mid face, she showed descending SOOF and malar fat pads. She had prominent folding of the nasolabial fold and loss of mandibular border definition. Her neck was a good shape for her age (Fig. 37.26a, b).

Treatment:

She underwent a standard facelift without a neck lift and simultaneous autologous fat augmentation malar, chin and perioral areas.

Post-operative findings:

The post-operative profile shows aesthetically pleasing contour with an unoperated look (Fig. 37.26c, d). A majority of ageing changes have been removed. She ideally should undergo perioral laser resurfacing to improve the skin quality.

Case Scenario 2 (Fig. 37.27)

A 73-old lady presented with ageing changes and was unhappy with the mid and lower face. She was concerned about the aesthetics of her neck (Fig. 37.27a, b).

She is an insulin-dependent diabetic and takes medication for hypertension.

Clinical features:

On examination, the mid face showed malar fat descent with prominent nasolabial fold. She had marked marionette lines, pre-jowl sulcus and prominent jowls. Examination of the lower face showed platysmal bands and loss of mandibular neck definition with submental fat projection.

Treatment:

She underwent a standard face and neck lift with platysmal and SMAS plication.

Post-operative findings:

Three month post-operative photograph shows correction for the ageing changes and a pleasing facial and neck profile (Fig. 37.27c, d).

Rhinoplasty

38

Nasir A. Nasser

38.1 Introduction

The nose occupies the centre of the face and receives enormous attention as a key aesthetic element. It is also an important organ contributing to vital functions of breathing and olfaction. A nose with ideal proportions creates a harmonious balance of aesthetic and psychological wellness. Whilst a rhinoplasty can significantly improve the quality of life of patients, there may be associated complications and undesirable outcomes. It is imperative that the surgeon desiring to practise the art and science of rhinoplasty should be familiar with the essential basics before embarking on this journey.

The aim of this chapter is to provide a clinical overview of the spectrum of rhinoplasty in an easily comprehensible manner. The primary section is focussed on the key elements of anatomy, diagnosis and documentation prior to any surgical procedure on the nose. Basic operative techniques including approaches, septoplasty, osteotomies and grafts are described in the next section. The management of most common nasal deformities is covered in the last section.

38.2 Surgical Anatomy of the Nose

The nose is a complex anatomic unit composed of skin, subcutaneous tissue and fibro-fatty tissue draped over a complex osteocartilaginous framework [1]. Understanding its overall morphology along with other characteristics helps in accurate diagnosis and management of various deformities. Based on the framework, the nose can be divided into external nose and internal nose. The important landmarks (Figs. 38.1A, B and 38.2) related to nasal anatomy are highlighted in Box 38.1.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_38) contains supplementary material, which is available to authorized users.

38.2.1 External Nose

A. **Skin and underlying tissues**: The features of nasal skin including color, consistency and thickness can vary between patients and are important determinants of outcome of rhinoplasty. Skin thickness varies in different parts of the nose and at different stages of life. The average skin thickness is the greatest at the radix (measuring 1.25 mm) and the least at the Rhinion (0.6 mm) [2]. The supratip area has abundant sebaceous glands especially in adolescent males. Skin thickness is reduced in the columella and mid-alar area and increased in the alar base area. Both the thickness of the skin and the presence of sebaceous glands in the caudal half of the nose make it difficult to achieve an ideal result in a predictable manner.

   Beneath the skin and above the underlying osseocartilaginous framework are the layers of the superficial musculoaponeurotic system (SMAS), fibromuscular layer, deep fatty layer, and periosteum/perichondrium [3]. The SMAS of the nose is the continuation of the sheath that extends across the entire upper half of the face with adipose tissues, vertical fibres and septi, extending to the skin. Under the SMAS is a layer of thin fibrofatty tissue that divides the superficial and deep muscles of the nose [4]. The deep fatty layer separates the fibromuscular layer from the underlying nasal framework. Major blood vessels, lymphatics and nerves run within it. Deep to this layer is the periosteum of the nasal bones and the perichondrium of the cartilaginous frame. The avascular plane of dissection is in the supra perichondrial plane just below the fibrofatty SMAS layer.

B. **External Vault**

The nose is divided topographically into thirds as shown in Figs. 38.3 and 38.4.

Upper third: The nasal bones constitute the upper one third. This part of the nose is pyramidal in shape, the narrowest portion being at the intercanthal line. Nasal bones vary in length and become thinner as they extend caudally toward the Rhinion. The nasal bones are attached to the frontal bone above at the radix which forms the frontonasal angle. They articulate with the ascending process of the maxilla. Caudally, the nasal bones overlap the upper lateral cartilages [Keystone area] [5].

Middle third: This contains the paired upper lateral cartilages (ULCs) and is referred to as the cartilaginous vault. The ULCs are fixed above to the under-surface of the nasal bones and fused with the septum, and they separate from the septum as they extend inferiorly. An important surface landmark in this region is the external lateral triangle; bounded above by the upper lateral cartilages, laterally by the frontal process of the maxilla, and caudally the cephalic border of the lower lateral cartilage. The angle between the caudal border of the upper lateral cartilage and the septum is usually 10–15° and constitutes the internal nasal valve (Fig. 38.5a, b).

Lower Third: The lower third or lobule of the nose is further subdivided into the tip, supra tip and infra tip regions. These specific areas of the lobule are formed by variations in the shape, size, and angles of the lower lateral cartilages (LLCs). The form of the lobule is defined by the tip or apex of the nose. The area defining the overlap of the LLC and the caudal aspect of the ULC is called the "scroll" area and has a fibrous attachment. The size of the scroll area along with the slope of the lateral crus contributes to the bulbosity of the lobule.

The lower lateral cartilages have four essential components: the medial crus, intermediate crus, dome and the lateral crus (Fig. 38.6a, b, c): The cephalic edge of the domal segment of the intermediate crus is responsible for the aesthetic point known as the pronasale. The supra tip is immediately cephalic to the pronasale. The infra tip is located between the pronasale and the apex of the nostrils. The infra tip region should have a gentle curve that

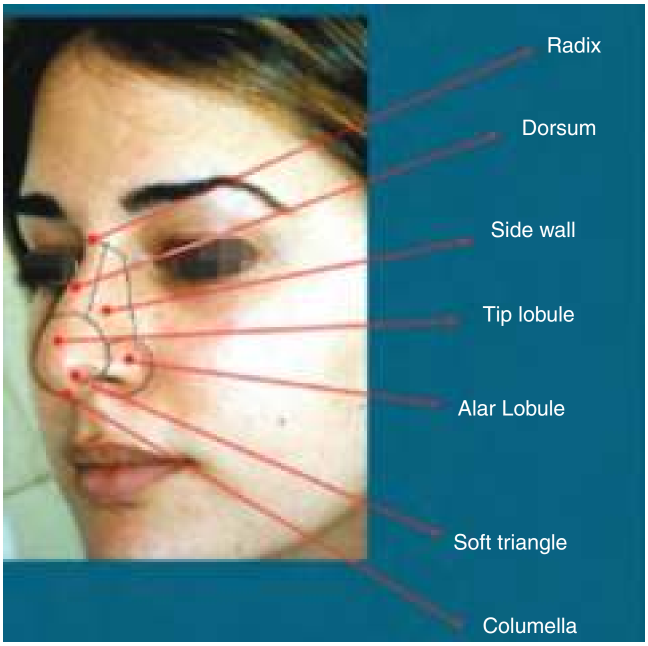

Fig. 38.2 Nasal anatomy landmarks—lateral view

Box 38.1 Rhinoplasty landmarks

Landmark	Definition
1. Nasion	Depression at the junction of the nose with the forehead Deepest point at the root of the nose
2. Radix	Area centred around the nasion.
3. Nasal pyramid	Part of the nasal frame made up of the bilateral nasal bone and frontal process of the maxilla
4. Keystone area	Junction of the perpendicular plate of the ethmoid with the septal cartilage at the dorsum of the nose
5. Rhinion	The point located at the osseocartilaginous junction over the dorsum of the nose
6. Nasal tip lobule	Caudal part of the nose bounded posteriorly by the anterior nostril edge, superiorly by the supra tip area and laterally by the alar grooves
7. Nasal tip	The most anterior point of the lobule
8. Anatomic dome	Most anterior projected portion of the lower lateral cartilages between the medial and lateral crus
9. Tip defining points (TDP)	Summit of the domes. Most projecting area on each side of the tip that produces external light reflection
10. Supratip area	Area just cephalad to the nasal tip at the caudal portion of the nasal dorsum
11. Infratip lobule	Portion of the tip between the tip defining points and apex of nostrils
12. Tip projection	Distance from the most projected portion of the tip to the most posterior point of the nasal–cheek junction
13. Alar groove	Oblique skin depression between the tip and the ala
14. Supra-alar crease	Groove immediately cephalad to the alar crease
15. Sub-nasale	Junction of columella with the lip

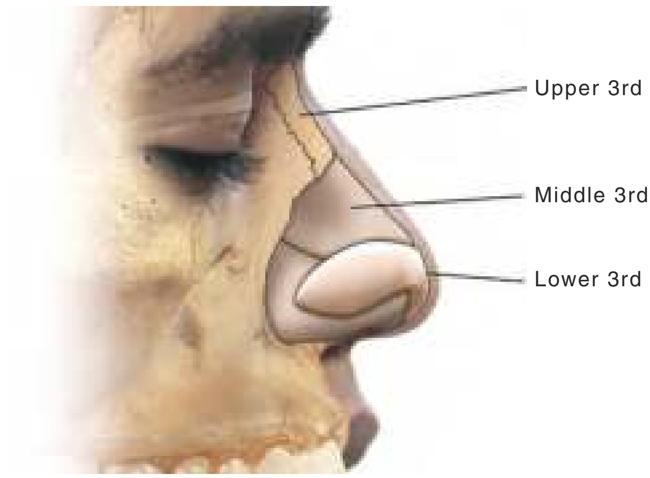

Fig. 38.3 External vault—lateral view

slightly projects inferiorly to the alar margins. The medial-lateral crura complex forms a tripod that is an essential concept to understand for correction of tip deformities. The lateral crura form the two cephalic lateral legs while the medial along with the intermediate crus form the caudal leg of the tripod (Fig. 38.7a, b, c).

Medial crus: The medial crus has two distinct segments: the footplate and the columella. The footplate varies in size and in the degree of lateral angulation, which governs the width of the columellar base.

Intermediate crus: It extends between the medial crus and the lateral crus. The length and width of the intermediate crus control the configuration of the infra-tip lobule.

Dome: The domal segment is the narrowest and thinnest portion of the lower lateral cartilage, yet is the most important in relation to the tip shape. In an ideal nose, the cephalic edges of the paradomal segments are in close approximation and the caudal portions are divergent. Whenever the cephalic margins diverge, they result in widening of the nasal tip. A wide domal angle with increased interdomal width results in a boxy tip.

Lateral Crus: It constitutes the larger component of the nasal lobule. It is narrow anteriorly, widens in the mid-portion and narrows again laterally. The anterior portion of this cartilage can curve with different angulations and controls the convexity of the ala. The lateral crus also provides support to the anterior half of the alar rim. This cartilage is usually oriented at a 45° angle to the vertical facial plane. Narrowing of the angle between the dorsum and the long axis of the lower lateral cartilage

Fig. 38.4 External vault—lateral view. Line diagram showing the three divisions

may cause dysmorphology of the tip called cephalic malposition or 'parenthesis deformity'.

Several fibrous attachments exist joining the cartilages to each other, namely, lower lateral cartilages to the upper lateral cartilage, from one lateral crus to the opposite in the supratip area (the Pitanguy ligament), dense fibrous bands between the caudal septum & the medial crura and between the medial crura themselves [6].

Muscles (Fig. 38.8): The muscles of the nose are divided by their functions into four categories; elevators, depressors, compressors, and dilators. The procerus, levator labii superioris alaeque nasi, elevates and shortens the nose. These muscles are important because they assist in opening the nasal valves. The depressor muscles consist of the nasalis and depressor septi. On contraction, this group of muscles adversely affect the tip rotation by displacing it inferiorly and elevating the lip superiorly [5]. The transverse nasalis muscle forms the compressor, while the dilator naris has the opposite function.

Blood Supply and innervation: Both external and internal carotid arteries contribute to the vasculature of the external nose (Fig. 38.9). The major blood supply is from

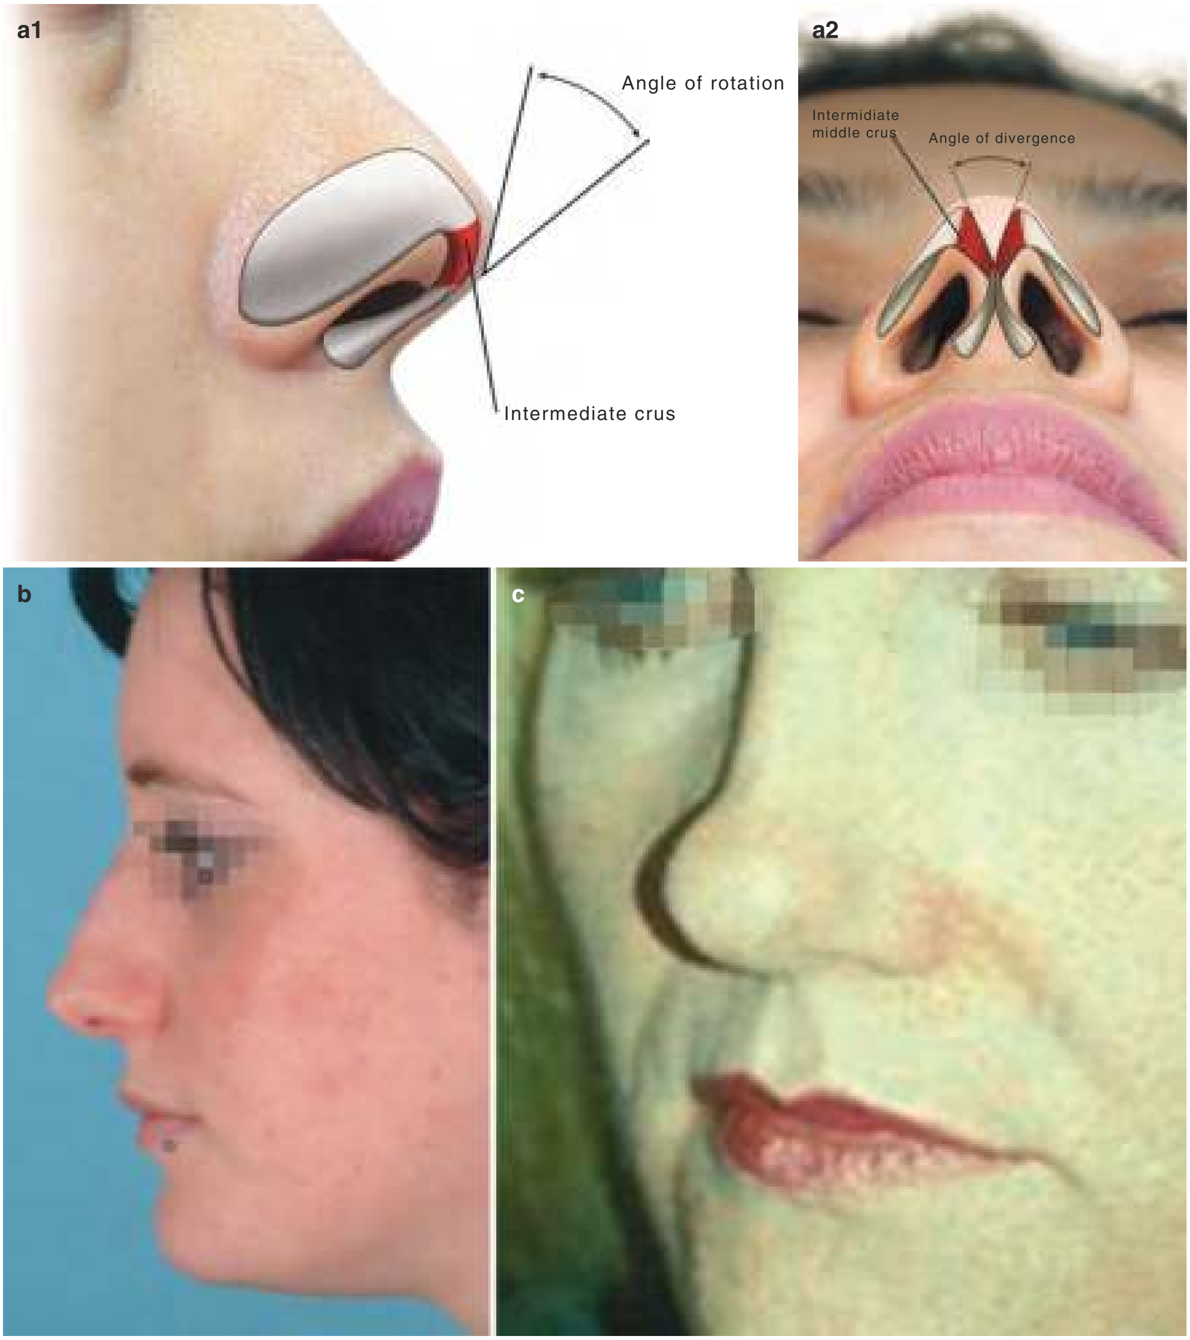

Fig. 38.6 Lower lateral cartilage (**a1**, **a2**) Diagrammatic representation and (**b**, **c**) clinical pictures

three vessels: the dorsal nasal artery—a terminal branch of the ophthalmic artery, the angular and superior labial arteries from the facial artery. The lateral nasal artery (branch of the angular artery) forms a plexus with the dorsal nasal artery, branches of infra-trochlear artery, and the external branches of the anterior ethmoidal artery. A small contribution is also received from the lateral branches of the infra-orbital artery.

Sensory innervation to the nose is provided by the maxillary and ophthalmic branches of the fifth cranial nerve [7].

38.2.2 Internal Anatomy

The internal nose is divided by the "midline" nasal septum. Anteriorly, the septum forms the medial boundary of the nasal vestibule whose lateral wall is formed by the lower lateral cartilages and their attachment to the pyriform rim.

The deeper part of the nasal cavity is bounded laterally by the medial wall of the antrum, medially by the osseocartilaginous septum, superiorly by the ethmoid and the sphenoid bones and inferiorly by the palatal process of the maxilla and

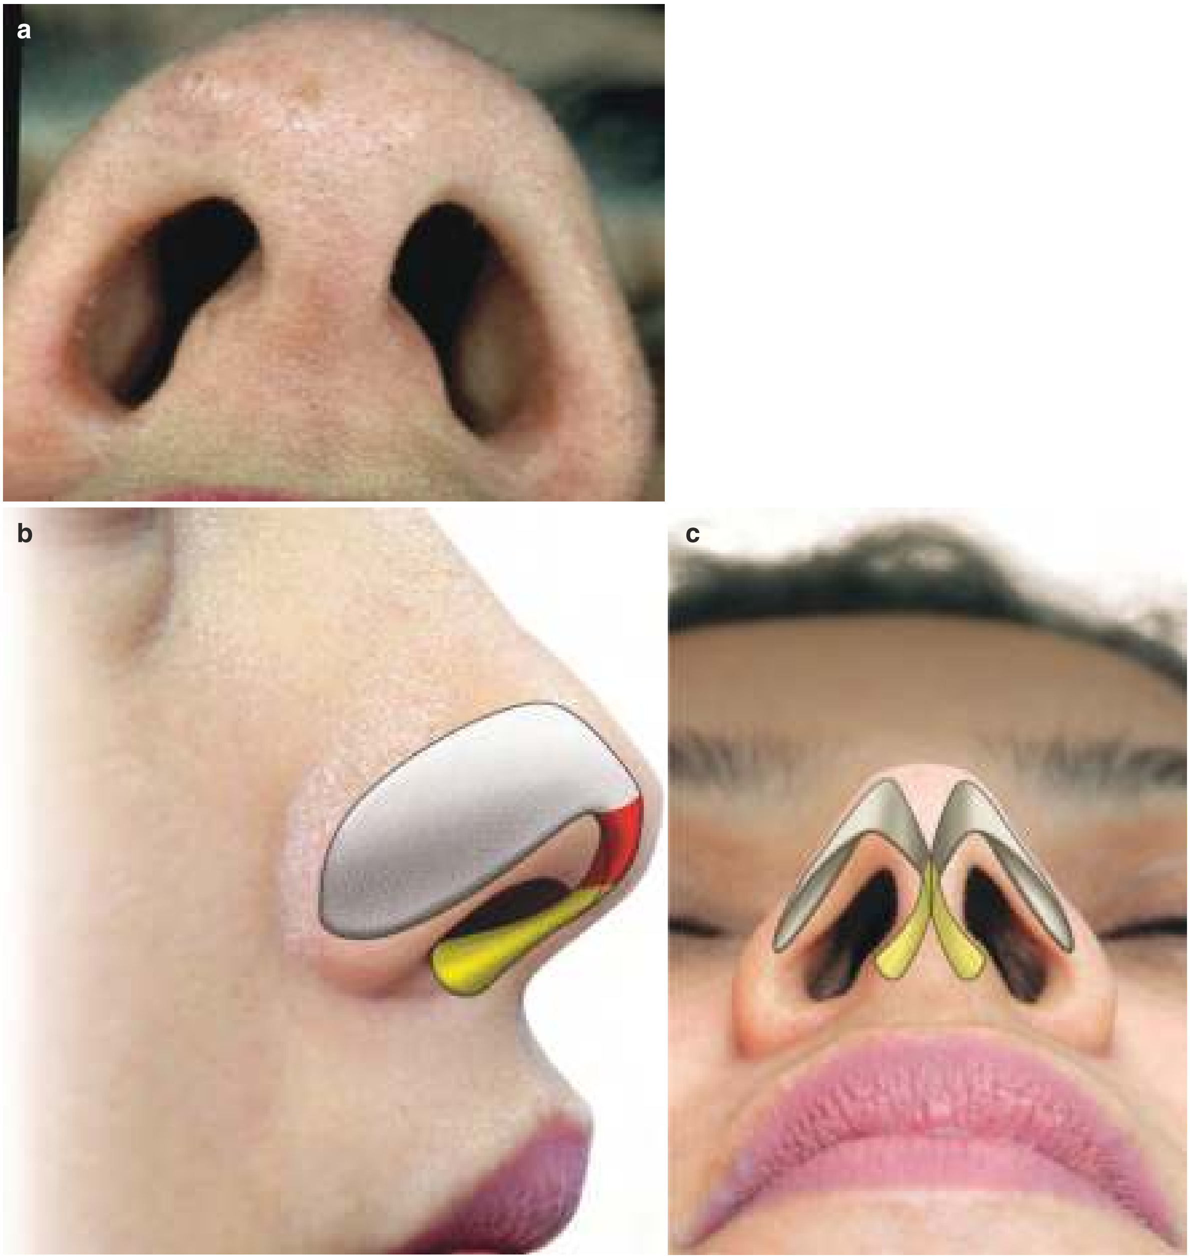

Fig. 38.7 Nasal tripod; (**a**) clinical photograph, (**b**) line diagram showing medial crus (yellow), intermediate crus (red) and lateral crus (grey) (**c**) line diagram showing basal view

the palatine bones. There are thin, curved, bony prominences in the lateral wall called the inferior, middle, and superior concha. The cephalic portion of the lateral nasal wall is bound with the ethmoid cells, interposed between the lateral wall of the nasal cavity and the medial wall of the orbit.

38.2.3 Nasal Septum

The septum is partly cartilaginous and partly bony. The ethmoid perpendicular plate forms the upper bony septum and is continuous with the frontal bone and the cribriform plate. The lower bony septum is composed of the vomer and nasal crest of the maxilla (Fig. 38.10a, b).

The cartilaginous septum is formed by the quadrangular cartilage that extends from Rhinion to the supratip area and supports the dorsum and the tip complex. Inferiorly, the cartilagenous septum is attached firmly to the anterior nasal spine and the maxillary crest. The junction between the dorsal and caudal portion of the cartilaginous septum is called the "anterior septal angle". There is tenuous attachment of the perichondrium and periosteum at the junction of the bony and cartilaginous septum. The membranous septum lies above the cephalic margins of the paired medial crura. It encases fibrous bands between two layers of soft tissue covering and the depressor septi muscle.

Box 38.2 Clinical examination for Rhinoplasty

	Local	
General/Systemic	**Facial**	**Nose**
Airway/breathing Mouth breathing	Intercanthal distance	Skin quality
Bleeding disorders	Inter-eyebrow distance	Nasal bone—width, length and symmetry
Hypertension	Frontal-bossing/glabellar projection	ULC (Upper Lateral Cartilage)—width and symmetry
Diabetes/ immunosuppression	Upper lip position	LLC (Lower Lateral Cartilage) • Cephalic malposition • Interdomal distance • Asymmetry of light reflecting points • Lobule position • Nostril-columellar relation
Psychological assessment	Chin position	Alar base • Vertical and horizontal position (in repose and smile) • Inter alar distance (should be 2 mm wider than intercanthal distance) • Insertion of the alar base

38.2.4 Lateral Nasal Wall

The lateral aspect of the nasal cavity is composed of three anatomic structures: the inferior, middle, and superior turbinates. The inferior turbinate forms a boundary of the internal nasal valve, where its specially adapted erectile tissues regulate the air flow and facilitate heat and moisture exchange.

Branches of the anterior ethmoidal artery accompany the external nasal branch of the anterior ethmoid nerve, passing between the nasal bone and upper lateral cartilages, and supply the soft tissues of the dorsum and tip of the nose. The posterior ethmoidal branches supply the smaller area above the superior concha on the lateral wall and a corresponding area high on the septum [8]. The posterior part of the internal nose is supplied by branches of the sphenopalatine ganglion of the second division of the trigeminal nerve (the long sphenopalatine, the nasopalatine and part of the greater palatine nerves).

38.3 Clinical Examination

Clinical examination should be comprehensive and include the assessment of systemic diseases (Box 38.2) [9].

General examination would include ruling out any syndromic deformities [9]. Obtaining correct history of systemic disease and bleeding disorders are of paramount importance. The extensive vascular network in the nose, in the presence of a coagulation disorder, may predispose the patient to severe haemorrhage in the intra- or post-operative period.

Existing breathing difficulty or any allergy-related symptoms such as rhinorrhea, sneezing, watery eyes, itching and loss of sense of smell and taste are observed. Majority of successful rhinoplasties are reductive in nature; an undetected or uncorrected underlying airway compromise may cause further deterioration and convert an aesthetic concern to a functional predicament. If the presence of any sinus infections and headaches is not recorded preoperatively, the patient may attribute these conditions to rhinoplasty [10].

38.3.1 Examination of the Face

The face in the frontal view is divided into thirds and fifths for assessment of proportion and harmony of various structures (Fig. 38.11a, b, c). In the upper third, the intercanthal distance and interpupillary distance is important in assessing the nasal bones, dorsum and radix. For a proper facial balance, the malar bone, maxilla, mandible and the nasal bones should be in an optimum spatial relationship. The length of the upper lip, its position during rest and smile, upper incisor show and its proportion in relation to the rest of the face are also assessed. The nose and chin may have a paradoxical relationship whereby a patient may have an overprojected nose and at the same time an underprojected chin and vice versa.

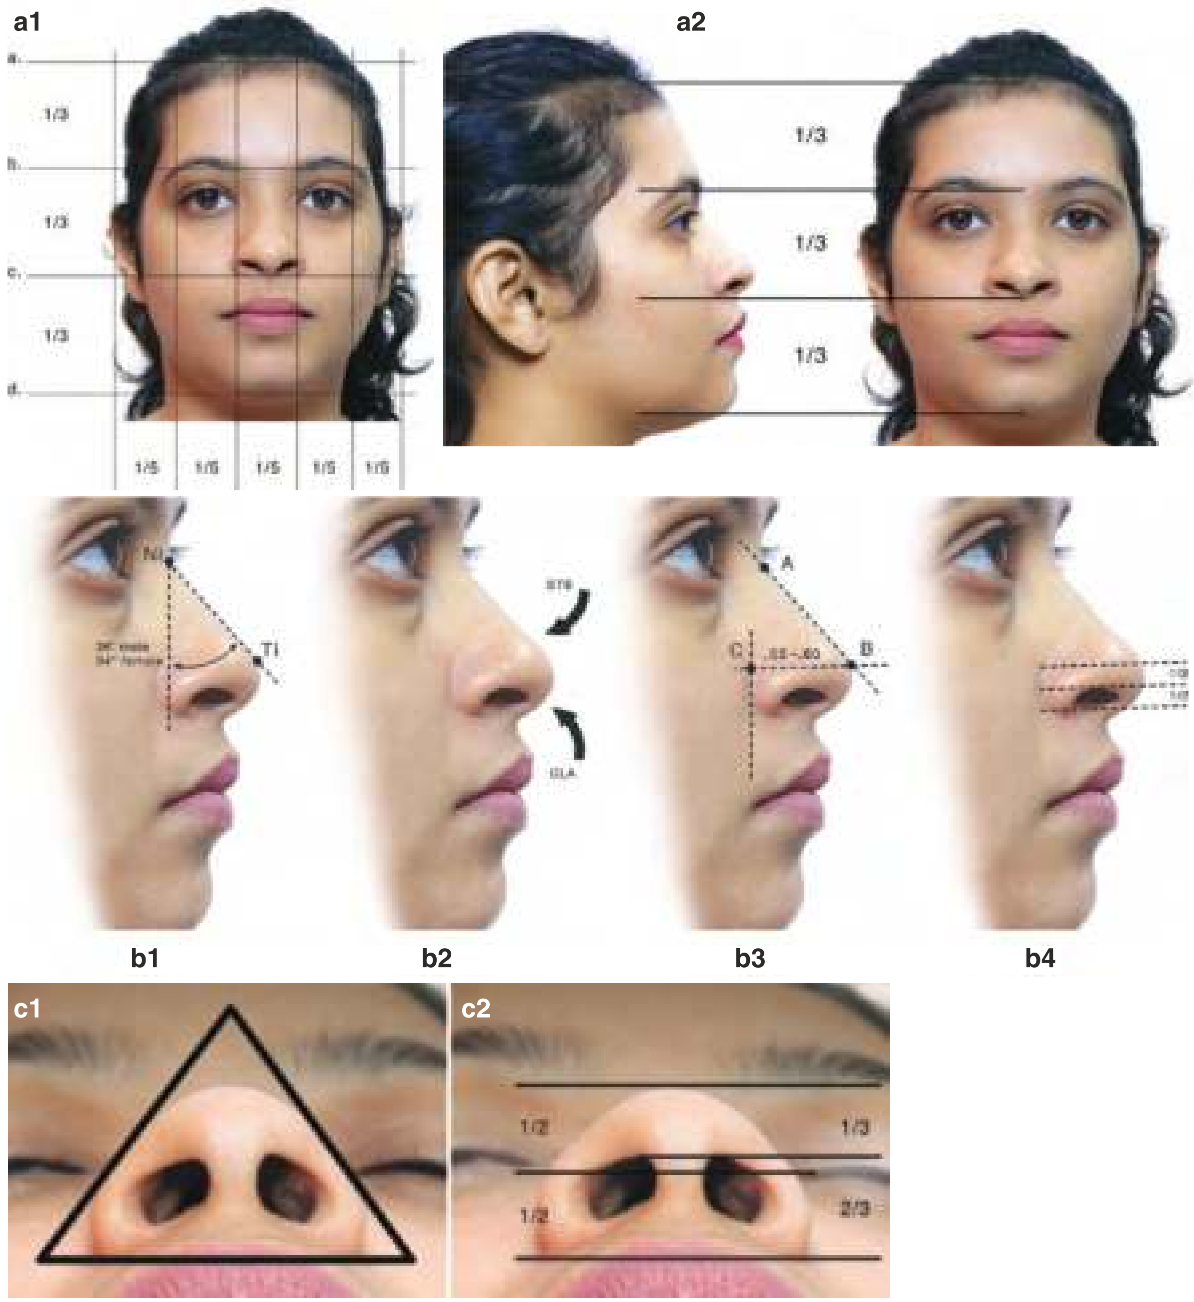

Fig. 38.11 (**a**)–(**c**) Examination of face and nose; frontal, lateral, basal. (**b1**) Ni - Ideal nasion, Ti Ideal tip. (**b2**) STB - Supra Tip Break, CLA - Columella Labial Angle. (**b3**) Nasal Length is measured from nasal radix to nasal tip (A–B), Nasal projection (C–B) is length from Naso-labial junction to nasal tip. The ratio between AB and CB (Goode's Ratio) should be ideally 0.55 to 0.60

38.3.2 Examination of the Nose

Visual analysis of the nose along with careful palpation allows the surgeon to assess the morphology and thickness of the skin and soft tissue envelope.

Frontal, profile and basal views should be used to assess the various components of the nose discussed above, individually.

38.3.3 Photographic Assessment

Patient's photographs are an important component of preoperative analysis and planning of the procedure. In addition, pre- and post-operative photographs are crucial for outcome monitoring and are indispensable from a medicolegal point of view [11]. With the advent of 3D imaging, image fusion and photogrammetry, preoperative and postoperative features can be compared in all dimensions [12].

There are four important photographic views that are used for analysis of the nose, namely, frontal, basal, lateral (at rest and smiling) and oblique views (Fig. 38.12). Photographs are standardised in relation to the Frankfurt horizontal plane. All four views are evaluated for the assessment of the facial horizontal thirds and vertical fifths. The quality of skin (thickness and Fitzpatrick type) and facial symmetry are also studied using all the views. The basic focus lies in the study of the loco-regional anatomy and the inter-relationships of the structures. The pictures are evaluated to assess any discrepancies in size, deviations or dorsal hump that may be immediately evident and recordable.

- **Frontal view**
  The length, width and the tip characteristics are well observed on the frontal views. The width is individually assessed in the upper, middle and lower thirds of the nose. Frontal views also show a straight or a crooked nose. The presence of a dorsal hump or a saddle deformity is noted as these may provide an illusion of the nose being narrow or wide, respectively. The presence of a truly wide nose may also demonstrate features of pseudo/true hypertelorism.

  The dorsal aesthetic lines should be studied in detail. They follow the eyebrows across the radix and along the dorsum to end at the tip defining points on either side.

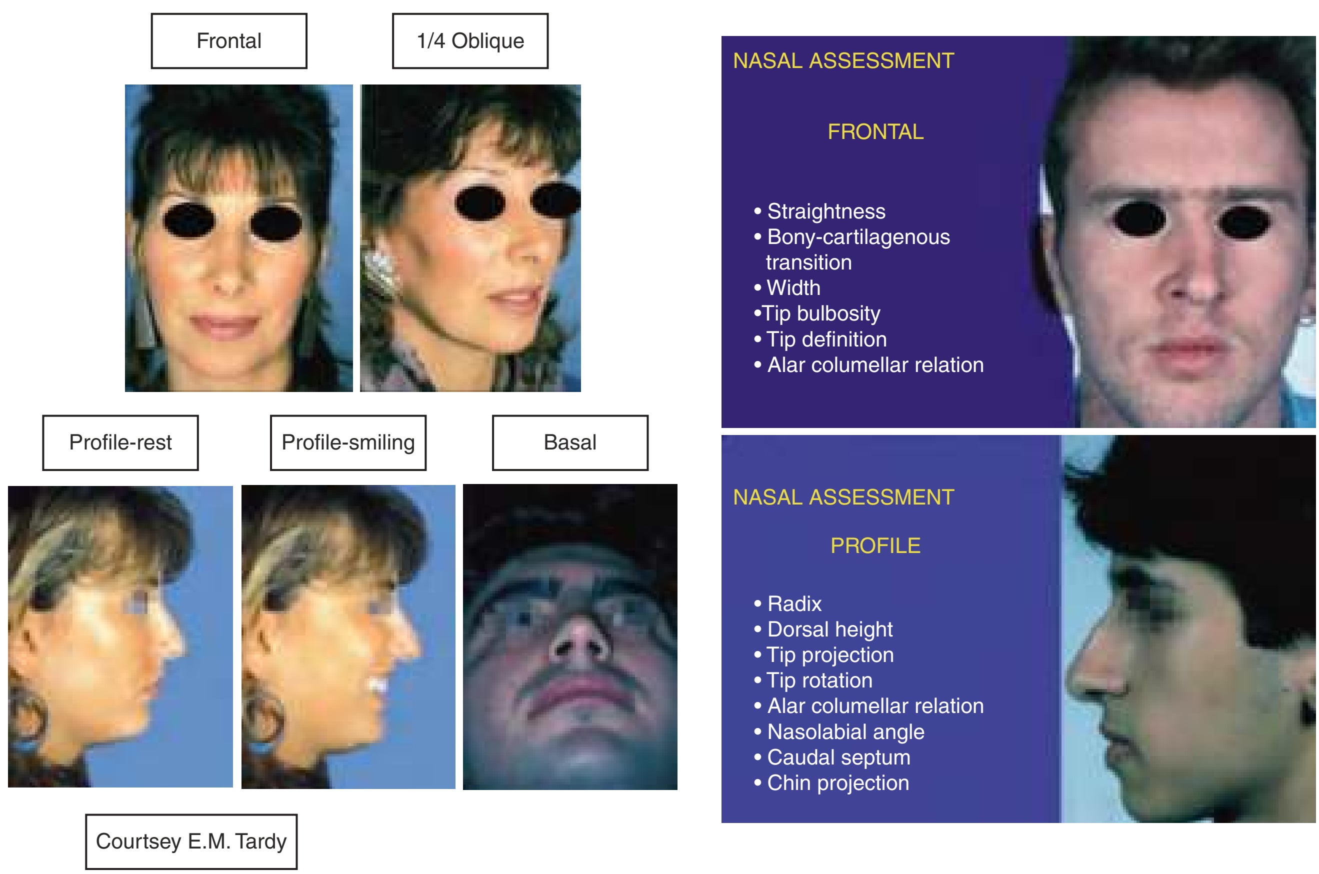

Fig. 38.12 Photographic analysis

The lines should be almost parallel with a smooth divergence at the brow but without any visible or perceptible breaks.

The nasal tip is assessed for symmetry and definition. The tip is also assessed for features of boxy appearance, bulbosity or bifidity. The alar base, ala and columella are also evaluated. The formation of a gentle "gull in flight" form should be appreciated for the relationship of the ala and the infratip lobule. An exaggerated curve may be indicative of a retracted ala or a plunging lobule. The position and insertion of both ala and their symmetry and direction are also noted.

- **Basal view**
  Assessment should include the study of lobule, columella, ala and the alar base. Emphasis should be placed on the evaluation of the triangular shape of the nasal base, symmetry and the ratios, namely, the columella/lobule ratio and the lobule to ala ratios. The nasal base should present as an isosceles triangle with a rounded apex. The alar sidewalls should demonstrate a gentle flare. Poor triangular form or a trapezoidal form is indicative of a broad dome. Nostril symmetry and the angulations are studied next. The nostrils are angulated at 30–45° to the midline and are pear shaped. The caudal septum is assessed for straightness and its position in relation to the maxillary crest and anterior nasal spine. The alar base width, flare and insertions are also assessed in this view.

- **Profile view**
  Key points that need to be evaluated from the lateral view include (1) a dorsal profile that may demonstrate a saddle/hump and the supratip break, (2) evaluation of the chin and mentolabial sulcus, (3) projection and rotation of the nasal tip, (4) nasal length, (5) assessment of the radix and (6) columellar show with double break.

  The ratio of nasal projection is evaluated by the method of Goode. The ideal ratio between the line joining the tip defining point and alar-facial groove tangent, to the line dropped from the nasion to the alar facial groove should be between 0.55 and 0.60. Rotation of the nasal tip is approximately considered 90º in Caucasian males and between 90 and 95° in Caucasian females.

  The length of the nose is relative to the person's facial profile and general stature. It may be categorized as the central nose length from the nasion to the nasal tip and lateral length from the nasion to the alar rims. A short or long lateral length may reflect as retracted or hooded ala, respectively. The nose may also show a relative increase or decrease in length depending on the depth of the radix. A deep radix may make the nose look short while a shallow radix makes the nose appear long.

  The columella is also assessed for over- and undervisibility with the evaluation of a columellar double break that is formed by the junction of the medial and intermediate crus.

- **Oblique view assesses the volume of the tip lobule and Brow tip aesthetic line.**
  Assessment of the oblique view may not provide objective details. However, the nose is most viewed at this angle thus making it an important view to assess the aesthetic balance of the face and nose. Important features that need to be assessed in this view include soft tissue facets, lateral aspect of the nasal bones, nasal length, dorsal contour and tip projection.

38.3.4 Investigations

- Inspection with speculum will demonstrate any septal curvatures, angulations or spurs.
- *Computed tomography* is helpful if sinus pathology is suspected.
- *Endoscopy* of the middle meatus should be done to rule out clinical evidence of sinus disease.
- *Tests for functions of internal nasal and external nasal valves* should be done. Careful observation of the nasal valves while the patient is asked to inspire will provide a significant amount of information. A speculum or Q tip facilitates proper examination. Cottle's Maneuver helps in localizing obstruction due to nasal valve dysfunction.
- *Acoustic rhinometry* is a recently developed objective technique for assessment of geometry of the nasal cavity. The technique is based on the analysis of sound waves reflected from the nasal cavities. It measures cross-sectional areas and nasal volume.
- *Rhinomanometry* has also been widely accepted and used as an objective method to assess nasal patency. However, these tools may not necessarily show clinical correlation [13].

38.4 General Operative Techniques

38.4.1 Surgical Approaches for Rhinoplasty

Rhinoplastic approaches: (1) open approach or the open structure rhinoplasty approach and (2) closed or the endonasal approach.

Open approach involves an external cutaneous incision while the closed approach involves intranasal incisions only (Fig. 38.13a, b).

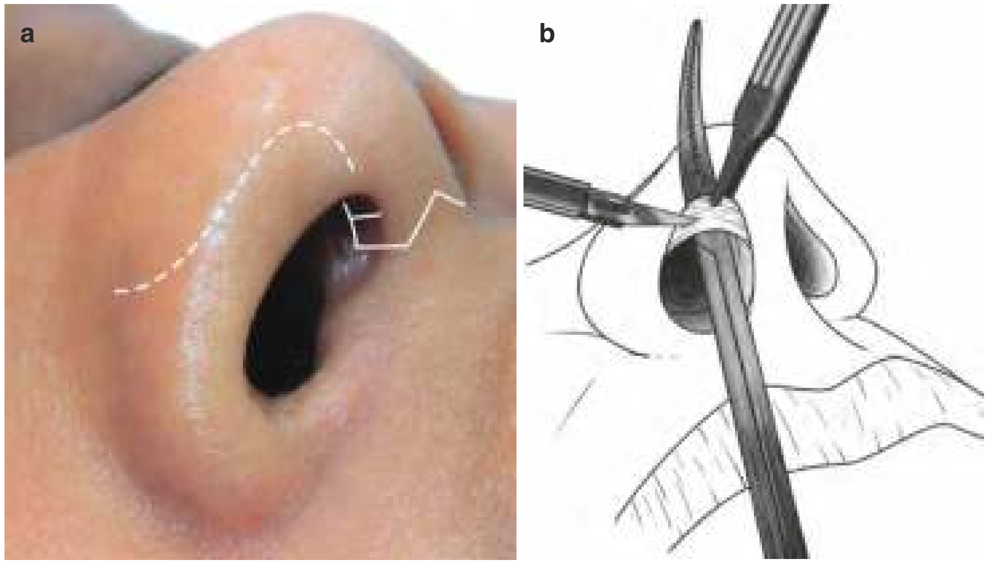

Fig. 38.13 Open (**a**) Vs Closed (**b**) approach

Choice of incision is based on the clinical problem to be corrected and the exposure required. The ideal incision must enable adequate and easy access to the nasal architecture without compromising the nasal structures. The differences between the different types of incisions are highlighted in Table 38.1.

A. **Open structure rhinoplasty**

The open structure approach is employed when extensive reconstruction is required. There is more emphasis on the preservation and realignment of structures of the lower third of the nose and also achieving balance of the nasal "tripod".

The open approach involves the use of a marginal and mid-columellar incision (Fig. 38.14b)

- *Marginal incision*
- The incision is placed along the caudal margins of the LLC, starting at the caudal margin of the medial crus, running along the entire dome and extended laterally along the caudal margin of the lateral crus.
- *Columellar incision*
- This is a transverse mid-columellar incision extending across to connect the marginal incisions on either side. Numerous modifications of the columellar incision have evolved over a long period (Fig. 38.15a, b, c).
  - Rethi transcolumellar incision 1931 (across the apex of the nostril aperture)
  - Sercer "nasal decortication" approach—1957
  - Bardach columellar base incision extending into prolabium (reserved for cleft rhinoplasty)
  - Goodman modification mid columellar 'V' facing upwards 1952
  - Johnson & Toriumi inverted 'V' midcolumellar incision
  - Stair-step mid columellar incision (Bahman Guyuron)

The **indications** for the open structure approach are highlighted in Box 38.3.

B. **The endonasal approach** (Fig. 38.14a)

Nondelivery/Partial delivery and delivery approaches (Fig. 38.16a, b).

1. **Nondelivery approaches are employed when** minimal reduction of the lateral crus or mild cephalic rotation of the tip complex is indicated.

   The technique in turn may involve either the cartilage splitting approach or the retrograde eversion approach.

- The *cartilage splitting method* involves a transcartilaginous incision through the most cephalic portion of the lower lateral cartilage that needs to be resected. However, extreme care is taken to preserve at least 8 mm of sound LLC to prevent structural compromise.
- The *retrograde eversion method* is difficult for beginners and hence not favoured in current practise, and most surgeons today prefer to use the delivery method.

2. The technique for the **delivery method** encompasses two incisions: the first inter-cartilaginous incision and the subsequent marginal incision to mark the chondrocutaneous unit of the LLC. The nonvestibular side of the LLC is

Table 38.1 Differences between the different types of incisions

		Closed/endonasal	
	Open/external	**Nondelivery Cartilage splitting Retrograde eversion**	**Delivery**
Incision	• Marginal • External (columellar)	• Transcartilaginous (Cartilage splitting) or • Intercartilaginous (Retrograde eversion)	• Marginal • Intercartilaginous
Exposure	Extensive	More of LLC exposure Less of tip exposure	Increased dome and interdomal visibility
Indications	Marked asymmetry Secondary rhinoplasty Need for structural grafting Post traumatic nasal deformity Nasal valve correction	Minimal tip correction Access to dorsum and middle vault Volume reduction of LLC Septal surgery Bony and cartilaginous hump removal	Allows more delicate tip work than the nondelivery approach septal surgery
Advantages	• Excellent visual control of entire nasal framework • Enhanced surgical access • Accurate structural grafting under direct vision • Ideal for demonstration and teaching • Predictable results	Less invasive Less disruption of support mechanisms of nasal tip May be used for septal cartilage harvesting	
Limitations	• External (transcolumellar) scar • Destabilization of tip support • Protracted edema • Risk of columellar necrosis (poor operative technique) • Sensory disturbances at the tip area	Steep learning curve No binocular vision Essential ENT experience Limits assistant's view of exposure Difficult to perform complex nasal tip surgery Spreader-grafts are difficult/impossible	

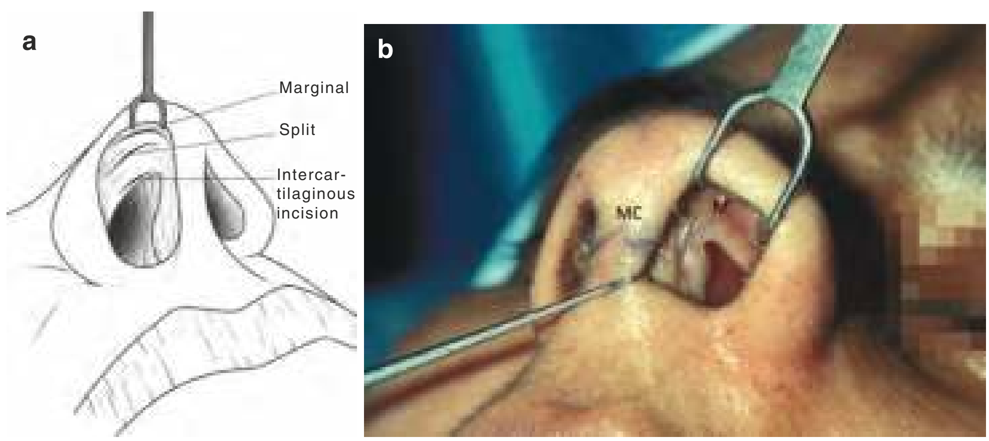

Fig. 38.14 Incisions for rhinoplasty: (**a**) closed and (**b**) open approach (MC- mid columellar, M- Marginal)

then dissected off the overlying SSTE permitting the delivery of the LLC chondrocutaneous unit as a bipedicled flap. Improperly positioned intercartilaginous incision may predispose to scarring at the valve area.

Incisions for the endonasal approach

- Intercartilaginous (limen-vestibular) incision
- Intracartilaginous (trans-cartilaginous/cartilage splitting) incision
- Infracartilaginous (alar marginal) incision
- Septal transfixion incision
  - Hemi-transfixion
  - Bilateral transfixion—partial/full
- Pyriform rim incisions for access to the lateral nasal wall
- Lateral nasal vestibular incisions for access to the paranasal premaxillary area
- Endonasal transmucosal medial osteotomy facilitated high up in the nasal vault.

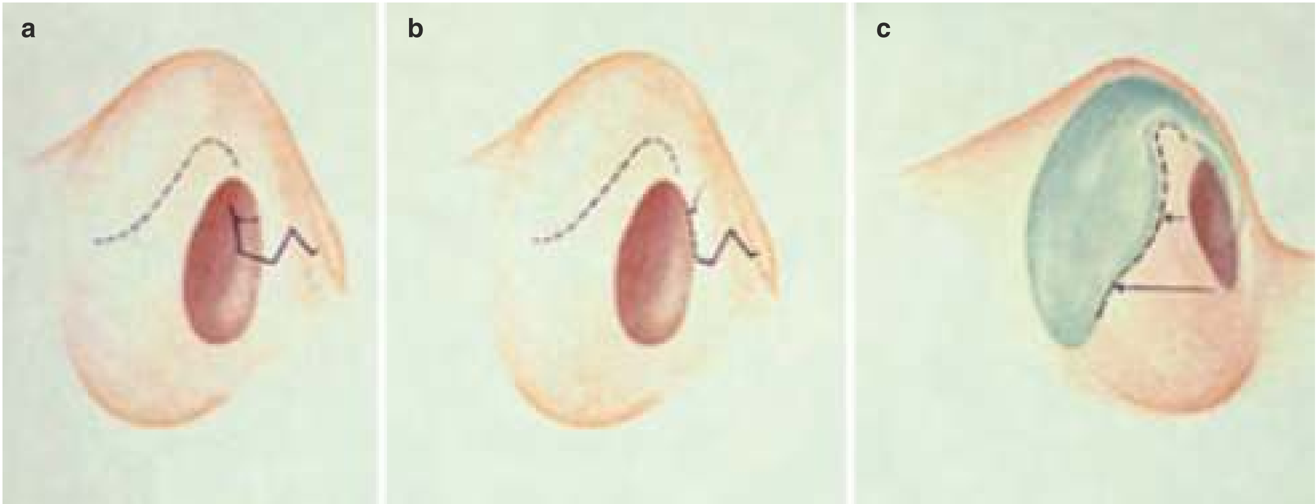

Fig. 38.15 (**a**–**c**) Modifications of columellar incision

Box 38.3 Indications for open Rhinoplasty
- Secondary/revision rhinoplasty
- Post-traumatic nasal deformity
- Cleft nasal deformity
- Need for structural grafting
- Septal reconstruction
- Nasal valve surgery
- Dermoid cyst excision

Indications for the endonasal approach

- Symmetrical anatomy
- Good size nostrils
- Principal deformity at the nasal vault
- Ability to insert cartilage grafts

The endonasal approach is, however, unsuited for the novice surgeon and does depend on the surgeon's experience and prior training in Rhinoplasty for optimal outcomes.

38.4.2 Grafting in Rhinoplasty

Reduction rhinoplasty can weaken the underlying nasal tip framework with subsequent buckling and late structural deformity. Cartilage grafting during primary and revision procedures helps to prevent such a secondary deformity [14–17]. An open technique is preferred as it offers better visualization for placement of grafts. The grafts used in rhinoplasty can be summarised as follows (Fig. 38.17a, b) (Tables 38.2 and 38.3):

38.4.3 Septoplasty

38.4.3.1 Deformities of Nasal Septum

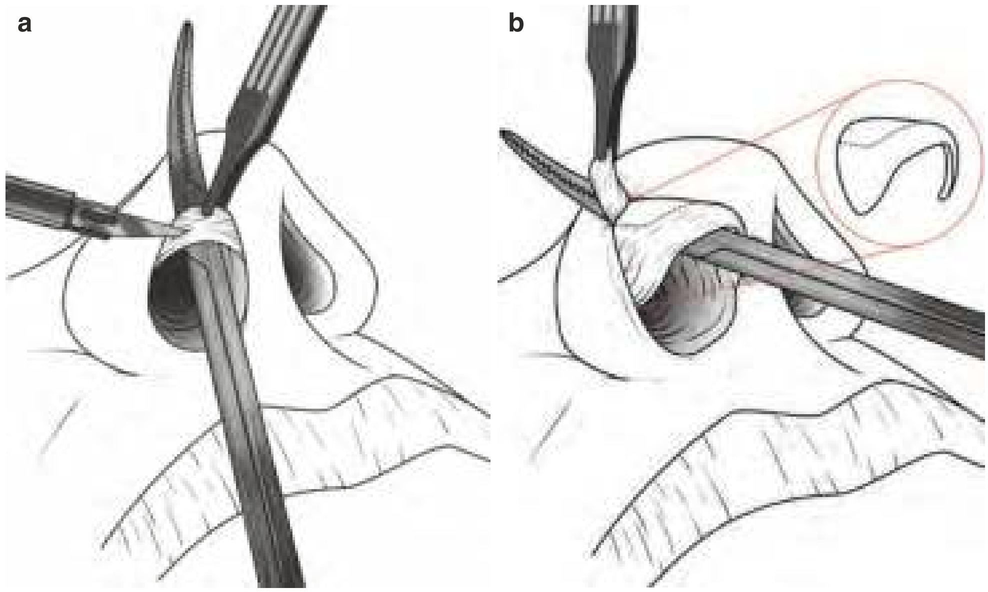
Deformities of the nasal septum may either be congenital or acquired. They are classified as shown in Box 38.4.

Septal deformities depend on alterations in the growth and direction of growth of the septal cartilage.

Deformities of the nasal septum may present clinically (Fig. 38.18a, b).

1. Dorsal excess may present as a tension nose
2. Dorsal deficiency causes concave or Saddle nose
3. Caudal excess causes increased columellar show
4. Caudal deficiency leads to columellar retraction
5. Lateral angulation of the septum is seen as a bent nose
6. Both lateral & AP curvatures give a twisted nose/crooked nose
7. Septal perforations and collapse may lead to a variety of deformities

Fig. 38.16 (**a**, **b**) Nondelivery vs. delivery method



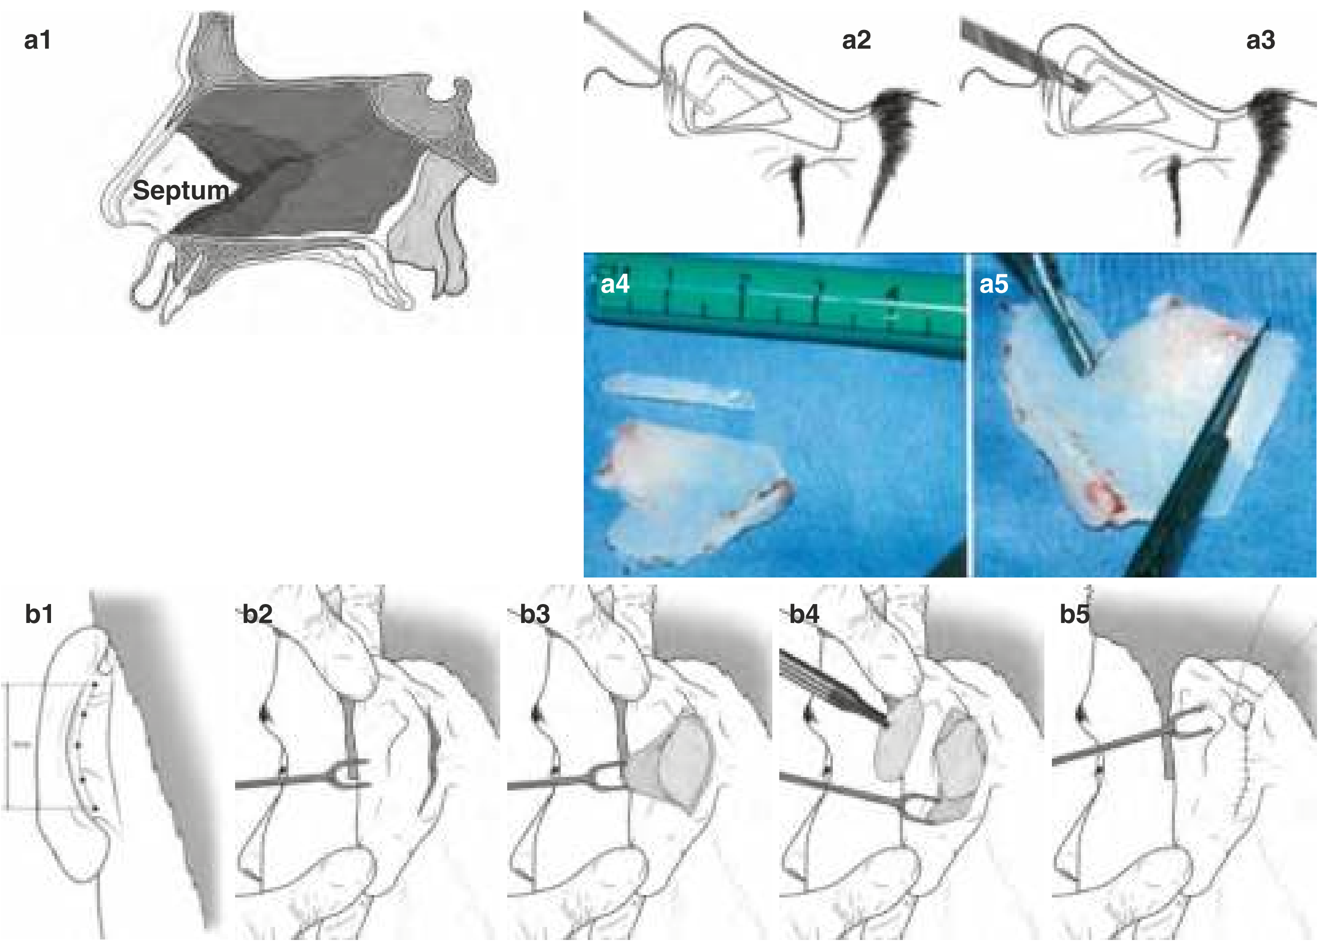


Fig. 38.17 Sources of cartilage graft; (**a**) septal cartilage graft (**a1**) anatomy of septum (**a2**) marking for cartilage harvest preserving L shaped dorsal strut (**a3**) incision for cartilage harvest (**a4**) harvested cartilage (**a5**) carving of harvested cartilage and (**b**) Harvest of auricular cartilage; (**b**)- marking on the ear (**b2**)- incision (**b3**)- reflection of sub perichondrial flap to expose cartilage (**b4**) cartilage harvest (**b5**) closure of donor site

Table 38.2 Autologous graft materials

Autogenous grafts—Donor site morbidity, increased operating time, predictable long-term results, minimal risk for extrusion and infection	
Nasal septal cartilage	Considered to the best grafting material as it is easy to harvest and contour
	Intrinsic anatomy of septal cartilage [firmness, resiliency, flatness] provides optimal aesthetic results
	Sufficient rigidity to provide structural support
	No donor site morbidity with excellent long-term results
	Insufficient when large volumes are needed/previous septal surgery
Auricular/conchal cartilage	Easy to harvest but difficult to contour due to its brittle nature
	Low strength and hence provides poor structural support
	Low donor site morbidity and with good long-term results
	Intrinsic anatomy [curved shape with elastic memory] of auricular cartilage makes it difficult to provide optimal aesthetic results
	Used if nasal septal cartilage is not adequate e.g. extensive revision cases and simultaneous multiple grafting procedures
	Useful when elasticity is needed e.g. lateral crus reconstruction
	Insufficient when large volumes are needed
Costochondral grafts	Abundant supply
	Sufficient rigidity to provide structural support
	Can be reharvested
Temporalis fascia	Used for cartilage-fascia grafts in primary and revision rhinoplasty. For smoothening contour defects and irregularities on the nasal dorsum.
	Easy to harvest
	Adequate size available
	Shows minimal resorption and is stable in followup
Perichondrium over rib	Used for repair of septal perforations and for smoothening irregularities over the dorsum
	Easily available and harvested contiguous with rib cartilage which is a commonly used graft in rhinoplasty

Table 38.3 Alloplastic graft materials

Alloplastic grafts—No donor site morbidity, reduced operating time, unpredictable long-term results and increased risk of extrusion and infection	
Silicone	Pliable, elastic solid that causes little tissue reaction
	Easy to handle, comes in prefabricated shapes—most commonly used alloplastic graft material
	Increased risk of displacement/extrusion as its nonporous nature prevents surrounding tissue in-growth, instead, leading to the formation of a fibrous capsule
	Easy to remove even after a long time as a fibrous capsule will form around the implant, without ingrowth in to the graft
	Asymmetric contracture of the capsule around the implant can deform the implant over time
	Low strength and hence provides poor structural support
	Preferred in Asians with thicker dorsal nasal skin
Medpor [high density polyethylene]	Easy to carve and bend due to thermoplastic property
	Poor aesthetic results and comfort due to its stiffness
	Sufficient rigidity to provide structural support
	Minimal risk for displacement due to its porous nature with subsequent ingrowth of surrounding fibrovascular tissue
	Difficult to remove in the long term as there will be extensive tissue ingrowth
	Tends to shed particles, when implanted in stress-bearing and mobile areas may cause a chronic inflammatory response
Gore-tex [expanded poly-tetra-fluoro-ethylene (PTFE)]	Porous implant composed of carbon and fluorine molecules with pores
	Second most widely used alloplastic implant, after silicone
	Better comfort and aesthetics due to its softness
	Minimal risk for displacement due to its porous nature with subsequent ingrowth of surrounding fibro-vascular tissue
	Poor long-term aesthetics as it decreases in volume over time
	Difficult to remove in long term owing to extensive tissue ingrowth
	Low strength and hence provides poor structural support
Injectable filler materials—No donor site morbidity; reduced operating time; unpredictable long-term results and increased risk of extrusion, infection and embolization	
Bovine collagen, human-derived collagen, hydroxyapatite microspheres, hyaluronic acid	Mainly used for minor augmentations
	Necessary to overaugment by 20–30% to compensate for long-term absorption
	Provides poor structural support
	High complication rate including persistent redness, contour irregularity, swelling and necrosis of surrounding dermis or soft tissue, hypersensitivity reactions, extrusion
	Patients may object on religious grounds

Box 38.4 Classification of septal deformites

Congenital:

- Syndromic
  - Cleft lip and palate
- Congenital syphilis

Acquired:

- Developmental: midline dermoid cyst, short nose/long nose
- Post traumatic: bent nose/crooked nose
- Iatrogenic
  - Incorrect or aggressive rhino/septal surgery.

  Lefort I maxillary impaction with inadequate trimming of septum
- Cocaine misuse: destruction of cartilage and bony septum

38.4.3.2 Sequencing for Treatment

The sequence to be followed for planning a proper septoplasty includes

1. Establishing an accurate diagnosis. Apply Mladini classification for septal deformities (See additional Reading)
2. A thorough external and internal examination of the nose
3. Internal examination should include (1) anterior rhinoscopy and (2) nasendoscopy
4. Imaging of the nose, septum and the paranasal sinuses is mandatory. This should include CT scans with both soft tissue and bony windows [18].
5. It is preferable to perform the surgery "in conjunction with ENT colleagues"
6. Gross iatrogenic nasal deformities need careful evaluation of previous surgical records before treatment planning
7. Informed consents to be obtained for the harvest and use of grafts (Septum, Concha or Rib cartilage)
8. Care should be exercised to preserve the integrity of the turbinates and the internal nasal valve.

38.4.3.3 Surgical Approaches

Septoplasty may be performed in conjunction with a formal rhinoplasty using an open or closed approach.

Closed approaches for septoplasty include;

1. Endonasal caudal vestibular access via a right or a left hemi-transfixion incision or
2. Bilateral septal transfixion incision [19, 20].

38.4.3.4 Surgical Technique (Fig. 38.19a, b, c)

The local anaesthetic solution is infiltrated with adrenaline for optimal haemostasis. This not only provides a clear field for surgery but also aids in developing planes by the process of hydrodissection. An incision is made at the caudal margin of the septal cartilage, which may be unilateral or bilateral. Cautious, careful, unhurried dissection in the correct anatomical plane is done, using sharp precise instrumentation (Cottle/Masing, Freer or Joseph's elevator). It is imperative to identify and stay in a bloodless sub-mucoperichondrial plane. The light blue colour of the septal cartilage ensures the correct plane of dissection. An anterior tunnel is first made, followed by an inferior tunnel to expose the entire septum. The plane is then expanded and separated further with a Killian forceps. This offers bilateral exposure of the dissected tunnel and the septum. Sharp curvatures, angles and fracture lines are negotiated carefully also bearing in mind that the transition zone between the mucoperichondrium and the mucoperiosteum is an area vulnerable to tears. Tears over the mucoperichondrium require careful repair with vicryl sutures on a round body needle. However, tears in the inferior tunnel overlying bone need not be sutured and may act as drains. The flap elevation is extended posterior to chondrovomerine and chondroethmoid junctions for complete exposure of the bony septum.

Bony spurs or angulations and bends are identified, which may contribute to airway block. The osteocartilaginous junction is then separated to free the septum in the posterior aspect. Takayashu forceps are used to nibble away any bony/cartilage spurs. This may also be performed using thin chisels and osteotomes. Buckling of the septum may be corrected by resection of overhanging cartilage in the caudal aspect. Adequate relief thus allows the passive return of the septum to midline. Measures such as scoring, suturing or the use of PDS sheets/cartilage grafts may be required to correct and straighten residual curvatures. Harvest of septal cartilage may be performed at this juncture and should be done posterior to the key area (imaginary vertical line joining the tip of the nasal bone and the anterior nasal spine). Stabilisation to the midline is achieved by the use of a PDS suture anchoring the dissected septum to the anterior nasal spine. The flaps are reapposed with one or two transfixion sutures to prevent septal haematoma. Nasal packing is outdated and has been replaced by silastic sheets and intra-operative control with Merocel packs.

Advantages of the endonasal approach include

1. Minimal trauma to local tissues
2. Reduced post-surgical oedema and
3. A-faster-recovery-to-normalcy

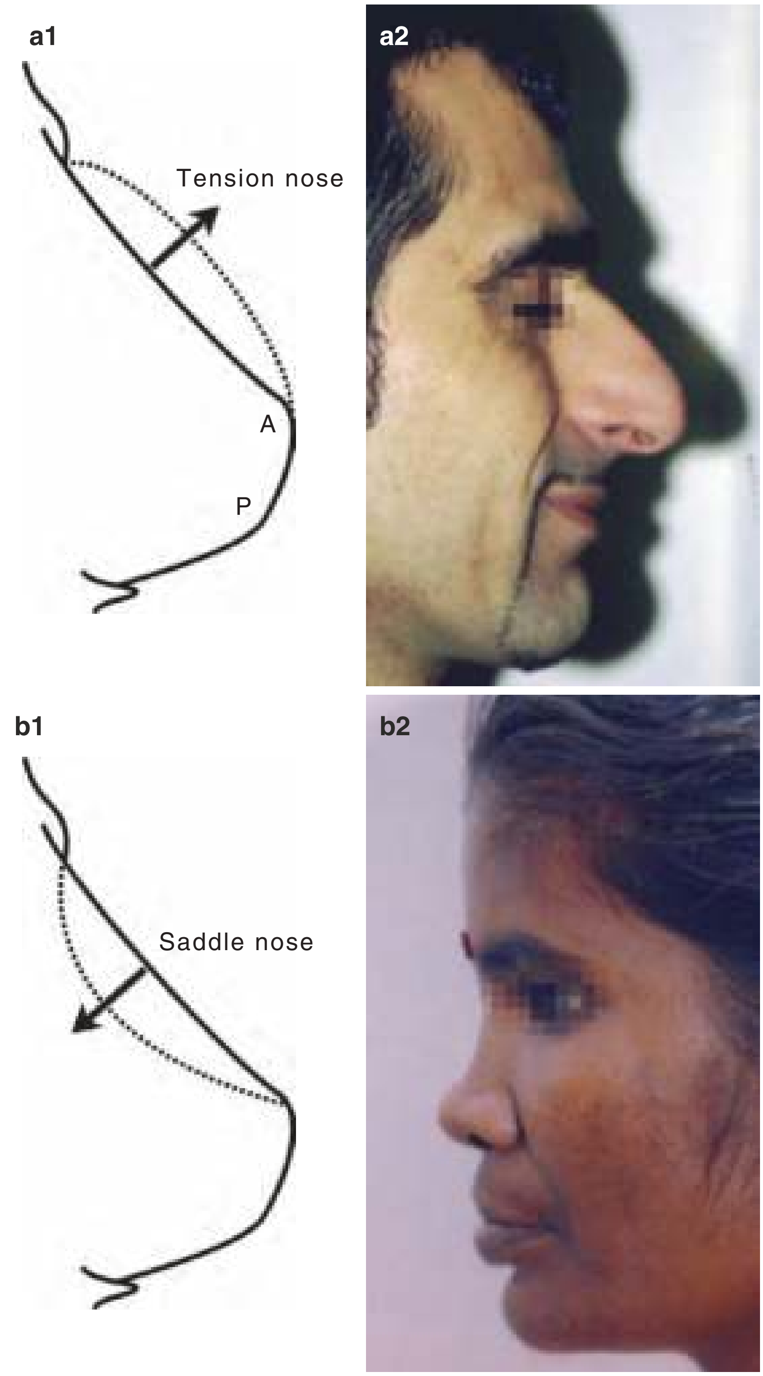

Fig. 38.18 Deformities of nasal septum; (**a**) tension nose and (**b**) saddle nose

Disadvantages of the endonasal approach are

1. Steep learning curve
2. Limited exposure & visualisation (headlight required)
3. Limited visualisation for the assistant
4. Difficult to place spreader grafts
5. Contour irregularities at the dorsal edge
6. Septal malposition/perforation
7. Increased risk for secondary deformities like saddling

38.4.4 Nasal Osteotomies

Nasal osteotomies are often required during correction of deformities of the nose as well as an adjunct to procedures which involve correction of the osseocartilaginous vault.

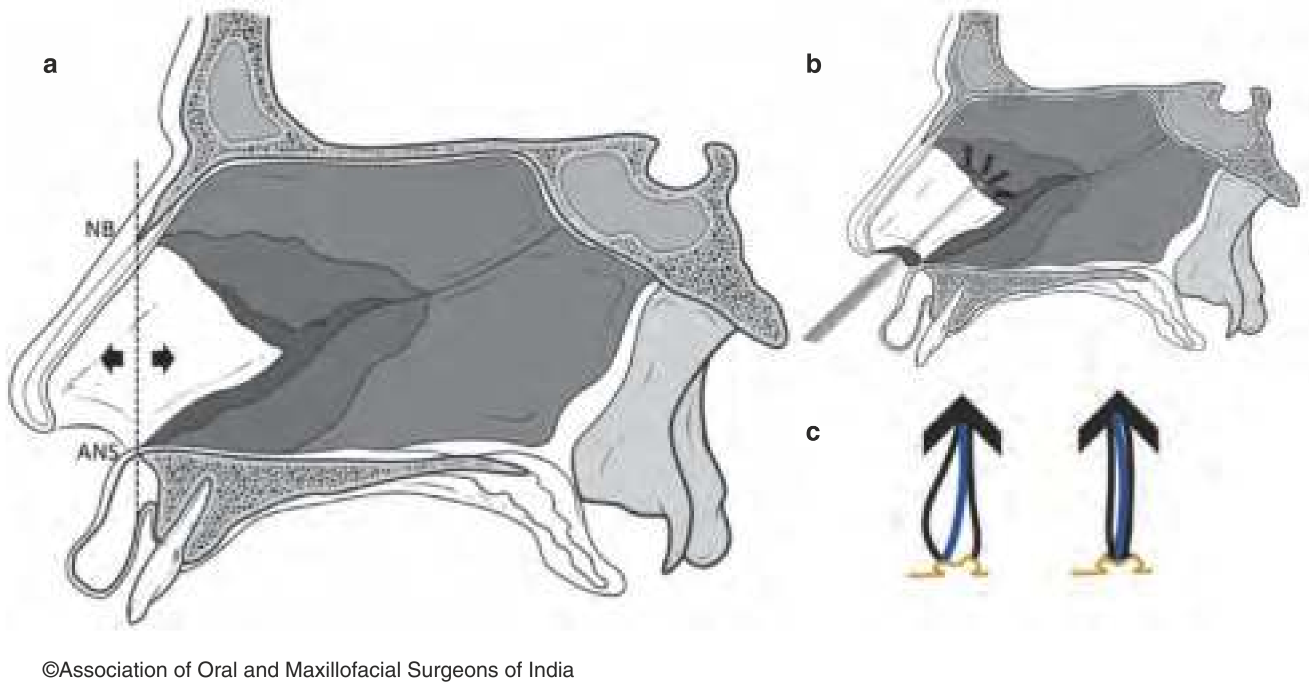

Fig. 38.19 Septoplasty intra-operative steps. (**a**) the part of the septum anterior to the line dropped from the tip of nasal bone (NB) to the anterior nasal spine (ANS) has tobe preserved. (**b**) Dysjunction of the cartilaginous septum from the bony septum. (**c**) Septal repositioning with sutures to the midline crest of the maxilla

38.4.4.1 Indications for Nasal Osteotomies

1. Close an open roof after dorsal hump removal
2. Correction of a deviated bony nasal vault (crooked nose/ bent nose)
3. Correction of concave or convex nasal bones
4. Reduce or narrow bony base width
5. Mobilise malunited fractured nasal bones prior to reduction

Different types of nasal osteotomies (Fig. 38.20a, b) are utilised for a variety of clinical indications [21, 22]. They are enumerated in Box 38.5.

38.4.4.2 Armamentarium for Nasal Osteotomies

- Chisels/Osteotomes
  - Straight osteotomes—2 mm microosteotome
  - Curved osteotomes
  - Guarded osteotomes—Nievert, Silver
  - Angled blade osteotomes—Murray-Parkes
  - Notched osteotomes—Walter
- Power instruments
  - Oscillating/reciprocating saws
  - Piezo saw

38.4.4.3 Surgical Technique

The different techniques for performing nasal osteotomies are (1) endonasal, (2) percutaneous, (3) endoral and (4) nasofrontal

Percutaneous technique (Fig. 38.21a, b, c)

The percutaneous technique involves the completion of a lateral osteotomy and a transverse root(superior) osteotomy. The local anaesthetic solution is infiltrated with adrenaline 10–15 min earlier for good haemostasis.

The sites of the lateral and superior osteotomies are marked on the skin. The cephalic end of the cross-over of these two osteotomies should be kept no higher than the level of the intercanthal line.

A small 2–3 mm stab incision is made on the skin at the middle of the lateral osteotomy marking. The incision is deepened down and to bone. The osteotome is swept along the entire length of the marking to provide good release of the skin and subcutaneous tissue and keep the angular artery away from the line of osteotomy. The osteotome is then positioned supraperiosteally at 2 mm intervals and struck with a mallet to produce an interrupted line of punch holes. The osteotomies are started at the pyriform rim and continued superiorly to the nasofrontal junction. The same technique is followed for the transverse root(superior) osteotomy. The contra-lateral nasal wall is osteotomised in a similar

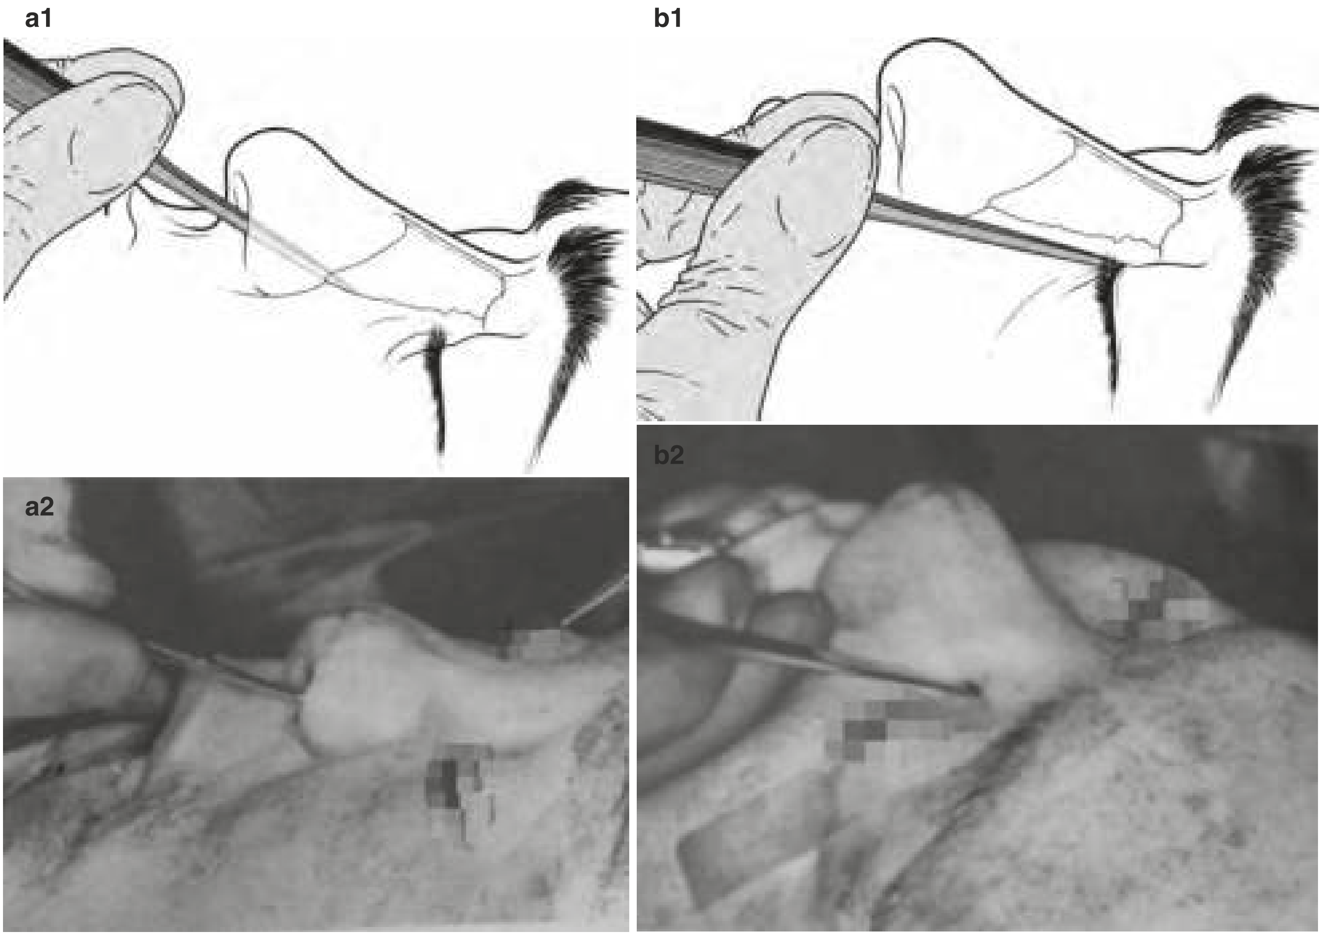

Fig. 38.20 Types of osteotomies. (**a**) Endonasal and (**b**) Percutaneous

Box 38.5 Osteotomies types
- Lateral osteotomy
  - Low to high
  - Low to low

  - True median
- Superior osteotomy
  - Transverse root
- Intermediate osteotomy
  - Vertical
  - Horizontal
- Fragmentation/comminution (largely outdated)

fashion. Once this is completed, the nasal bones are held with firm/controlled pressure between the thumb and the fore-fingers of both hands over a gauze square and then fractured along the already osteotomised punch holes. Moderate pressure over the wound helps with haemostasis and prevention of ecchymosis. No sutures are required and the skin is dressed with a Steri-Strip.

Complications include comminution, unpredictable fracture line, loss of lateral wall support, avulsion/displacement of upper laterals, step deformity, residual deformity and failure to in fracture/mobilise nasal bones.

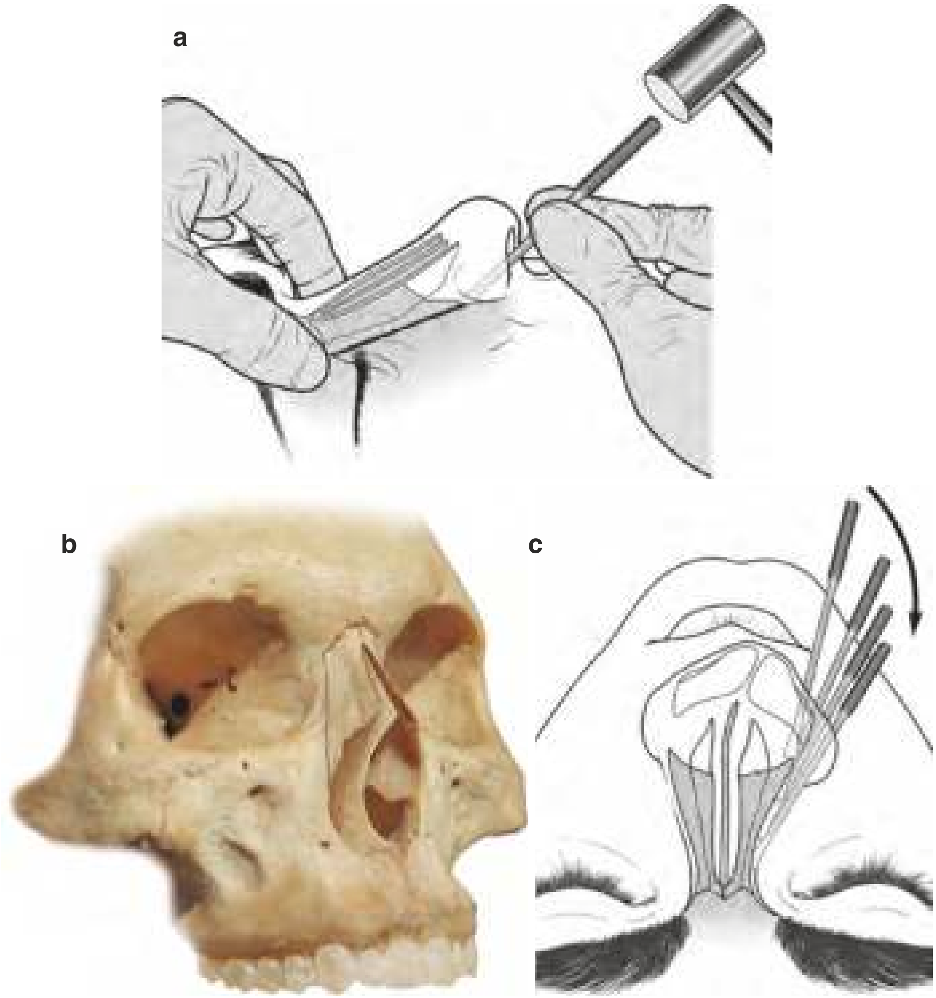

Fig. 38.21 Steps in nasal osteotomy. (**a**) Start of the lateral osteotomy. (**b**) Osteotomy marking on skull. (**c**) Movement of the osteotome for lateral osteotomy

38.5 Surgical Management of Basic Nasal Deformities

38.5.1 Dorsal Hump Deformity

The dorsal hump is the most common problem for which a patient may seek rhinoplasty. Based on the anatomical units involved, three main types of dorsal hump may be identified [23, 24];

1. Osseous/bony hump that exclusively involves the bony vault,
2. cartilaginous hump that involves the cartilaginous middle vault with septal and upper lateral cartilages and
3. the osseocartilagenous hump that is a combination of the two.

38.5.1.1 Types of Dorsal Humps

Dorsal humps can also be categorised as true and pseudo-humps. True humps may occur isolated or may occur in conjunction with other nasal deformities. The pseudohump may produce a relative appearance of a dorsal hump, while in reality, the appearance may be due to a high anterior septal angle, supratip prominence or tip ptosis (Box 38.6).

38.5.1.2 Clinical Assessment of a Dorsal Hump (Fig. 38.22a–d)

- Palpation of nasal bones, normal, long or short
- Ascertain area of hump requiring reduction
- Dorsal line—imaginary line from the radix extended along the nasal dorsum
- Assess if tip projection is adequate; reduced or increased, prior to hump reduction
- Assess if tip support is adequate; weak or strong, prior to hump reduction

38.5.1.3 Armamentarium for Dorsal Hump Reduction

The armamentarium required for dorsal hump reduction are shown in Box 38.7.

Box 38.6. True vs. Pseudo humps

True dorsal hump	Pseudo hump
Hump associated with the following clinical situations • high dorsum • low dorsum • short nasal bones • wide bony base • narrow bony base • deviated nasal bones • cleft nose deformity • under-projected nasal tip • over-projected nasal tip • short nose • long nose	• High anterior septal angle • Supra-tip prominence • Loss of tip projection

Box 38.7. Bony vs. Cartilaginous hump, (Armamentarium)

Bony hump	Cartilagenous hump
Manual nasal saw. • Joseph saw • Bull saw (guarded tip) Osteotomes. • Rubin (dorsal fin) • Cinnelli (guarded edges) • Aiach (wire guide) • McIndoe grooved chisel (not recommended) Bone cutters/nibblers • Sulsenti • Heanley Rasps • Graded two way tungsten carbide rasps (Rees) • Pull rasp/push rasp (Daniel) • Diamond rasps Power saw • Rhinobur (Toriumi) • Piezoelectric saw	• Scalpel (11 bard Parker) • Fomon scissors (angled on flat) • Turbinate scissors (angled on side) • Kaplan scissors (double action) • Cautious, conservative reduction at osteocartilaginous junction only • Preserve leading edges of ULC to create spreader flaps (prevent middle vault narrowing)

38.5.1.4 Dorsal Hump Reduction (Profile Lowering)

The procedure for dorsal hump reduction (profile lowering) is facilitated by two important steps, namely, (1) bony hump removal and (2) cartilaginous hump removal.

Bony hump removal (Fig. 38.23A–K)
En-bloc bony or cartilaginous hump removal requires experience as there is a high risk of excessive reduction when the surgeon may be inexperienced. The procedure begins with infiltration of lidocaine 2% with 1 in 100,000 adrenaline.

After exposure of the osteocartilaginous vault is completed, the osteotome is engaged at the caudal edge of the nasal hump (osteocartilaginous junction) and the bone is removed using an osteotome and mallet (18 oz Heath mallet) with firm blows to follow a careful alignment. It is better to always under-reduce, rather than over-reduce as it may cause severely compromised results. The dorsal edges can then be rasped down to the desired extent. Care is taken not to rasp the cartilage as it may produce irregularities, tears or avulsions.

When separation of a large hump is desired, placement of a superior stop-cut as described by Tardy allows precise and clear separation at the desired level. Diamond rasps are used to smooth irregularities at the dorsal edge of the nasal bones. Removal of an osteocartilagenous hump results in an open roof deformity of the nasal dorsum, which needs to be closed with an osteotomy [23].

38.5.1.5 Complications

- Unpredictable hump reduction
- Avulsion of upper lateral cartilages
- Fenestration of the skin envelope
- Residual irregularities
- Excessive overzealous hump reduction
  - Bony saddle
  - Loss of support to ULC
  - Loss of key area support to septum
- Inadequate hump reduction
  - Residual hump
  - Failure to follow dorsal line: superior bony spur

38.5.1.6 Preservation Technique of Hump Removal (Regnault & Daniel)

This technique advocates aggressive removal of the large hump with osteotome. The under-surface of the hump is then reduced extracorporeally with a bur. The reduced hump is replaced in the dorsal defect. This obviates the need for nasal osteotomy and provides optimal results of a corrected dorsum.

38.5.2 Saddle Nose Deformity

A saddle nose deformity is defined as a wide and flat nose with a concavity on the nasal dorsum.

Classical clinical presenting features of this deformity are

- Loss of height of the nasal dorsum (appearance of a shortened nose)
- Increased width of the nasal dorsum (wide nose)
- Underprojected tip due to inadequate septal support to the tip complex

38.5.2.1 Classification

Saddle nose deformity can be classified based on the underlying structural problem into

Fig. 38.22 Dorsal hump - clinical presentation. (**a**) Profile and (**b**) frontal pictures of patient 1. (**c**) Profile and (**d**) frontal pictures of patient 2

1. Bony saddle
2. Cartilaginous saddle
3. Combination of bony and cartilaginous elements

The causes responsible for saddle nose deformity are many, namely, septal hematoma following trauma, iatrogenic—inappropriate surgery to the septum, bony vault &

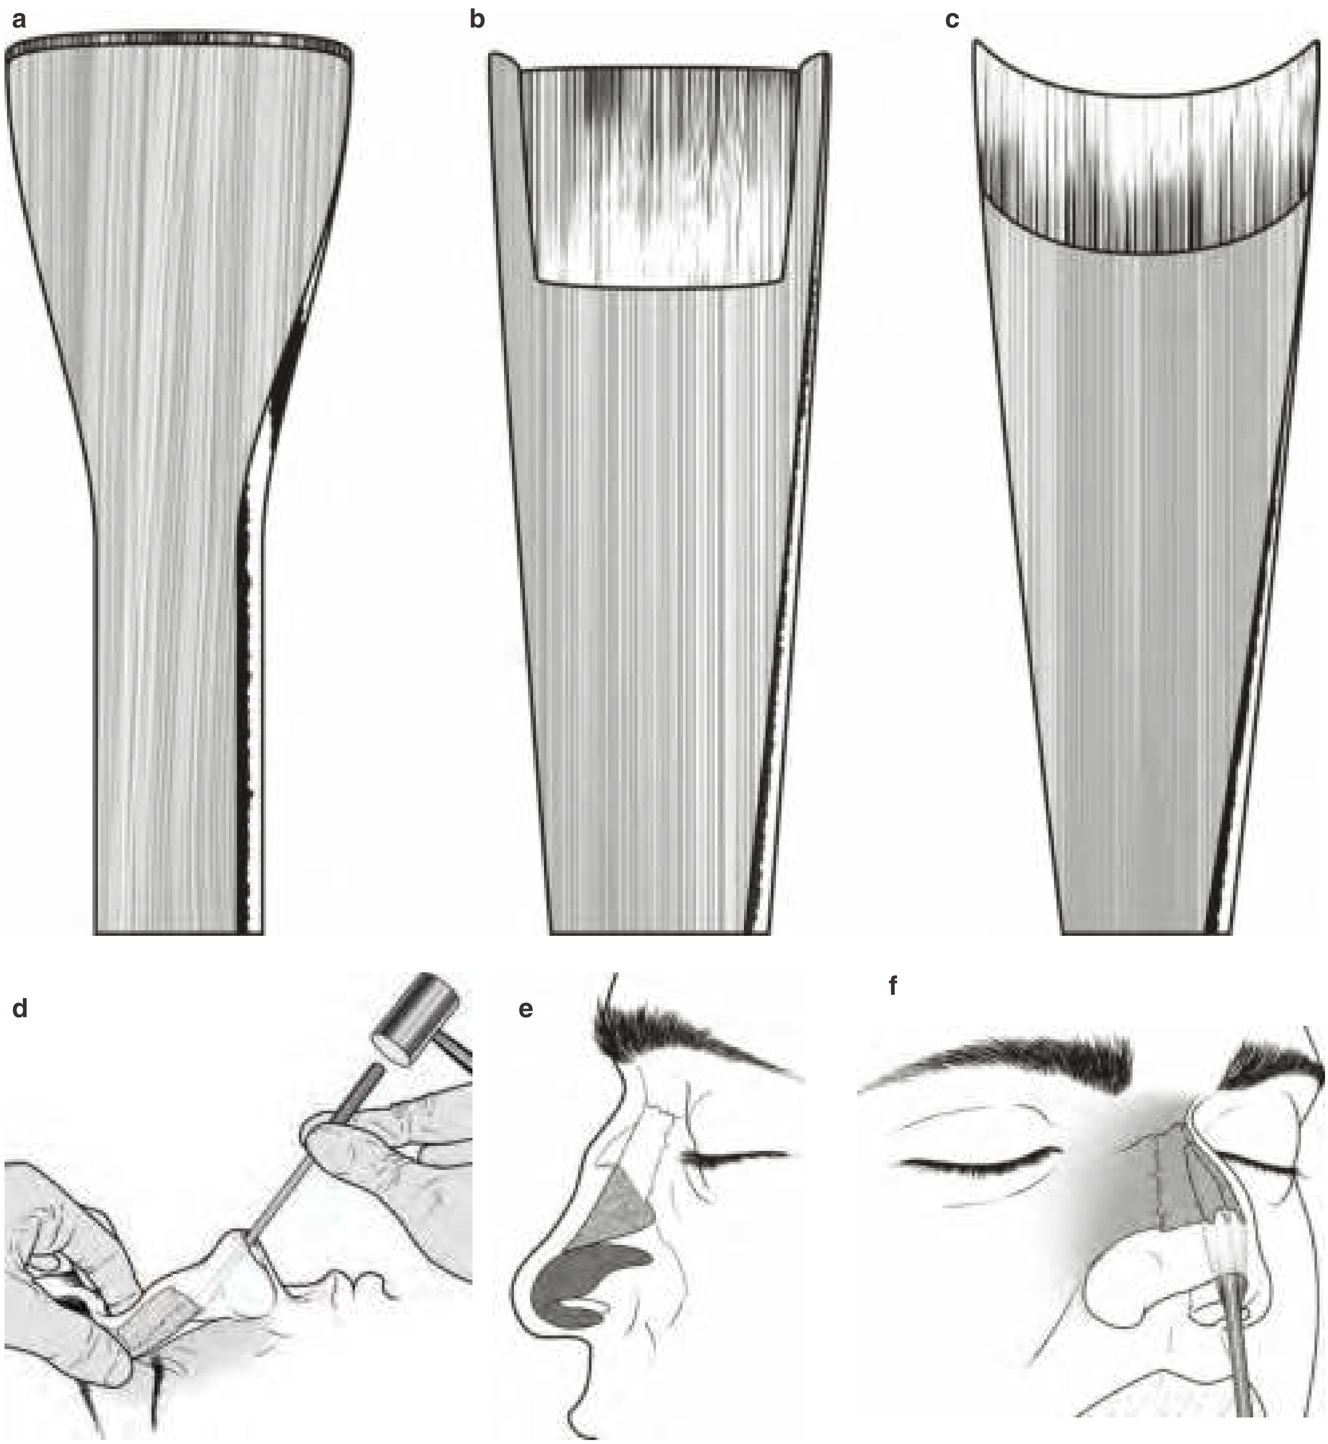

Fig. 38.23 Hump reduction technique: Armamentarium (**A**, **B** & **C**). Surgical technique (**D**, **E** & **F**) Removal of the dorsal hump with the osteotome, (**G**–**K**) Preparation of the "open roof" deformity for closure

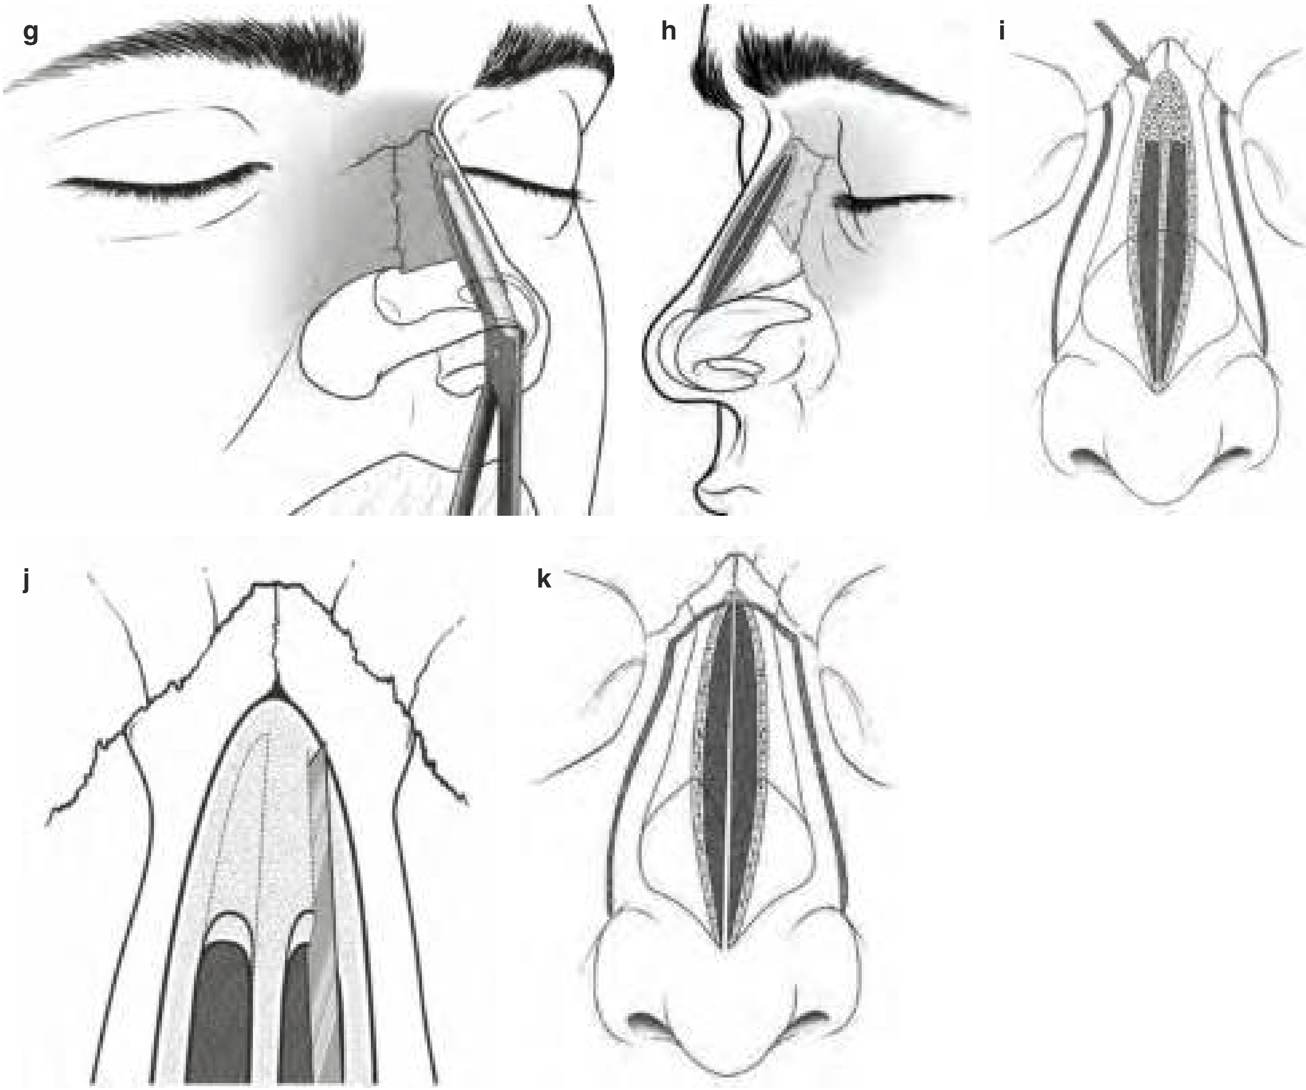

©Association of Oral and Maxillofacial Surgeons of India

Fig. 38.23 (Continued)

middle vault and substance abuse (cocaine), diseases like congenital syphilis/leprosy and racial predisposition—African, Afro-American, and Asian.

38.5.2.2 Clinical Features

The salient features (Fig. 38.24) demonstrable on a patient with saddle nose deformity are enumerated in Box 38.8.

The septum may exhibit deformity with twisting/deficiency or at times may be totally absent.

The skin and soft tissue envelope may show a "concertina" effect due to loss of structural support.

38.5.2.3 Surgical Management (Fig. 38.25a, b)

Surgery for the correction of saddle nose deformity may be planned in a staged manner with the first stage involving the correction of the foundation of the nose and the second stage involving the aesthetic makeover [25, 26]. The aim of the procedure is to re-establish the tension between the nasal tip

Box 38.8 Features of saddle nose deformity

Frontal:

- Wide nasal dorsum
- Loss of dorsal lines
- Epicanthal folds due to the lateral movement of dorsal skin
- Loss of tip definition
- Increased tip width
- Presence of a flat alar-columellar line

Profile:

- Loss of dorsal height
- Marked concavity of the nasal dorsum
- Loss of tip support and projection
- Tip rotation may be increased or decreased
- Retraction of the columella
- Relative increase of the upper lip length (columellar skin migrates downward)

Basal:

- Wide alar base
- Shortened and deformed columella
- Loss of nostril orientation
- Ballooning of the internal nasal valve

Fig. 38.24 Saddle nose clinical photo

complex and the dorsum, which has been lost due to the concertina effect.

Surgical correction involves three essential steps that are independent of each other.

- Establish the height and length of the septum to restore structural support to the entire nose. This involves the use of a robust septal extension graft, fashioned from harvested rib cartilage (preferably the eighth rib).
- Correction of the dorsal deficiency using a dorsal strut graft that extends from nasion to under the domes.
- Provision of support for the tip complex. This is achieved with the use of a columellar strut graft to restore tip projection.

This procedure involves the use of strong and robust cartilage grafts. The eighth rib provides an adequate amount of cartilage which is ideal for this situation. Ear cartilage lacks rigidity, while banked cartilage tends to undergo resorption.

38.5.3 Correction of the Deviated Nose

Deviated noses can be of two types

1. "Bent" nose where the nasal bones and the upper lateral cartilages point to the same side, and
2. "Crooked" nose where the nasal bones and the upper laterals face in opposite directions

38.5.3.1 Aetiology

The most common causes of a deviated nose

1. Developmental—unilateral cleft nasal deformity
2. Post trauma to the face and nose—following road traffic accidents, sports injuries or interpersonal violence
3. Iatrogenic—as a result of earlier surgical procedures; Maxillary impaction by a LeFort 1 osteotomy without addressing the septum or septoplasty with excessive scoring, resection and weakening

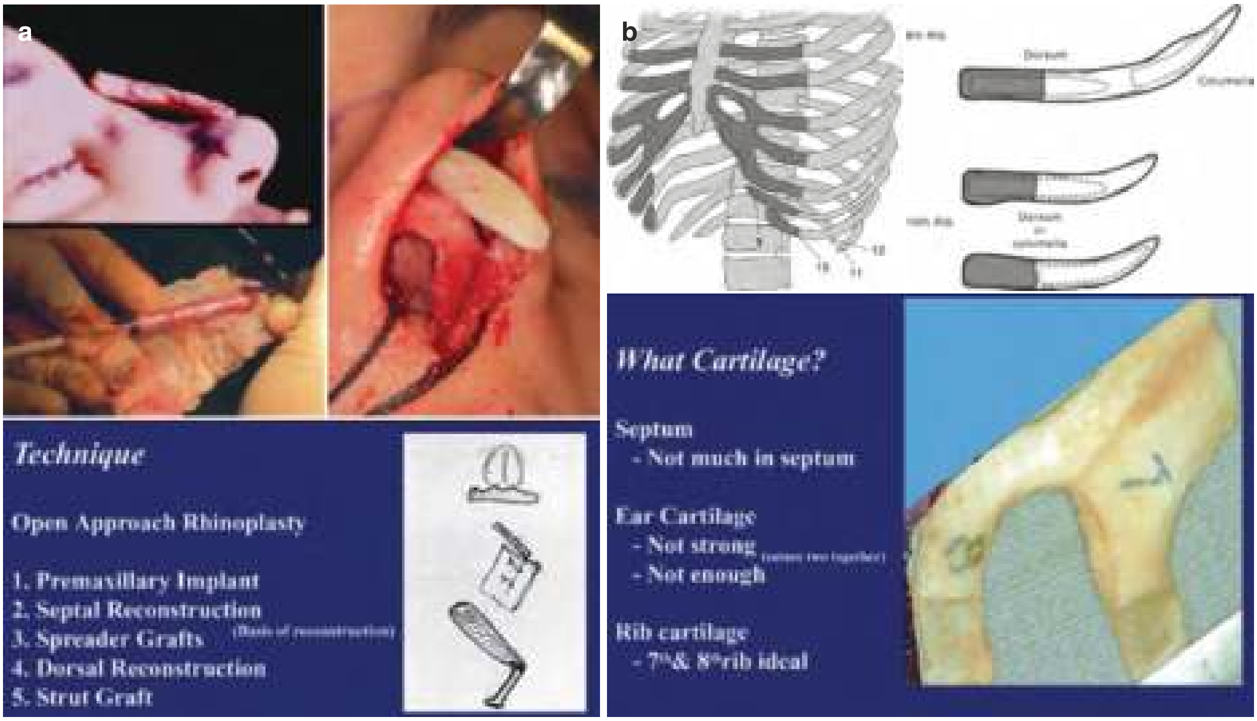

Fig. 38.25 Saddle nose-intra op. (**a**) intra-operative pictures demonstrating use of rib cartilage for dorsal nasal reconstruction. (**b**) Landmarks for rib harvest

38.5.3.2 Clinical Features

Clinical features of a deviated, bent or crooked nose include both functional and aesthetic issues

1. Blockage of the nasal airway, unilateral or bilateral
2. Visible deformities affecting the upper, middle and lower thirds of the nose
   (a) Frontal
   - Deformity of the nasal pyramid
   - Twisting or angulation of the nose
   - Constriction or bulge at the middle vault
   - Bending of the nose showing midline discrepancy
   - Unequal height of the nasal bones
   - Tip deformity secondary to the loss of septal support/angulation

   (b) Profile
   - Patient may present with a dorsal hump or a saddle deformity
   - Loss of tip projection
   - Nasal tip ptosis
   - Retraction of the columella

   (c) Basal
   - Deviation of the nasal tip or middle vault
   - Angulation or shortening of columella
   - Displacement of the caudal septum from the maxillary crest into the nasal vestibule
   - Nasal valve obstructions

   (d) Varied presentations of septal deformities (Mladini classification)

38.5.3.3 Treatment (Fig. 38.26a–g)

Septorhinoplasty is required to correct the deformity. Some prefer single-stage correction, while others may choose staged procedures (first stage septoplasty followed by a second stage external deformity correction). However, a single-stage correction is preferred. This is usually performed using an open structure approach with exposure and separation of the septum from the upper lateral cartilages. Straightening of the septal cartilage is performed by excision and/or partial division of the cartilage and may be followed by scoring or sutures as indicated. Some surgeons prefer the use of a PDS sheet to splint the corrected septum. However, costal cartilage may be harvested for reinforcement of the straightening

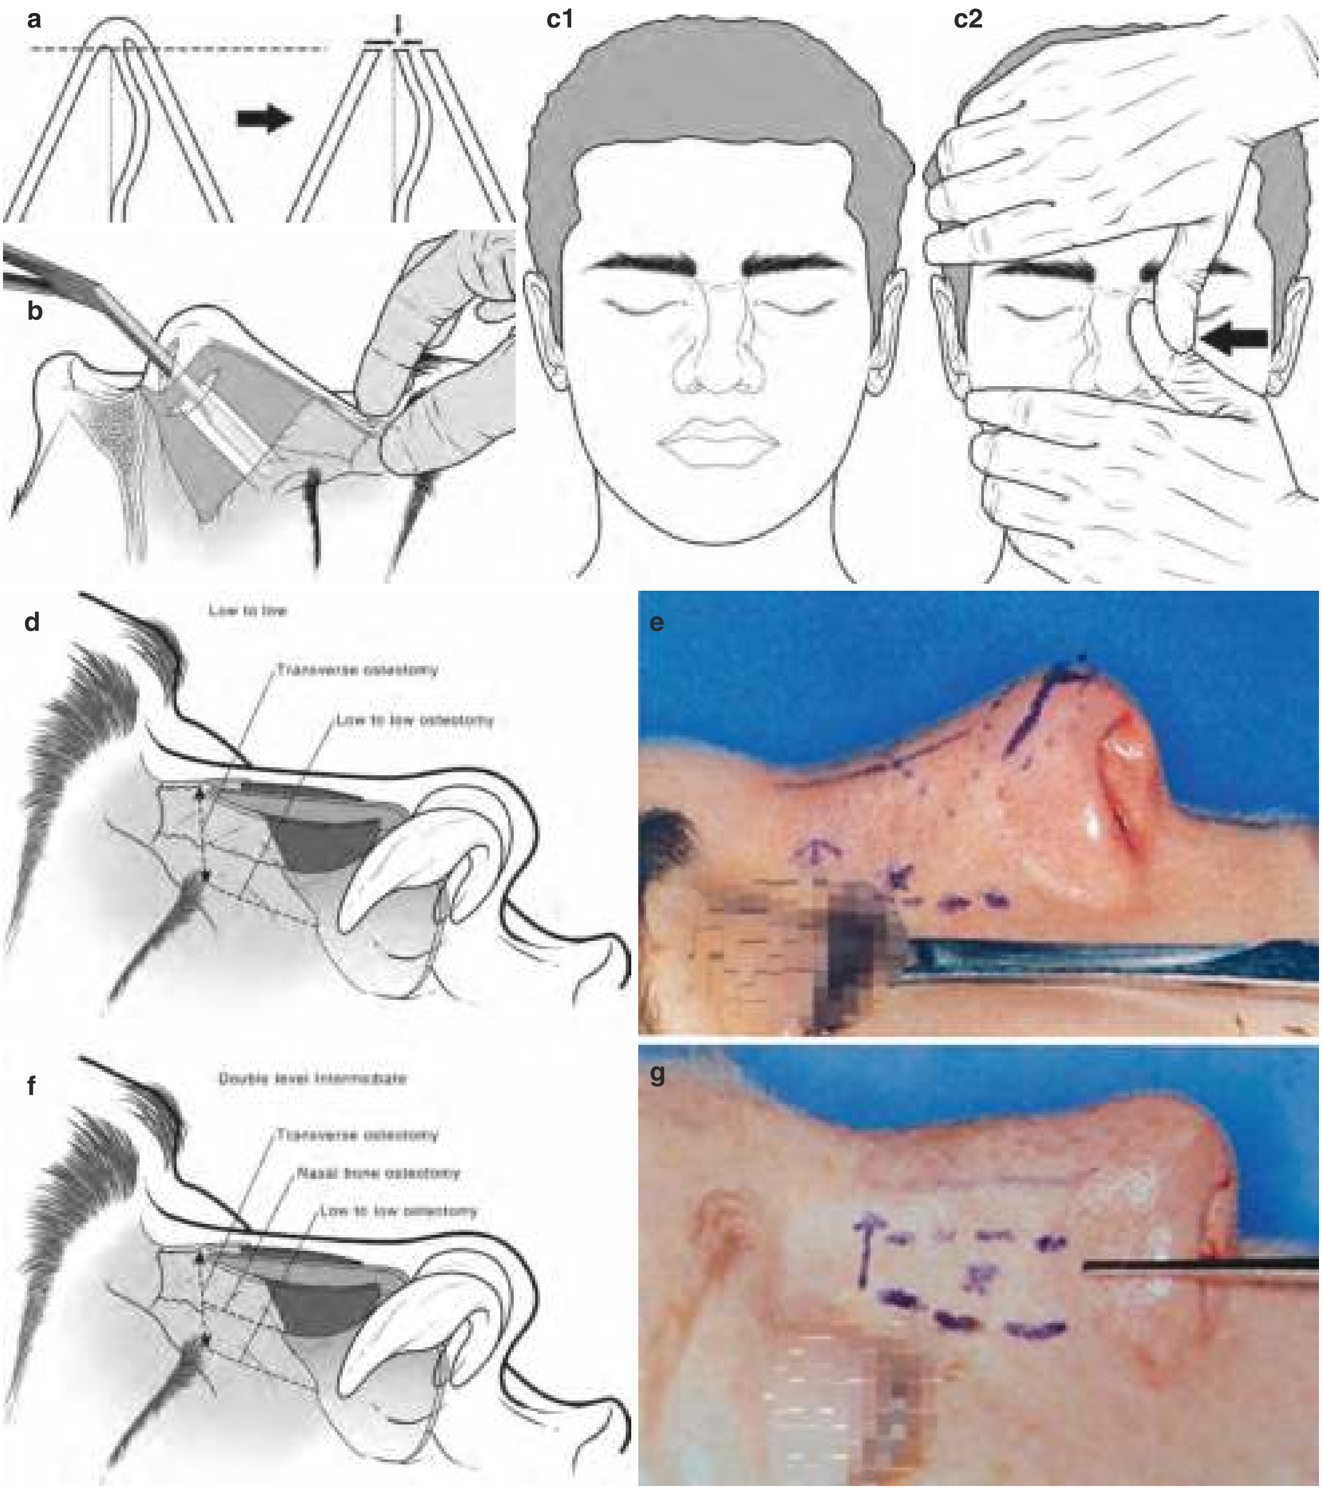

Fig. 38.26 Techniques of reduction of crooked nose deformity with twisting/angulation of septum, (**a**) differential reduction of hump prior to ostetotomy, (**b**) septal repositioning, (**c**) digital reduction/manipulation after osteotomy, (**d**) line diagram of "low-to-low" osteotomy, (**e**) intra-operative picture with osteotome positioning (low-to-low), (**f**) line diagram of "nasal bone osteotomy", (**g**) intra-operative picture with osteotome positioning (nasal bone osteotomy)

and to provide a spreader effect to correct the nasal valve simultaneously. Osteotomy of the nasal bones is often required to correct the angular deformity of the bony vault. A tip plasty may be necessary in most cases to correct the nasal tip tripod deformity secondary to nasal deviation.

It is to be borne in mind that the results for the correction of deviated noses are not always satisfactory. There is a possibility of residual deformity, recurrent deformity, loss of tip support and saddling.

38.5.4 Tip Plasty

The nasal tip is the centre of focus for both nasal anatomy and aesthetics. It is a very important anatomical subunit and can be most challenging to refine surgically.

Nasal tip deformities may show varied morphology and diverse clinical presentations (Fig. 38.27a–f). They may occur in isolation or concomitant with deformities of the dorsum or septum.

Fig. 38.27 Types of tip deformity. (**a**) Wide bulbous tip, (**b**) ball-ended amorphous tip, (**c**) plunging infra-tip lobule, (**d**) amorphous bulbous tip with deviation and constriction of right lower middle vault, (**e**) over-projection of nasal tip owing to prominent ANS & overtly long lower lateral cartilage with normal naso-labial angle, and (**f**) nasal tip over-projection with upward over-rotation

Tip deformities can be enumerated as follows as in Box 38.9.

38.5.4.1 Wide Nasal Tip

A tip is considered abnormally wide when the width of the tip is greater than the width of the dorsum. Normally, the tip width is equal to the width of the dorsum.

This can be further subclassified as mild, moderate or severe.

A wide nasal tip may be caused due to three morphological alterations:

1. increased interdomal width (wide interdomal angle)
2. increased intradomal width, where the domal angle is wide, and
3. increase in both intradomal width and interdomal width

Box 38.9 Types of tip deformities

- Wide
- Bulbous
- Over projected
- Under projected
- Over-rotated (piggy nose/toffee nose)
- Under-rotated (ptotic tip)
- Asymmetric

Surgical management

Surgery for the nasal tip can be performed either through a closed or open structure rhinoplasty approach. This may depend on the clinical indications involved as well as the skill and experience of the operating surgeon. Steps for correction of a wide nasal tip include reduction of the interdomal width by placing a permanent interdomal suture with 5-0 prolene or 5-0 PDS (semipermanent). This is followed by the creation of a new domal angle (transdomal suture followed by the interdomal suture). One should also consider surgical removal/excision of a segment of the intermediate crus for better tip definition (Fig. 38.28a, b).

38.5.4.2 Bulbous/Boxy Tip (Fig. 38.29)

Bulbous tips have problems associated with thick SSTE (skin & soft tissue envelope), excessive subcutaneous fat, strong convex and bulky lateral crura and a concertina effect of a shortened nose in general.

Surgical management

This involves careful degloving of the SSTE leaving the subcutaneous fibrofatty tissue on the lateral crura. Careful defattening and thinning of the subcutaneous plane should be performed. A modest cephalic trim is performed to correct the large and bulky lateral crura. As this is a more general deformity involving not only the tip but also the associated SSTE, a careful distribution of volume to produce balance may be required. This helps camouflage the deformity to a great extent while improving outcomes.

Excessive or injudicious defattening of the nasal tip may cause ischemia/necrosis of the skin of the nasal tip,

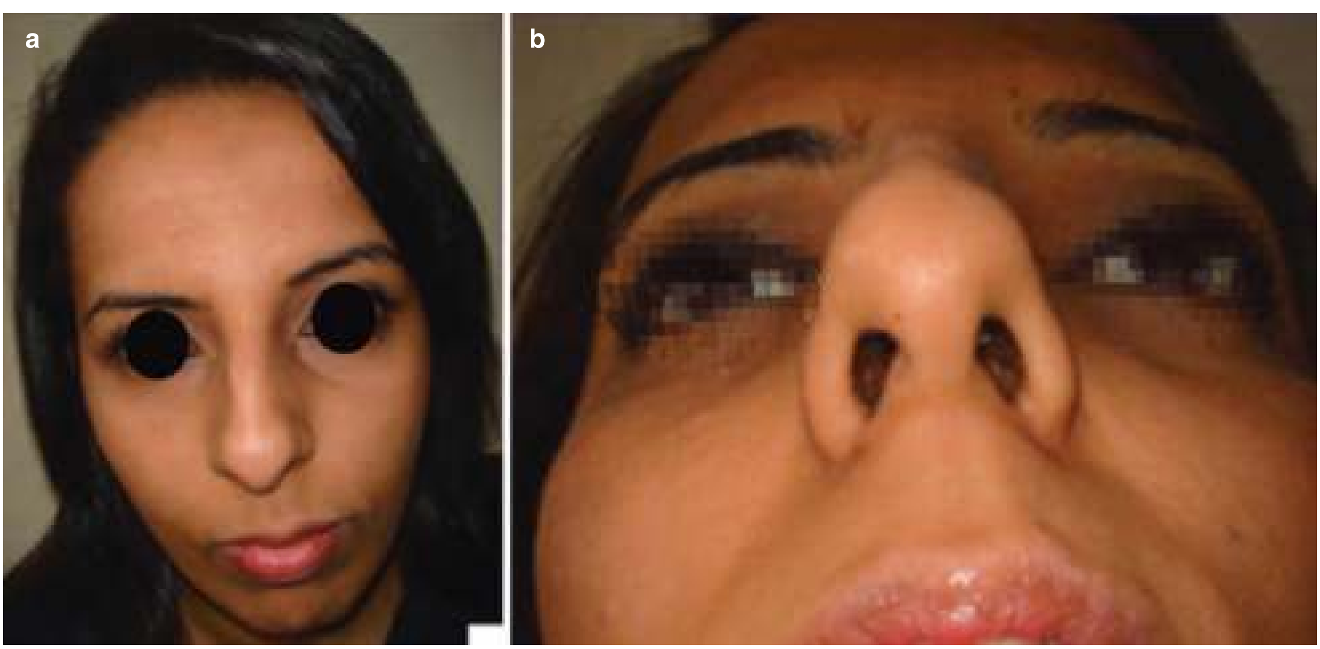

Fig. 38.28 (**a**, **b**) Wide nasal tip clinical

blanching of the tip skin with exposure to cold, contour irregularities of the underlying cartilage to become visible and may also lead to the skin pores communicating to the underlying tissues.

38.5.4.3 Overprojected Nasal Tip (Fig. 38.30a–c)

Nasal projection is defined as the distance along a perpendicular line from the vertical facial plane to the anterior most point on the nasal tip. The nose when not in normal facial balance can either be overprojected or underprojected.

The key to correction of the overprojected nasal tip is to establish the cause. This may be due to the increased length of the anterior nasal spine, excess caudal septal height or overtly long alar cartilages.

Fig. 38.29 Bulbous tip clinical

Surgical management

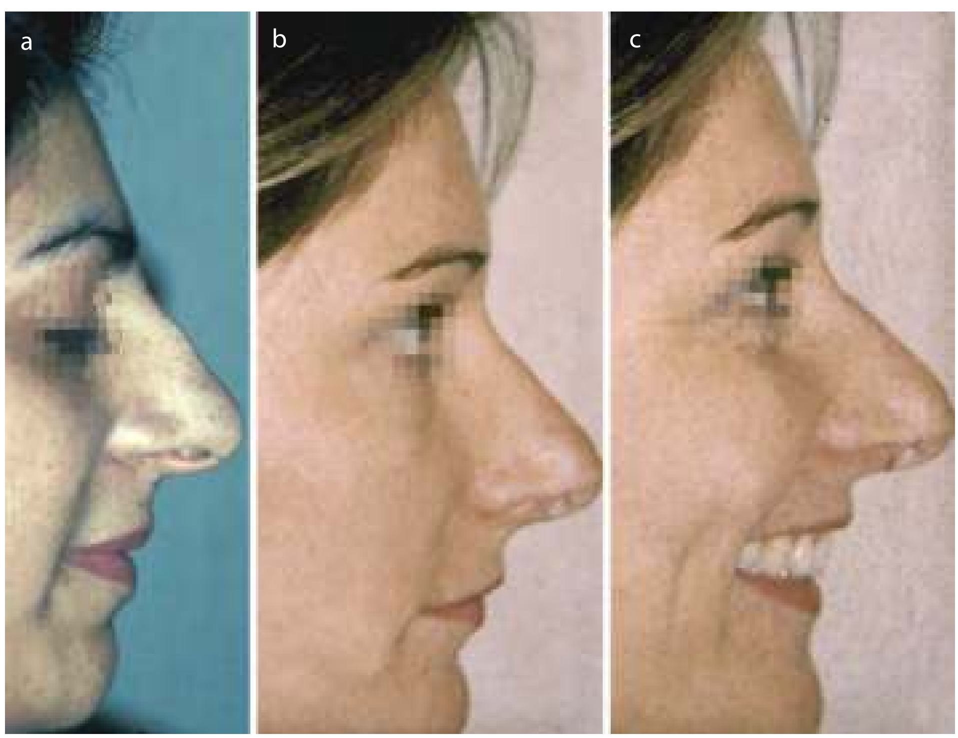
Surgery for the overprojected nose should be performed through a full bilateral septal transfixion incision with the aim of deprojecting the nose by 4–5 mm. The anterior nasal spine is reduced judiciously followed by the resuspension of the upper lip to the ANS. The anterior septal angle is lowered to achieve further deprojection. Deformities of the alar cartilage may be varied and may require division and overlap of the medial crura, division or resection of the medial footplates. A lateral crural overlap with resection of a segment is performed 1 cm from the dome. Domal resections are to be avoided as they may produce secondary deformities: irregularities, angulation, and bossa formation. They may produce a sharp angulation with a pointed tip (pinched nose), which may require a shield graft for tip camouflage. Care should be taken to avoid/prevent loss of tip support during these manoeuvres.

38.5.4.4 Underprojected Tip (Fig. 38.31a, b)

It is important to establish the cause for underprojection prior to treatment. Causes of underprojection may include

- Short medial crura (short columella)
- Underdeveloped lower lateral cartilages e.g. binders
- Deficient height of caudal septum

Fig. 38.30 Overprojected nasal tip (**a**) profile of patient 1, (**b**) profile of paitent 2 at repose and (**c**) profile of patient 2, smiling



- Deficient or absent anterior nasal spine/premaxilla
- Bilateral cleft lip nose

Surgical management

Surgery for the underprojected nose should follow the sequence provided below: the columella is strengthened with a strut graft, a transdomal suture is placed to project the dome. A shield, cap or an umbrella graft may be used to increase tip projection. A caudal septal extension graft is added to strengthen the septal support and increase projection. Finally, a transcolumellar suture is performed through the medial foot-plates. In patients with the deficiency of the premaxilla or the total bony maxilla (cleft maxillary hypoplasia) where loss of bone support contributes to the loss of nasal projection, advancement of the maxilla or Onlay grafting of the premaxillary segment may offer the correct solutions.

38.5.4.5 Over-Rotated Tip (Piggy Nose) (Fig. 38.32b)

Tip rotation denotes the angle formed by the columella to the upper lip. The point of reference here is the nasolabial angle. Deformities of the nasal tip related to the rotation can be either over-rotation or under-rotation (ptotic nose).

Over-rotation of the nose may arise due to various causes: post-traumatic (caudocephalic impact to the nose) or an inherently short nose. Over-rotation may also be a complication of prior rhinoplastic procedures due to over-zealous caudal septal reduction, excessive cephalic trim of the lateral crura or injudicious lowering of the anterior septal angle.

Surgical management

Surgery for the correction of over-rotation of the nasal tip should include techniques for de-rotation of the nose like placement of a caudal septal extension graft and/or extension of the dorsal graft beyond the domes. These procedures require extensive cartilage grafting to lengthen the shortened nose.

38.5.4.6 Under-Rotated Tip (Ptotic Nasal Tip) (Fig. 38.32a)

Under-rotation denotes cephalocaudal rotation of the nasal tip, which makes the tip point downward. This needs to be differentiated from an underprojected tip. However, occasionally both problems may co-exist. It is also important to identify the presence of pseudo-ptosis in which the tip is normal but a more prominent anterior septal angle makes the tip appear ptotic.

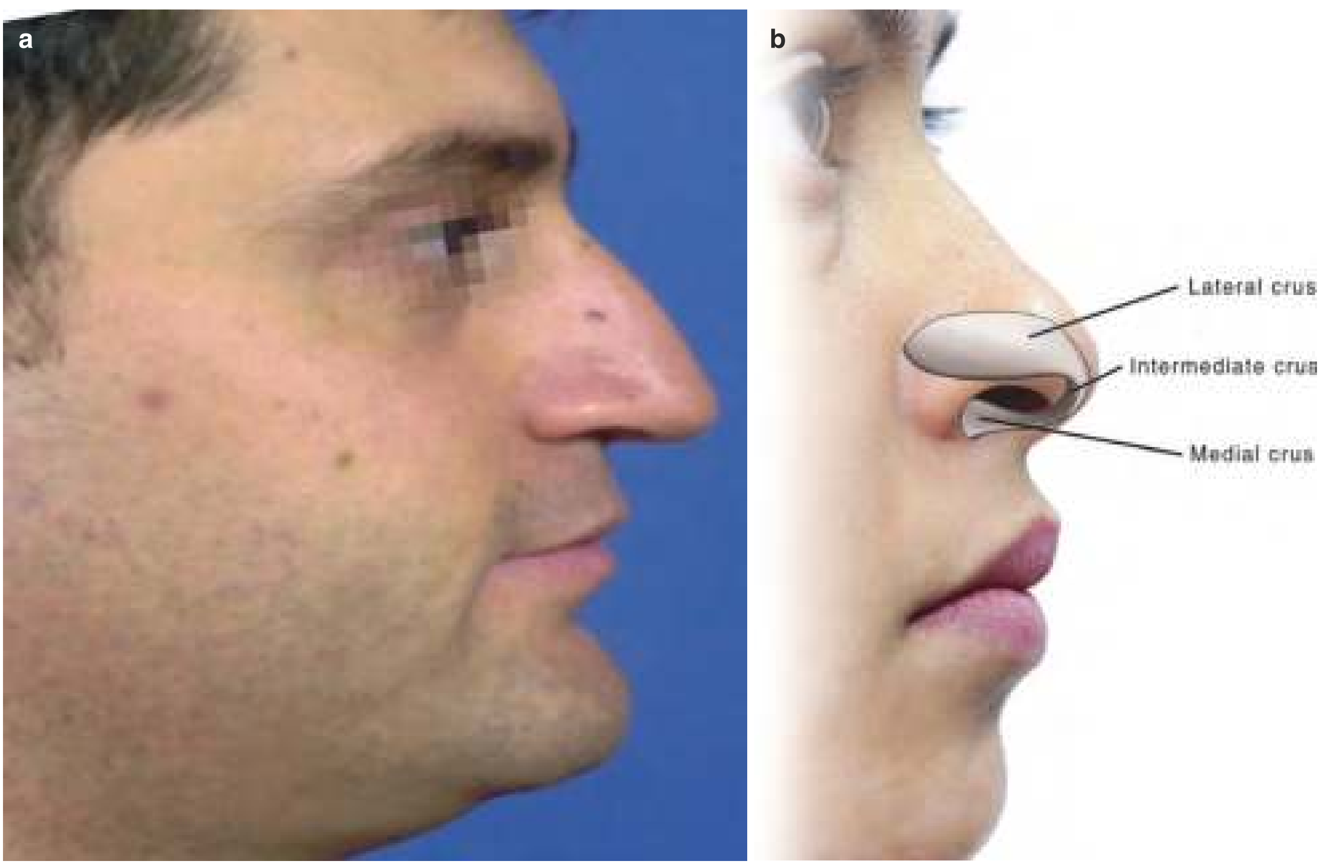


Fig. 38.31 Underprojected tip. (**a**) Clinical picture and (**b**) diagrammatic representation

Ptotic tips need to be examined both at rest and dynamically. The dynamic inferior movement of the nasal tip may occur due to the downward pull of a strong depressor septi muscle. Care should also be taken to look for any other associated deformities.

Causes for an under-rotated or ptotic tip may be hereditary as in the noses of people from the Mediterranean countries, developmental due to heavy SSTE and weak cartilages or the presence of excessive skin in the membranous columella. Patients with bilateral cleft lip deformities are predisposed to have underprojected and under-rotated noses due to columellar deficiency.

Iatrogenic causes for tip ptosis include: poorly planned and executed septorhinoplasty with loss of septal support, inadequate maintenance of tip support or reattachment of the tip support structures. It may also be a complication following (1) prolonged intubation with the nasotracheal tube not anchored well and (2) tumour ablations with inadequate reconstruction.

Surgical management

Correction of the ptotic tip should be based on the anatomy involved. It is best to follow an algorithm for planning the surgical procedure. The structures contributing will enable us to plan and perform the correct procedure.

- An elongated septum producing the ptosis is corrected by a wedge excision of the excessive septum and the overlying mucosa (Fred technique).
- Elongated lower lateral cartilages can be managed by two methods depending on the tip projection; in underprojected tips, a columellar strut is provided for enhancing support and augmented with the tip rotation suture, while in the case of an overprojected tip, transection of the LLC is performed with overlapping and suturing. The tip rotation suture may be optional depending on the clinical indication.
- In the case of a shortened medial crura, a columellar strut or a medial crural anchor suture is placed with the tip rotation suture again being optional.

38.5.5 Managing the Wide Ala

The normal width of the ala falls within or just beyond an imaginary vertical line dropped from the medial canthus to the upper lip. The ala may be either narrow or wide. A wide

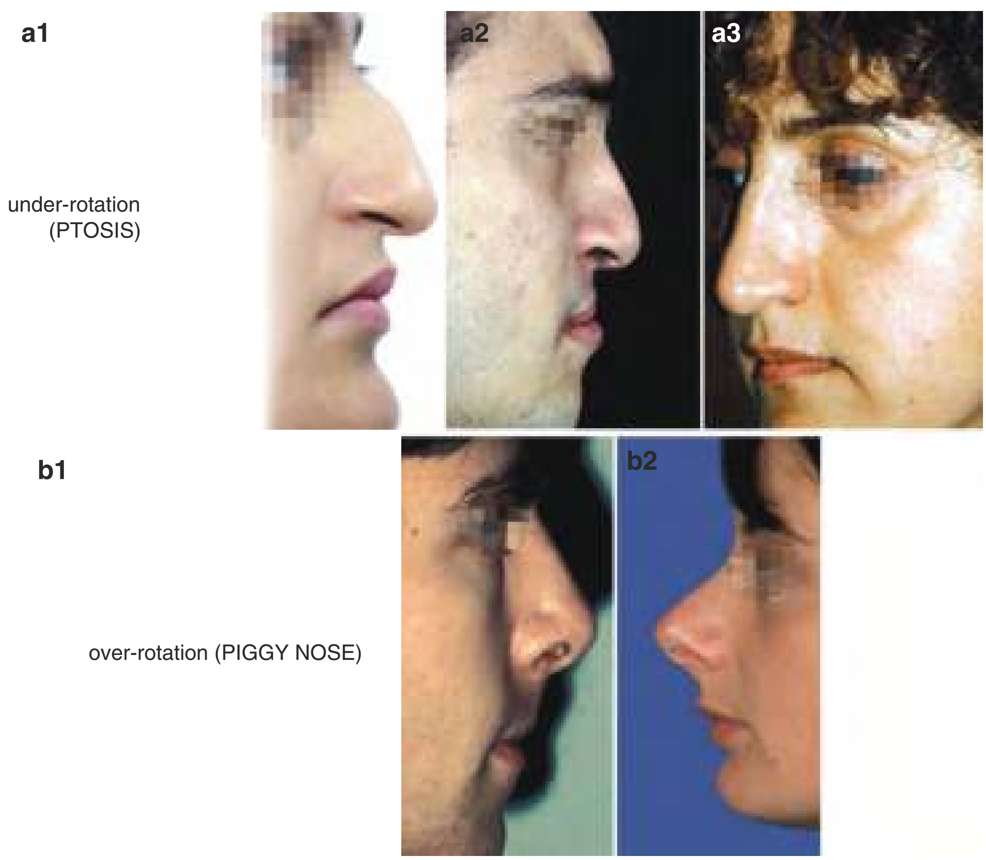

Fig. 38.32 Nasal tip rotations clinical. (**a1**, **a2**, **a3**) Under-rotation of tip and (**b1**, **b2**) Over-rotation of tip

ala compromises facial aesthetics and is often a complaint for which the patient seeks help.

38.5.5.1 Causes of Variations in Alar Base Width

A wide alar base may be a characteristic of racial variations, for example, African and Asian races exhibit increased width of the alar base. It may also be wide in patients with congenital anomalies like cleft lip and palate. Wide alar base may also be due to iatrogenic causes like

1. after a Le Fort 1 maxillary advancement or impaction surgery,
2. injudicious rhinoplasty with loss of tip projection due to loss of septal support

38.5.5.2 Clinical Features

Patients with a wide alar base exhibit a nose that looks flat and broad; the alar columellar line may be straight and they may have an associated wide nasal tip. In the basal view, the nose presents with reduced tip projection and short or distorted columella. The alar side walls show increased bulk and increased flare, and the alar insertion into the nasolabial area may be horizontal or oblique. The alar sill width may also show an increase. The premaxillary base that supports the alar complex may be normal, deficient or asymmetric.

38.5.5.3 Evaluation

The nose should be evaluated for the cause of alar widening. This is the basis on which the treatment may be planned. When there is a doubt regarding the width of the ala, it may be wise to abandon the idea during a primary rhinoplasty and perform the alar correction as an isolated secondary procedure.

38.5.5.4 Surgical Treatment (Fig. 38.33a, b)

Surgery for the wide ala needs to be sequenced after assessment of the cause; this may be a wide ala demonstrating

1. significant flaring,
2. flaring with increased sill width,
3. rarely isolated increase of sill width and
4. presence of a lateral insertion of ala on the face.

- The treatment of choice for the flaring ala is wedge excision (Weir) (Fig. 38.34), which helps to preserve the natural contour of the ala as well as provide a good camouflage

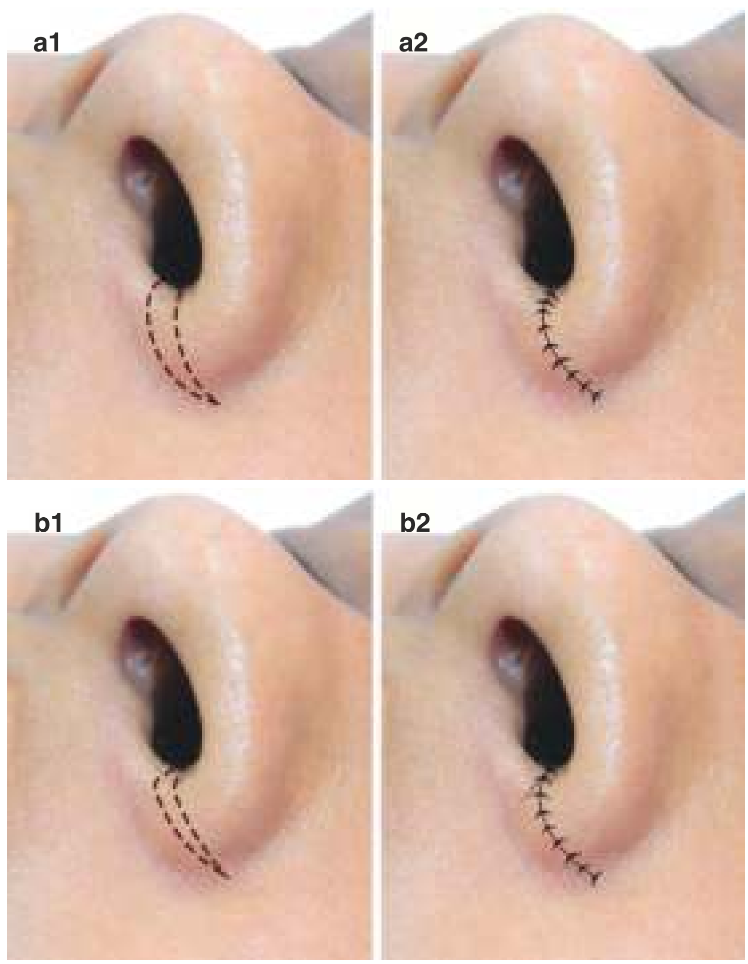

Fig. 38.33 Wide ala surgery techniques. (**a**) Traditional Weir excision (leaves a notch deformity) and (**b**) modified excision incorporating a lateral advancement which prevents notch deformity and restores continuity of alar rim

Fig. 38.34 Wedge technique for alar base reduction

of the scar. A medial flap excision technique as described by Sheen may also be a good alternative to this. The decision regarding medial repositioning of the alar base should be in accordance with Sheen, who recommends it only in cases of extreme lateral divergence.

- When flaring is associated with a wide sill then a wedge with a sill excision may be preferred to correct the deformity. In rare instances an isolated sill excision may be indicated for a problem of increased sill width alone.
- When the nose demonstrates a lateral insertion of the alar base on to the face, then a "V to Y" plasty is performed as described by Bernstein, which helps relocate the alar base medially.

38.5.6 Septal Perforations

Septal perforations are pathological defects in the nasal septum which form communications between the right and the left sides of the nasal cavity. These may present as anterior, mid-septal or posterior perforations (Fig. 38.35a, b).

The most common aetiological factors producing septal perforations are

1. Cocaine misuse
2. Trauma to the face and nose—e.g. NOE fractures
3. Iatrogenic—injudicious septal surgery or poor techniques during septorhinoplasty
4. Self induced—obsessional nasal toileting or habitual nose picking
5. Granulomatous diseases
6. Malignancy

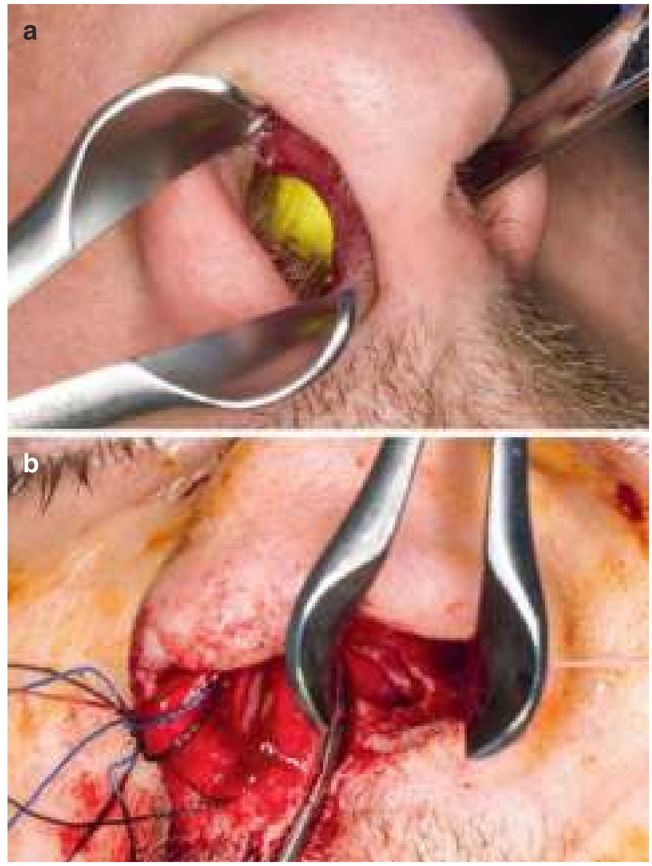

Fig. 38.35 Septal perforation; (**a**) clinical presentation, (**b**) intra-operative picture

38.5.6.1 Clinical Features

The occurrence of septal perforations also leads to a variety of sequelae that produce secondary deformities of not only the nose but also significantly affect the face and the oral structures. The nose may show a saddle deformity, columellar retraction and narrowing of the nasal valve. Furthermore, the loss of nasal cartilage and bony framework may lead to a concertina deformity of the skin envelope. Perforations may expand in an inferior direction with associated necrosis of the vomer and maxillary crest, thus causing a palatal fistula. Other symptoms include nasal airway block, nasal discharge, crusting, epistaxis, midfacial pain, and a characteristic whistling noise.

38.5.6.2 Investigations

Investigations for perforations of the nasal septum include a thorough clinical evaluation of the nasal cavity, oral cavity and the face for accurate diagnosis. The patient is also subjected to a rhinoscopy and a nasendoscopy for assessment of the intranasal deformity. This is followed by a biopsy from the margins of the perforation. A swab may also be performed for culture and sensitivity when there are signs of acute infection of the region.

38.5.6.3 Treatment

Treatment is initiated in a conservative form with counselling, wound care and topical medication. This involves abstinence from cocaine use with rehabilitation under supervised care. Regular inspection of the nasal cavity and nasal toileting with seawater douches. Topical administration of Naseptin cream alternating every 2 weeks with Bactroban (Mupirocin) ointment is mandatory prior to surgical intervention.

Surgical management (Fig. 38.36a, b, c) for septal perforations is extremely challenging and often give disappointing results. Any treatment is bound to be compromised due to resurgence of the cocaine addiction and poor vascular status of the involved anatomy resulting in a high incidence of residual defects after surgery.

There are also risks of total failure of procedures with secondary donor site deformities, adding to the post-surgical morbidity in these patients.

38.5.7 Nasal Valve Problems

To understand the problems associated with the nasal valve, it is important to see the distinction between the "nasal valve area" or the internal nasal valve, the "nasal valve" and the external nasal valve: The nasal valve area is the empty triangular space that is bounded medially by the nasal septum, laterally and superiorly by the caudal margin of the upper lateral cartilage and its attachment to the pyriform rim and inferiorly by the bony nasal floor. The nasal valve specifically denotes the slit that is seen between the caudal end of the upper lateral cartilage and the nasal septum. Physiologically, the internal nasal valve is the area offering the highest resistance to airflow, and any deformities of this region may compromise the air-flow dynamics.

38.5.7.1 Anatomy of the Nasal Valves

The components of internal and external valves are projected in Box 38.10.

The aetiology of nasal valve problems are enumerated in Table 38.4.

Box 38.10. Components of nasal valves

Components of the external nasal valve	Components of the internal nasal valve
• Alar rim and alar side wall • Columella • Caudal septal margin • Nasal sill	• Caudal septum • Caudal margin of the upper lateral cartilage • Floor of the nose • Head of the inferior turbinate

Table 38.4 Etiology of nasal valve problems

External nasal valve	Internal nasal valve
• Inherently weak alar sidewall (collapsing on inspiration) • Caudal septal deflection • Deviated footplate of the medial crus • Narrow/scarred nasal sill • Wide columellar base • Iatrogenic causes (knock-knee deformity of the alar sidewall due to excessive cephalic trim) • Medialisation of lateral crus following domal suture	• Caudal septal deviation • Mid-septal bulge impinging on the upper lateral cartilage • Inferior turbinate hypertrophy • Iatrogenic causes – Misplaced intercartilagenous incisions – Medialisation of the inferior turbinate due to an injudicious lateral osteotomy – Narrowing of the middle vault due to closing of an open roof deformity

Fig. 38.36 (**a–c**) Septal perforation surgical technique

38.5.7.2 Clinical Examination of Nasal Valve Problems

It is extremely important to identify the exact location of the nasal obstruction to obtain the best surgical outcomes. This can be accomplished using

1. Clinical testing using “Cottle’s sign”
2. Endonasal examination and rhinoscopy
3. Dynamic photographs or video recordings of the “external valve flutter”
4. Air-flow studies using CT scans and computer simulation models

38.5.7.3 Surgical Management

Sequencing of treatment for the management of nasal valve problems should include certain empirical steps. The first step is to perform an optimal septoplasty to relocate the septum to the midline. This is followed by straightening and strengthening of the alar sidewall using alar batten grafts and rim grafts. Narrowing of the columellar base may be performed in cases of true columellar widening. Collapse of the nasal valve can be corrected by the use of spreader grafts that help in widening. In certain cases, there may be webbing or scarring along the nasal valve area. This may need a “Z” plasty for release and correction. Finally, judicious removal of the inferior turbinate may be contemplated in indicated patients after due consultation with the ENT surgeon.

38.6 Complications Following Rhinoplasty

A sequela may be defined as a natural consequence following a disease process or a surgical procedure while a complication implies undesirable sequelae or process following surgery.

This section with dwell on the common sequelae and complications that may occur following rhinoplasty and will help providing tips for reducing or preventing complications.

Common sequelae following rhinoplasty may be tabulated as early and late in Box 38.11.

Box 38.11. Complications of Rhinoplasty

Early sequelae	Late sequelae
Swelling Bruising Paraesthesia Swelling of the tip and supratip area	Infra-orbital discoloration Loss of tip-lobule definition Lateral shortening False “polly-beak” deformity

Most sequelae are self-limiting and may not require any active intervention. However, it is imperative to follow certain steps to minimise or avoid complications as discussed below.

The key to minimising or preventing unfavourable outcomes depends on proper case selection after a thorough evaluation of the patient both physically and psychologically (perceived complaint vs objective deformity). A good clinical examination should follow with optimal documentation (clinical analysis and photographs). The subsequent consultation should include obtaining informed consent from the patients after discussion of the indications and anticipated complications associated with the surgical procedure. It is important to understand our limitations and accept them while not refraining from seeking professional help/support when needed.

Complications in rhinoplasty may depend on the area of surgery and the procedure performed as indicated below:

1. *Complications associated with the nasal dorsum* include loss of dorsal height, concavity or saddle deformity (due to over-resection), residual hump, supratip prominence or a true “polly-beak” deformity due to under-resection. There may be bony or cartilaginous irregularities (inadequate removal). An open roof deformity may present if the nasal bones are not infractured after hump reduction. An incomplete lateral osteotomy may result in a lateral wall step deformity, while medialisation of the upper lateral cartilages may result in an inverted “v” deformity. Another complication is the appearance of a visible dorsal septal edge.
2. *Complication of tip deformities* may present as a “pinched tip” or a “knock-knee” alar deformity (over-resection of the lateral crus). It may also show tip changes like “button-tip” deformity, tip/domal asymmetry, supra-alar concavity or alar retraction. Loss of tip support produces ptosis of the tip, loss of tip projection may produce infratip slip below the anterior septal angle and excess resection of the caudal septum may lead to over-rotation of the tip complex.
3. *Alar base reduction complications* may include narrowing of the nostril circumference, which may contribute to increased nasal airway pressure. The surgery by itself may cause a web scar at the alar-facial junction. It may also result in distortion and secondary deformity of the nose, cheek and lips.
4. *Complications following septal surgery* include failure to straighten, midline deviation, tip deviation secondary to caudal septal displacement and septal collapse leading to a saddle nose deformity. The columella may develop retraction or scarring and rarely necrosis.

   The skin and soft tissue envelope may also show scarring, ischemia/discolouration and at times telangiectasia.

Management of complications may be necessary when the deformity is visible to both the surgeon and the patient. This necessitates revision or secondary surgery which may be indicated in about 5–8% of the patients. Even when indicated, it is better to wait for a year prior to attempting revisions or secondary interventions. This is to facilitate a careful assessment of long-term changes following the procedure and the final outcome prior to intervention.

38.7 Conclusion

Rhinoplasty in most realms is considered as the epitome of aesthetic surgical skill. This burdens the surgeon with the responsibility of performing the surgery with accurate planning and prediction of outcomes. It is also important for both the young surgeon and the patient to understand that the final outcome of the surgery is not in the immediate future but is a culmination of all the surgical manoeuvres and their response over a period of time. This is the same fact that makes rhinoplasty among the most difficult to master. Rhinoplasty has transgressed from the early procedures of sole nasal reduction to encompassing not only the aesthetics of the nasal complex but also improvement of the function and establishing a balance for today's patient. This chapter is aimed to provide the reader with the basics of surgical techniques. Perhaps, this is one surgical skill where the surgeon still holds all the cards while the others are losing the battle to technology.

Advances in Oral and Maxillofacial Surgery

39 Lasers in Oral and Maxillofacial Surgery

Shravan Renapurkar and Robert A. Strauss

39.1 Introduction

The first successful demonstration of laser was performed by Maiman in 1960 who also predicted one of its uses to be in medical science [1, 2]. Decades after the first medical use in the oral cavity and face, lasers are not just an adjunctive tool today but are an integral part of an Oral and Maxillofacial Surgeon's (OMS) armamentarium. Although CO_2 laser has been the traditional workhorse for an OMS, advancement in the capabilities of CO_2 lasers, as well as the development of other types of lasers, has helped grow their utility. Increasing use of lasers in turn has created greater evidence of its efficacy and safety record. Use of lasers has not only added advantages to conventional OMS procedures, as opposed to a scalpel, it has also given rise to newer procedures, which were not possible with conventional tissue-cutting tools.

39.2 Laser Physics

Modern lasers are simple to use but a lack of knowledge on the physics of lasers, inadequate training and caution in handling lasers, can give rise to potential adverse outcomes and unwanted complications. The term "laser" stands for light amplification by stimulated emission of radiation and was first used by Gordon Gould in 1957 [3]. The laser, as opposed to a regular light source, is composed of monochromatic, coherent and collimated beams, which, when they strike a suitable target, create photoacoustic, photochemical, photoablative, and photothermal effects. Laser light energy can undergo absorption, reflection, transmission, and scattering based on the optical properties of the target tissue or matter. For surgeons, the most desirable action is absorption into the tissue, which creates the predictable photothermal outcome of coagulation and then vaporization of tissues [4].

The basic component of a laser unit includes a "laser cavity" where the laser beam is produced via the phenomenon of stimulated emission as postulated by Albert Einstein. The laser cavity is composed of an active medium, an excitation source acting as a pumping mechanism, and an optical resonator (Fig. 39.1). The active medium is the chemical (gas/liquid/solid) that the type of laser is named after and is the material that undergoes stimulated emission. The photons of energy produced are collimated and amplified to produce the laser beam, which is then delivered to the target tissues via an appropriate delivery mechanism, either a flexible fiberoptic system, semiflexible hollow waveguides, or articulated mirrored arms (Fig. 39.2a–c). Lenses focus the active laser beam to create a "focal point," the point at which the energy is condensed to the smallest area to create the maximum effect. Some fiberoptic laser systems utilize a quartz or sapphire crystal at the tip of the fiber to enable the beam to be absorbed by this crystal and allow contact with tissues at the tip of the fiber, while others are used in a noncontact mode. A laser beam is an electromagnetic beam of radiation, which can fall anywhere in the spectrum of visible or invisible light. Nd:YAG, CO_2, and erbium lasers fall into the infrared invisible spectrum; hence, they are often accompanied by a visible aiming beam, which helps the surgeon to know the point in the tissues where laser beam hits the target tissues. Aiming beams can be another low power laser or a regular light source [4] (Fig. 39.3).

The factors related to the use of lasers that are under control of the surgeon include the spot size, power, and time on target. The spot size of the laser is the width of the laser beam on target. At the focal point, the maximum energy is focused to produce the smallest spot size or the thinnest possible incision but to the greatest depth. When the tip of the laser delivery system is moved away from the tissues, the laser beam diverges causing a bigger spot size and the energy is then distributed over a larger area and the related depth is

Fig. 39.3 Low-level laser-aiming beam

decreased [5]. Laser emission modes and the surgeon's hand speed can affect the temperature rise and effect in the tissues. Lasers can be emitted in "continuous-wave" mode or in a "pulsed mode." Lasers used in pulsed mode allow time for tissues to cool before the next pulse of laser radiation is started while continuous wave mode of laser must be stopped manually to allow the tissues to cool. The time between pulses can help avoid thermal effects on surrounding tissues or excessive thermal effect on target tissues. The lasers with pulsed mode of emission can be of two types, "gated pulsed" or "true pulsed." True-pulsed lasers are pulsed by a mechanism within the laser cavity, while the gated-pulsed lasers have a shutter-like mechanism outside the laser cavity [4].

39.2.1 Advantages of Laser

Lasers have obvious advantages, which make them superior to conventional cutting tools. An ability to provide better hemostasis is a great advantage for surgeons to maintain visibility and reduce blood loss. Since spot size, power, and time on target are regulated by the surgeon, lasers provide better control of desired tissue changes, which enhances the precision of surgery. Increased precision of the depth of tissue damage along with fewer myofibroblasts in laser wounds compared to scalpel wounds, allow for improved tissue healing and decreased scarring. The mentioned advantages are presumed to decrease postoperative pain with the use of lasers, although the pathophysiology for this effect is not well understood.

39.2.2 Disadvantages of Laser

Despite several advantages of lasers in surgery, the provider should make sure the benefits outweigh the risks and disadvantages. Hard-tissue lasers such as Er:YAG and Er:CR:YSGG do not match the speed of bone or tooth cutting as do conventional tools such as burs or saws. Soft-tissue healing after laser-assisted incision or excision is slower (although with decreased scarring) than tissue healing using scalpels. The associated learning curve and costs of the laser equipment add to the drawbacks of using lasers.

39.3 Selection of Lasers

The type of laser to be used is based on the laser's physical characteristics, interaction with the target tissues, and the goals of the procedure. For example, CO_2 laser's excellent affinity for water, which is the main component of soft tissues, makes it the most widely used laser for soft-tissue surgical applications. The most commonly used CO_2 laser is the 10,600-nm wavelength, although 9600-nm and other wavelength variants of this laser exist. The CO_2 laser is currently the most ideal laser used for most intraoral and extraoral soft-tissue procedures. The absorbed energy causes vaporization of the intracellular fluid causing tissue vaporization, while lateral heat conduction causes contraction of collagen and closure of blood vessels of approximately 500 µ or less in diameter. High-power CO_2 lasers are generally delivered via articulating arms, but new hollow waveguide systems suitable for office use provide increased accessibility intraorally along with their ease of use [6, 7].

Fig. 39.4 Diode laser

Other lasers include the Nd:YAG (a crystal of Ytrrium, Aluminum, and Garnet doped with the rare earth element Neodymium) laser, which functions in the near-infrared electromagnetic spectrum at 1064 nm, and has minimal water and superficial tissue absorption leading to deeper tissue penetration. Hence, the Nd:YAG can be used for coagulation of deeper and larger (2–3 mm) diameter vessels. These qualities of Nd:YAG have led to its use in treating angiomatous or vascular tissue lesions, although this same lack of water absorption limits its utility for the OMS. Depending on the desired effect, the Nd:YAG laser can be used both in contact and noncontact modes [8–10].

The Er:YAG laser works at a 2940-nm wavelength and is even more highly absorbed in water than the CO_2 laser leading to rapid absorption by the superficial layers of tissue and minimal penetration. This can be an advantage in some cases but also means that this laser is less effective on tissue than the CO_2 laser. As an example, when used for cosmetic skin resurfacing it shows much more superficial effects, which heal quite quickly, but also shows much less of a result than CO_2 laser does. For this reason, it has fallen somewhat out of favor for this purpose [11–15]. Owing to limitation of its thermal effects mostly in superficial layers of soft and hard tissue, Er:YAG laser has become popular in implant dentistry. It can be used on both soft and hard tissues and finds its application in bone preparation, second-stage surgery, treatment of peri-implantitis. Being reflected off the surface, it has minimal or no apparent adverse effects on dental implants [16].

The Holmium:YAG laser is generated at a 2100-nm wavelength, which enables it to be delivered in contact mode via fiberoptic cable also demonstrates very little water absorption but is well absorbed by other tissue components [17]. This allows it to be transmitted through water-rich environments while having similar tissue effects as the CO_2. Minimal lateral thermal damage, precise depth of cut, and good coagulation combined with its ability to be used in presence of saline/lactated Ringer's solution makes it the preferred laser for operative TMJ arthroscopy [18].

Diode lasers at wavelengths between 805 and 980 nm have been reported to be compact, inexpensive, and easy to use in OMS procedures (Fig. 39.4). These can be used in continuous or pulse modes with contact or noncontact handpieces. However, it should be understood that these wavelengths are not well absorbed by soft tissues (although pigmented tissue will absorb it the most), the use of this laser wavelength would lead to very limited effects on surface tissue and very deep, poorly controlled, and undesirable tissue penetration. This is bypassed by using a material on the tip of the fiber that absorbs these wavelengths (either pigmented material such as ink paper or a suitable crystal material) and creates a red hot thermal tip, which is then used in surgery. In reality, the laser wavelength produced is not actually used for surgery; it is only absorbed by the fiber tip to essentially produce a thermal cautery. Although diodes are cheap and easy to use due to their fiberoptic contact tip, this thermal cautery effect rather than the use of the actual laser beam is very inefficient for surgery and severely limits its use by the OMS [19].

39.4 Applications of Lasers in Oral and Maxillofacial Surgery

Three basic categories of application of lasers in OMS can be classified as follows:

1. Incisional/excisional procedures
2. Vaporization (tissue ablation)-based procedures
3. Surgical hemostasis

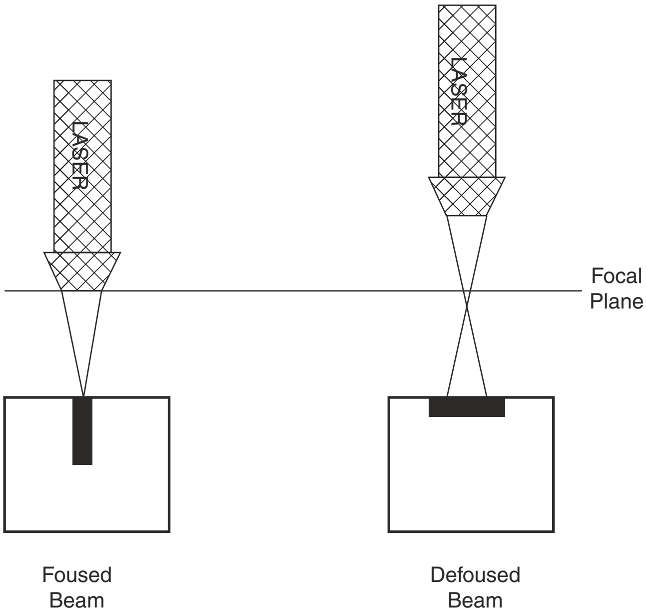

Fig. 39.5 Focused vs. defocused beam

Incisional procedures require a precise thin cut with careful control of the depth of the cut. The thickness or thinness of the cut with a laser is controlled by the spot size (usually 0.1–0.4 mm). The laser beam's focal length is usually between 1 mm and 1 cm, depending on the delivery system, and is where the smallest spot size can be achieved with maximum power density. This is called "focused mode" (Fig. 39.5). The laser can be controlled by a foot pedal, but it is often useful to limit time on tissue to speeds faster than a foot control allows. Hence, a "gated/pulsed mode" can be used to generate 2–20 pulses per second to create or mark a dotted outline with lesser depth and allow careful delineation of the margins of the excision. This is then followed by a continuous mode (using the foot pedal) to "connect the dots" and complete the excision. The settings to obtain a desired depth of cut vary from one tissue to another due their different water content and absorption coupled with the surgeon-controlled factors as mentioned earlier. It is not possible to have standard laser parameters for all types of tissues or lesions. The smallest spot size possible with 4–10 W power can be a good initial setting. The initial cut then gives the surgeon ability to observe the clinical effect and depth of incision, which then can be used to lead to adjustments of the power and time on target to achieve the desired changes. Common soft-tissue lesions that can be incised or excised using lasers include fibromas, mucoceles, epulis fissuratum, mucosal or gingival lesions, papillomas, etc. Wound closure after a laser-assisted incisional biopsy or excisional procedure is often unnecessary due to the limited scarring and excellent hemostasis and is up to the surgeon's discretion, as healing is excellent regardless of closure. Closure does not usually effect hemostasis or pain relief (Fig. 39.6a–c) [5].

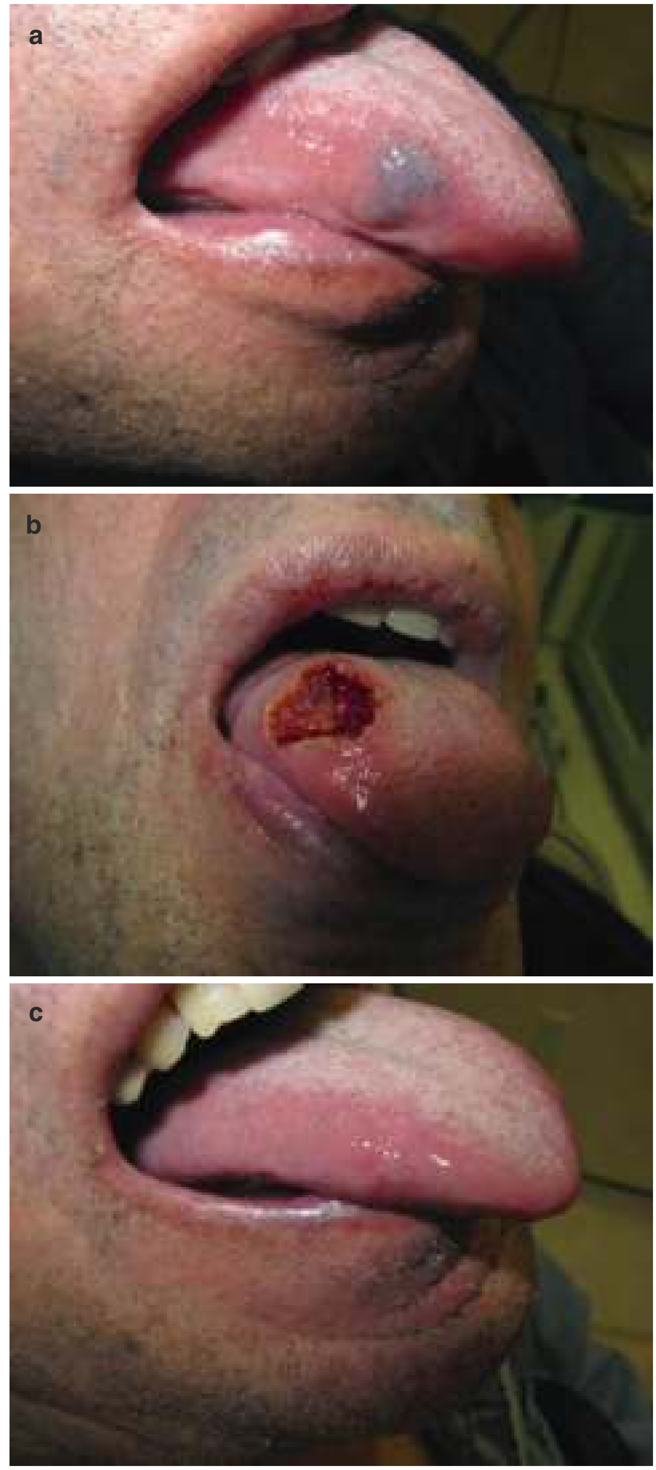

Fig. 39.6 (**a**) Lesion of tongue. (**b**) Tongue after laser excision with no closure. (**c**) Excellent healing

Ablative or vaporization procedures are done when the surgeon wants to remove only a superficial layer of the tissue. Lasers, cryotherapy, chemical peeling, and scalpel can be used for this purpose, but the precision of cut and control of the depth of tissue changes along with excellent hemostasis make lasers the preferred tool for vaporization procedures. Lasers, when used for vaporization procedures, are used defocused so as to decrease the power density (the energy per unit area) and limit the depth of effect while increasing the area of the tissue ablation. The spot size used for vaporization ranges from 1.5 to 3 mm and allows large surface areas to be removed very superficially (literally cell layers at a time if desired). This is ideal for large but flat and superficial lesions such as hyperkeratosis, dysplasia, lichen planus, etc. The laser is again used in gated mode to carefully and precisely outline the margins. This is followed by passing the laser in overlapping "U"-shaped patterns to cover the entire area. The parameters can be adjusted by the surgeon, just as in incision cases, after the first pass is done at 4–10 W power. As implied by vaporization, there is no tissue available for biopsy in these cases. Hence, a definitive diagnosis should be established prior to performing ablative or vaporization procedures on mucosal lesions (Fig. 39.7a–c).

Due to the ability of CO_2 lasers to constrict blood vessels rather than coagulate blood, it can be an excellent tool to obtain hemostasis in most surgical wounds where the vessels are smaller than the thermal effect of the laser in tissue (about 500 μ). The lateral thermal effect of the laser beam should be equal to or greater than the diameter of the bleeding vessels. If the vessel is of larger diameter, conventional hemostatic techniques should be used. For small superficial vascular lesions, the CO_2 laser can be used to excise the lesion (since the feeding vessels are usually smaller than 500 μ), while deeper or larger vascular lesions are best treated using lasers that are specifically absorbed by hemoglobin, leading to true coagulation of the lesion itself [6].

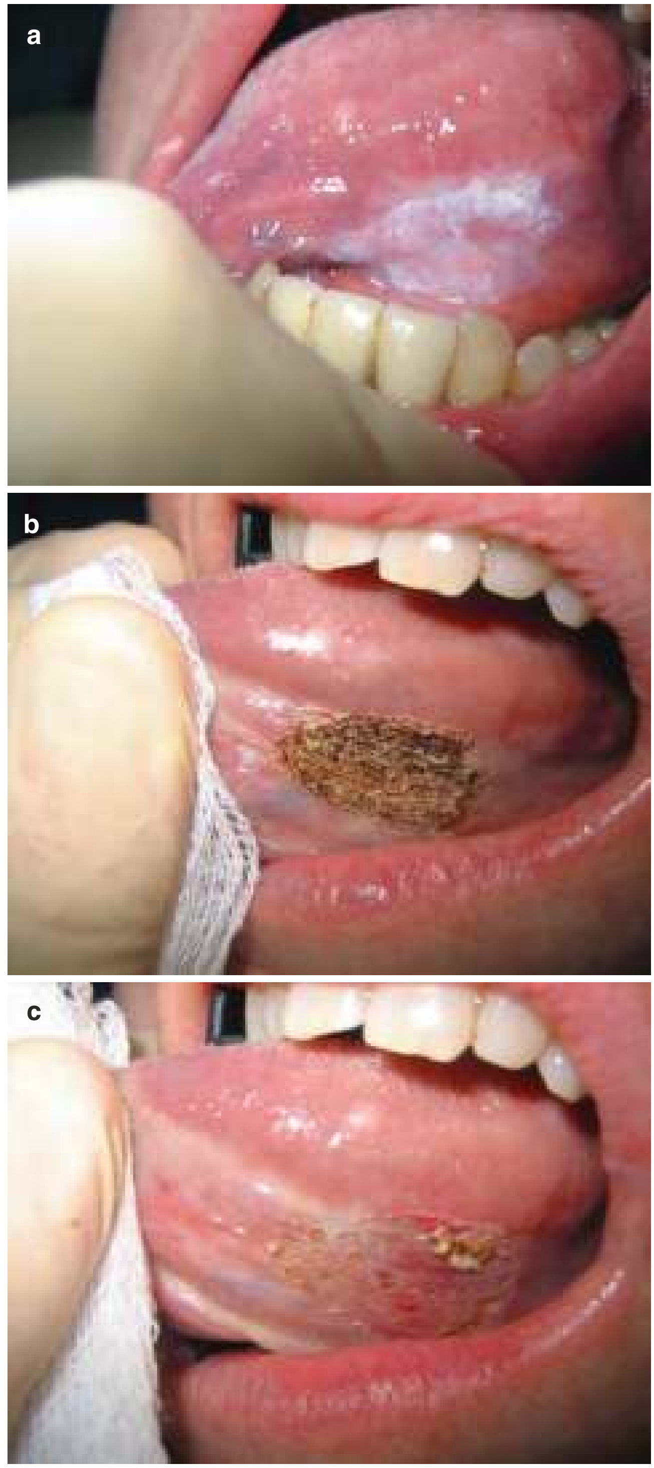

Fig. 39.7 (**a**) Hyperkeratosis of lateral tongue. (**b**) Laser ablation of tongue. (**c**) Healing after laser ablation

39.5 Specific Examples of Application of Lasers in Oral and Maxillofacial Surgery

1. ***Cosmetic facial surgery:***

   The use of lasers in cosmetic surgery has changed these procedures significantly over the years. The advantages of lasers as previously described, including the capability of lasers to only affect the superficial layers of skin with precise depth control, turned out to be its critical advantage. Lasers in cosmetic facial surgery can be used both for incisional or ablation procedures based on indication [20].

   Lasers used for laser skin resurfacing (removal of superficial skin wrinkles from the face) are an example of ablation or vaporization procedure. In skin resurfacing procedures, the superficial layers of the epidermis and papillary dermis are removed while leaving behind the reticular layer of the dermis with its adnexal structures. This layer, if intact, provides epithelial cells that are required for rapid re-epithelialization of skin in a uniform

Fig. 39.8 Laser cosmetic skin resurfacing of face

manner. As opposed to chemical peels or dermabrasion, lasers offer more precise depth control, which is crucial in uniform healing and improved outcomes. CO_2 and the Er:YAG are the commonly used lasers for skin resurfacing, although recent improvements in the way CO_2 is used to improve results with lessened postoperative healing time, have severely diminished the use of the Er:YAG. Although the CO_2 laser is most commonly used and is more effective, it can be associated with long-term erythema and greater risk of scarring if exposure is done too deeply. Since CO_2 is a continuous-wave beam, which means that even at a short "pulse" the laser would be on tissue too long and lead to scarring, it must be electronically "pseudopulsed" at high powers to obtain the short times needed to reduce risk from lateral thermal damage to the unintended underlying dermis (roughly less than 1000 μs). On the contrary, the Er:YAG laser has less penetration in skin owing to its higher affinity to water in tissue. It is also a true pulsed laser and hence it allows higher power with shorter pulse duration. Although this is an advantage of Er:YAG laser, which helps reduce risk of excessive ablation and scarring, as mentioned before, it also decreases the effectiveness and results of the Er:YAG laser and most surgeons have abandoned its use in favor of newer CO_2 lasers that create very deep but thin vertical columns in the skin, allowing for tissue contraction with quick healing and less chance of scarring [21].

In skin resurfacing, as opposed to ablation of intraoral mucosal pathology, the passes of laser should not be overlapping to avoid excessive tissue ablation (Fig. 39.8). Computer pattern generator handpieces (CPG) can be used, which automatically create a uniform pattern of coverage on the skin (Fig. 39.9a, b) [22].

Skin resurfacing principles are also used in scar revision procedures. The prominence or visibility of a scar is mainly affected by the surface depression or elevation. The CO_2 and Er:YAG lasers can be used to reduce the elevation of the scar tissue or decrease the elevation of the surrounding skin to make a depressed scar tissue blend well with it (Fig. 39.10a–c). Healing scars can also have hypervascularity as evidence by prolonged erythema. This can be managed by decreasing the vascularity within the scar by use of vascular-specific lasers such as 532-nm KTP:YAG or Pulsed Dye Lasers (PDL) lasers [23].

In blepharoplasty, the CO_2 laser can be used to make a transconjunctival incision on the lower eyelid as well as the skin incision for the upper eyelid blepharoplasty. The use of laser to then excise muscle or fat with excellent hemostasis provides great visualization and tissue control (Fig. 39.11).

In endoscopic brow lift techniques, lasers are passed through either flexible fiberoptic cables or through small diameter hollow waveguide extensions in order to be used for incisions made within the optic cavity. The advantage of using lasers in endoscopic procedures is to provide precise incisions with excellent hemostasis, which aids in better visualization. Laser is used to incise the periosteum and/or muscle attachments. CO_2 laser is a commonly used laser for this purpose.

2. ***Intraoral mucosal surgery:***

Lasers have been extensively used in intraoral mucosal surgeries. Common applications include incisional/excisional biopsy of intraoral soft-tissue lesions (Fig. 39.12a–c), frenectomy (Fig. 39.13a, b), ablation of premalignant lesions, preprosthetic procedures such as vestibuloplasty and excision of epulis fissuratum (Fig. 39.14a–d). As mentioned previously in this chapter, advantages of lasers stand superior compared to traditional scalpels in terms of wound healing, tissue handling, and hemostasis, which ultimately help improve patient experience when used for intraoral procedures as well. Vaporization or ablation of tissues intraorally is usually performed on premalignant lesions, commonly for white lesions such as hyperkeratosis or mild epithelial dysplasia. More severe dysplasias are best excised with the laser to allow for margin control. Definitive diagnosis with the help of a biopsy is a precursor for management of premalignant lesions with laser vaporization since there will be no specimen to biopsy [24].

Although diode, ND:YAG, Er:YAG and CO_2 lasers can be used for intraoral mucosal surgeries CO_2 lasers stand out as the workhorse and most studied laser over the

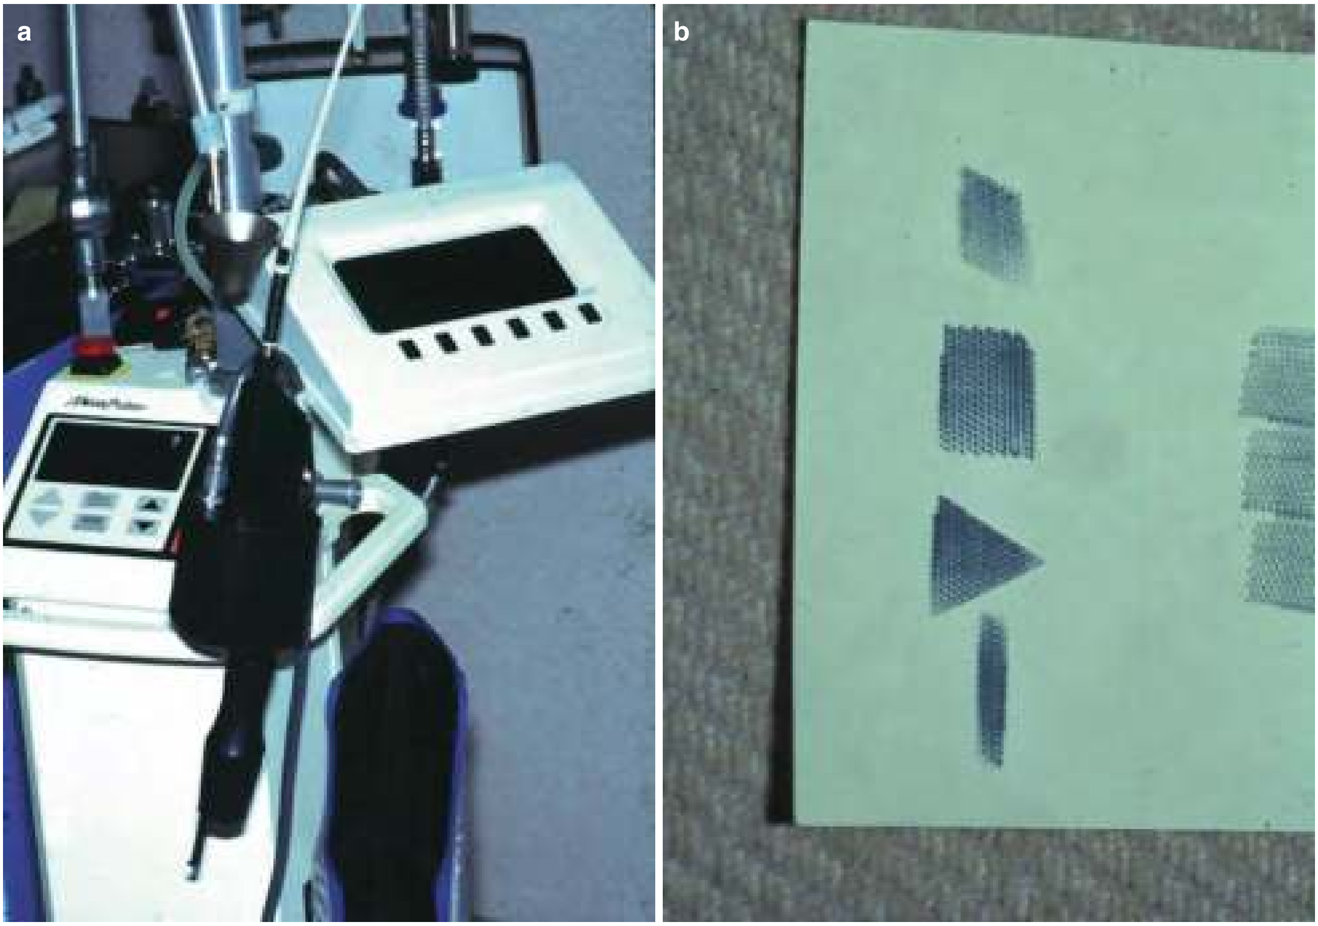

Fig. 39.9 (**a**) Computerized pattern generator (CPG) for laser skin resurfacing. (**b**) Optional patterns for CPG

past four decades. When using lasers intraorally on intended soft tissues, care must be exercised to protect adjacent hard/soft tissue from inadvertent damage or devitalization due to pulpal damage. This is done with either a moist gauze, a mouth guard, a wet tongue blade, or nonreflective plastic instrumentation [25]. The use of lasers as compared to scalpel is presumed to also provide a decreased chance for lymphatic and hematogenous seeding as an added advantage in the management of premalignant or malignant lesions. Principles and technique of incision and ablation have been detailed elsewhere in the chapter.

3. ***Implant surgery:***

   Lasers are also useful in the management of peri-implant soft tissues. 10,600-nm wavelength CO_2 laser and 980-nm diode are the commonly used soft-tissue lasers in implant surgery. ND:YAG laser, due to its inherent high depth of penetration and risk for damage to adjacent tissue and implant surface, is considered unsafe for use on implants. Er:YAG laser, which has been approved for use on hard tissues, has been used in uncovering a thin layer of bone in second-stage implant uncovering and initiating the implant osteotomy, but there is need for further data on the use of Er:YAG for complete preparation of implant osteotomy. 9300-nm CO_2 laser has been used for hard-tissue applications, but more data on its safety and efficacy are needed. Advantages of using lasers in implant surgery include the precision, atraumatic tissue handling, bloodless field of view, and decreased bacterial contamination. Lasers have been used for several indications in implant surgery, including implant site preparation procedures such as the release of frenal attachment, excision of redundant tissue, and incision placement prior to bony osteotomy. Placement of incisions with lasers as opposed to scalpel creates less inflammation, swelling, and postoperative discomfort to the patient as well as added property of tissue sterilization from antibacterial effect. They can also be used for second-stage surgery, including removal of soft tissue and, in the case of Erbium lasers and 9300 nm CO_2 lasers, bone covering the implant [26].

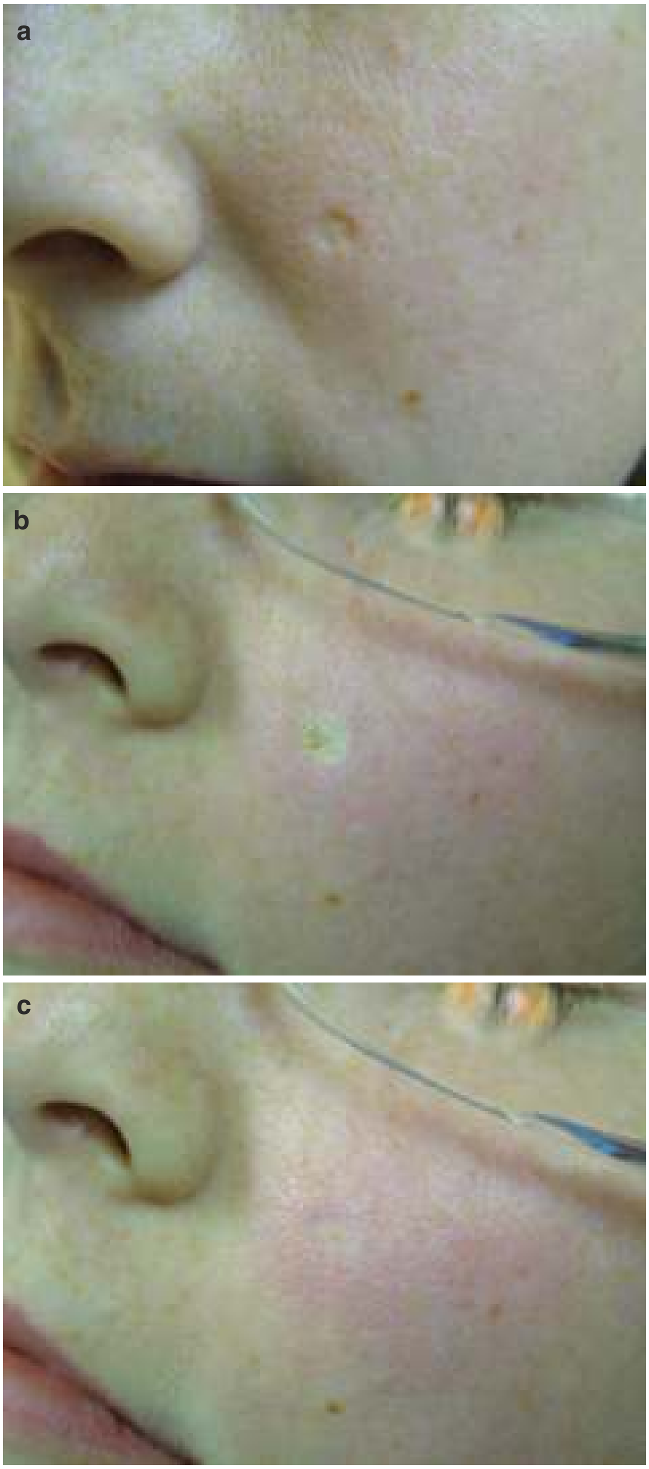

Fig. 39.10 (**a**) Depressed scar of face. (**b**) Blending of scar using CO_2 laser. (**c**) Results of laser scar revision

Fig. 39.11 Laser blepharoplasty

Treatment of mucositis and peri-implantitis around implants is a challenging problem in implant surgery with limited efficacy when managed via conventional treatment protocols. If an implant with signs of peri-implantitis is deemed stable without severe bone loss and/or mobility, then treatment is attempted to salvage. Treatment of choice includes debridement of the granulation tissue accompanied by the administration of antibiotics around the implant for the eradication of as much bacteria as possible followed by bone graft of any defect created. Traditional tools include plastic instruments, citric acid, chlorhexidine, and topical Tetracycline. A laser-assisted algorithm for management of peri-implantitis includes obtaining access to the implant in question via a laser incision and reflection of flap leading to exposure of implant and surrounding bone. Then, the pathologic tissue is vaporized by laser energy and the implant surface and bony defect are decontaminated by the laser, which is accomplished by ablating the surface at low energies to kill off any bacteria on the surface as well as any attached soft tissue. Bone grafting, if necessary, can then be performed. Data have shown significantly better outcomes in cases of peri-implantitis as compared to conventional tools. As in other laser-assisted surgeries, healing is enhanced because of reduced inflammation and decreased postoperative pain as opposed to conventional tools [26] (Fig. 39.15a, b).

4. ***Temporomandibular joint surgery (TMJ):***
   Arthroscopic TMJ surgeries have been proven to be efficacious, minimally invasive, and efficient procedures to treat and manage several aspects of temporomandibular joint disorders. Arthroscopic surgery utilizes various modified cutting instruments, which are passed through a narrow trocar to be able to release the disc attachments, remove redundant inflamed tissues, and/or perform synovial biopsies. These conventional cutting tools are difficult to maneuver, increase the risk of bleeding, which creates a poor visual field and a higher risk of complications. Use of lasers administered via narrow-diameter fiberoptic cables adds advantages in maneuverability, which makes it easier to sweep through the small-sized TMJ and make precise incisions and ablation with better hemostasis in a noncontact mode. Due to their high water absorption, CO_2 and Er:YAG lasers cannot be used for this purpose. Ho:YAG is the commonly used laser for the purpose of TMJ arthroscopy. With low water absorption, it is less affected by the presence of the synovial and lavage fluids, while low penetration (~0.5 mm) decreases the risk of damage to adjacent tissues. Other TMJ procedures such as disk repositioning and removal have been described with the use of arthroscopic techniques and laser assistance with significant success (Fig. 39.16) [17, 18].

39.6 Safety Concerns with Use of Lasers

Efficient and safe use of lasers starts with operator's familiarity with details of the laser system in use. All laser systems come with a user's manual, which lists all required technical details as well as recommended indications for use of that laser system. Common safety issues with lasers happen with accidental exposure of surrounding tissues.

1. ***Personnel protection:***
   Patients, providers, and the assistants are all at risk of inadvertent irradiation with lasers. Any reflective surface in the area of laser target can divert the beam away from the intended area and potentially cause harm. Use of special protective glasses (that are matched to the specific wavelength of the laser) can help avoid injury to eyes of patients or personnel in the operatory. Everyone in the operatory should be familiar with the basic functioning of the laser equipment and nonreflective tools should be used and reflective surfaces intraorally such as crowns be protected with a wet sponge or nonreflective retractors. Posting a "danger" sign for use of laser on the door of the operatory in order to avoid unprotected personnel from entering the room, while laser is in use could avoid accidental injuries as well (Fig. 39.17a, b) [6].

Fig. 39.17 (**a**) Wavelength-specific eyewear for protection of operator, patient, and assistants. (**b**) "Danger" sign outside the operatory along with closure of any see-through glass panels on the door

2. ***Fire hazard:***

   Lasers in an oxygen-rich environmental such as the oral cavity of a patient being provided supplemental oxygen, or inside an endotracheal tube, can pose a significant fire risk. To avoid fire, supplemental O_2 concentration should be kept to a minimum required level or use of room air is recommended. For endotracheal tubes, compressed air can be substituted for oxygen to keep the inspired concentrations of oxygen to below 30% [6].

3. ***Laser plume:***

   When a laser is used for incision or vaporization procedures, the tissue that is being handled will create a "plume," which consists of potentially hazardous particulate debris, which is considered infectious. There are studies, which showed the presence of viral DNA in the plume, but to date there hasn't been any clinical significance or transmission proven. Nevertheless, for protection of the provider/staff, high flow suction made of a nonreflective material such as plastic should be used to remove the plume. Wearing masks and other personal protective barriers such as eyeglasses will help avoid infection transmission as well [27–29].

39.7 Conclusion

Lasers have changed the OMS practice significantly to a point that it is today an essential surgical tool in many ways. Development of lasers in future may overcome current disadvantages and increase utility and safety. Use of lasers in hard tissue is still somewhat limited in comparison to soft-tissue applications. Further research and development could help improve this aspect of laser.DisclosureAuthors have no financial conflicts to disclose.

40 Piezosurgery in Oral and Maxillofacial Surgery

Shravan Renapurkar and Sowjanya Nagamalla

40.1 Introduction

The term "piezo" has been derived from the word "Piezien," which implies pressure in the Greek language. Piezoelectric effect was first described by Jacques and Pierre Curie in 1880 and involves the appearance of an electric charge across certain crystals when they are under mechanical pressure. Inversely, when an electric current is applied across them, they deform. This phenomenon of deformation when under alternating current creates microvibrations or oscillations of ultrasonic frequency [1]. Although ultrasonic microvibration technology was experimentally used earlier, it was in 1988 that Italian oral surgeon Tomaso Vercellotti developed the first commercially available Mectron® piezoelectric bone surgery unit to cut bone tissue while minimizing the limitations of conventional tools [2, 3]. The first use of piezoelectric surgery was for osteotomies by oral and maxillofacial surgeons and later on used for neurosurgical and orthopedic procedures. This revolutionary tool not only lowers the chance of damage to adjacent vital soft-tissue structures such as nerves and vessels during osteotomies, but also preserves osteocytes, which in turn complements bone healing [4, 5].

40.2 Equipment and Principles of Use

Piezoelectric surgery devices are generally small portable units comprising a handpiece with a working tip and a foot control switch, which are connected to the main power-generating unit. The main power unit also features holders for the handpiece and irrigating/cooling fluid (Fig. 40.1a–c). The handpiece is the critical part of this device, containing within it the ceramic chips where the microvibrations are created and later transmitted to the working tip. Commonly used ceramic chips in Piezoelectric surgery units are Barium Titanate or an equivalent material. The amount of deformation in the crystals within the handpiece and resultant vibrations in the insert depend on the power applied [6].

The working tips of a piezoelectric system used for surgical purposes are interchangeable inserts, which can be of different shapes, sizes, and cutting edges based on the intended clinical applications. These inserts can be made of different materials and be coated with titanium or a diamond layer to improve the cutting efficiency. To create a cutting effect rather than a debriding effect, the vibrations of the insert enter into a resonance with the ceramic chips, which increases the energy output. This, combined with the form of the insert, acts like a micrometric oscillating saw. The main energy unit has an interactive touchpad, which allows the operator to control the frequency of vibrations, power of the unit, and the amount of irrigating or coolant fluid. The pressure applied on the insert can also be manually controlled by the operator and can affect the frequency delivered to the target tissue, which in turn affects the cutting efficiency. When higher pressure is applied at the tip, it impedes the cutting efficiency of the insert and releases the energy as heat, which is detrimental to the bone as well as adjacent soft tissue [6, 7].

The Piezoelectric unit also allows for election of modes of operation, which are preset power modes with varying frequencies to match the clinical application. The frequency is usually set between 25 and 29 kHz, which can create micro-oscillations of 60–210 μm amplitude, providing the handpiece with power exceeding 5 W. The vibrations produced in the "Low mode" result from average ultrasonic powers, without frequency overmodulation, and allow the operator to perform endodontic procedures. On the contrary side, the "high mode" and the "boosted mode" are characterized by vibrations with higher ultrasonic power and frequency overmodulation, which allows cutting of mineralized tissue. The "boosted mode" has frequency overmodulation with an increased rate that is most efficient for osteotomy and osteoplasties in surgical procedures, while the "high mode" is less

Fig. 40.1 (**a**) The Piezosurgery® unit from Mectron® is made of a power supply unit, a handpiece, its holder, an irrigant solution holder, foot control switch. (**b**, **c**) Inserts or working tips of a piezosurgery unit. (**b**) shows working tips for Sinus lift and (**c**) shows osteotomy tips

efficient but more helpful in periodontal procedures and bone smoothening [6–8].

The device includes an irrigating system for cooling that creates an adjustable jet of coolant solution through a peristaltic pump at rates between 0 and 60 ml/min and helps remove debris from the cut surface and helps maintain hemostasis because of its cavitation effect. This enhances visibility, particularly in difficult-to-reach anatomical zones, by scattering coolant liquid as an aerosol. The irrigation liquid should be refrigerated at 4 °C for effectual cooling [6, 8, 9].

For optimal use and maximum efficiency, the operator could select the proper power based on the surgical tissue, apply light pressure with the tip, and adjust the rate of delivery of the irrigating solution to avoid overheating the tissue and decrease the chance of damage to soft tissues. Although the device has a safe frequency range along with the cooling irrigation liquid, there is a possibility of damage to soft tissues due to high pressure and overheating [10].

40.3 Advantages

Used in many therapeutic surgical procedures, piezosurgery has several advantages when compared to traditional methods of surgical instrumentation used for osteotomies or osteoplasty. These are as follows:

- *Decreased risk of damage to adjacent soft tissues*: This is the major advantage with use of a piezoelectric surgical unit. When used as recommended, at the appropriate frequency, the micrometric oscillating motion decreases the chance of damage or cutting of adjacent soft tissue while cutting through hard tissues. For example, it allows improved Schneiderian membrane preservation during osteotomy of the maxillary lateral wall during a sinus lift and preservation of the inferior alveolar nerve (IAN) during mandibular osteotomy.
- *Improved visibility*: With use of piezosurgery, better visibility is secondary to the decreased amount of bleeding and the phenomenon of cavitation. Cavitation refers to the phenomenon of "microboiling" occurring in liquids in a solid-liquid interface at intermediate frequencies of vibration secondary to the creation of imploding bubbles when the irrigating solution contacts the insert. Improved visibility helps the operator to place the osteotomy in the preferred location with increased accuracy [6].
- *Increased patient comfort:* Due to the micrometric nature of the vibrations and decreased noise, use of a piezosurgery device improves patient comfort and decreases anxiety during procedures done under local anesthesia. When used for bone harvesting, it also reduces the need for use of chisels, which can help improve the patient experience and reduce stress.
- *Improved survival of osteocytes:* Bone harvested with various techniques, including rotary instruments, chisels, rongeurs, and a piezosurgery device, was studied with histomorphometry evaluation by Berengo et al. The piezosurgery device was shown to be one of the best methods of harvesting bone along with gouge chisels, back action chisels, and rongeurs in terms of the viability of the harvested bone and number of osteocytes. Bone harvested with rotary instruments, including burs and safe scrapers, was noted to be completely nonvital with an absence of osteocytes. In another histomorphological study done with the placement of porous titanium implants in minipig tibias, neo-osteogenesis was noted to be consistently more active in bony samples from implant sites that were prepared using piezoelectric surgery, and there was an earlier increase in BMP-4 and TGF-2 proteins and fewer proinflammatory cytokines in bone around the implants [5, 11].

40.4 Disadvantages/Limitations

Although piezosurgery has numerous advantages as listed here, it is associated with some drawbacks as follows:

- *Low efficiency/increased operating time*: One of the major drawbacks with ultrasonic/piezo surgery osteotomes is the increased time required for the procedure. The cutting efficiency of a piezosurgery device has been reported to be 3–4 times less than that of conventional osteotomes for some procedures [12, 13]. For example, in a randomized prospective crossover clinical study done by Stefano Sivolella, piezoelectric osteotomy of a lower third molar took 9.4 min longer than rotary tools to complete [14].
- *Expense*: The cost of equipment is sometimes an additional burden to the provider. Each individual cutting tip in a piezosurgery equipment setup is generally more expensive than traditional cutting tools such as burs, chisels, or saw blades. These tips can also potentially break or fracture when improperly used, which can again increase the need for more equipment.
- *Learning curve*: Use of piezo requires a short learning curve to attain maximum efficacy, which could be frustrating to the operator. The digital pressure applied by the surgeon while using conventional tools such as saws and drills is quite different from piezoelectric surgery as it mandates less pressure and failing to calculate the pressure according to the speed of the insert prevents microvibrations of the insert. When the microvibrations are prevented due to excessive pressure on the working tip, energy not used for cutting will be transformed into heat, which, if it continues for long time, would damage the tissue.
- *Pacemakers and defibrillators*: Piezosurgery is *relatively* contraindicated for use in patients with pacemakers, although there is no evidence of electromagnetic interactions produced by piezoelectric devices according to one in vitro study [15].

40.5 Applications for Piezosurgery

40.5.1 Dentoalveolar Procedures

Piezosurgery can be applied toward multiple dentoalveolar procedures where there is a requirement for meticulous bone preparation, atraumatic tooth extraction/exposure, and when the location of the surgical site is in proximity to vital anatomical structures. Example of applications in dentoalveolar surgery include ankylotic tooth root extraction, impacted third molar extraction, surgical exposure of impacted teeth, and extractions in patients with a thin periodontal biotype. In all of these indications, piezosurgery has the potential to limit bone loss and maximize maintenance of alveolar bone integrity, especially when the alveolar bone is thin and the procedure requires a high degree of precision. A split-mouth design, randomized, clinical trial conducted by Mantovani et al. studied differences in postoperative pain, orofacial swelling and duration of the procedure when using a rotary bur for third molar ostectomy versus a piezosurgery device. They found that, although the duration of the procedure was longer, the postoperative pain and swelling were less in the piezosurgery group [16].

40.5.2 Dental Implant Surgery

40.5.2.1 Sinus Floor Elevation

Perforation of the Schneiderian membrane during lateral wall osteotomy, and/or while raising the maxillary sinus floor manually, is a common complication, which can affect the bone grafting procedure. Use of piezosurgery in sinus lift procedures not only minimizes the chance of perforation during osteotomy but also eases the separation of the membrane as well (Fig. 40.2a–c). In the commonly used lateral approach technique for sinus lift, piezoelectric devices have a superior action in each technique or step compared to traditional instruments. The chance of membrane perforation with conventional techniques is reported to be 14–56%, while studies on the use of piezosurgery devices report it to be 5–7% [8, 17, 18].

- Thinning buccal wall: With traditional instruments, it is difficult to thin the buccal wall with good control. Piezoelectric device makes precise osteoplasty easy and the bone fragments produced during osteoplasty can be used as grafting material.
- Bony window/osteotomy: Piezosurgery makes the frame of the bony window optimal with respect to the sinus

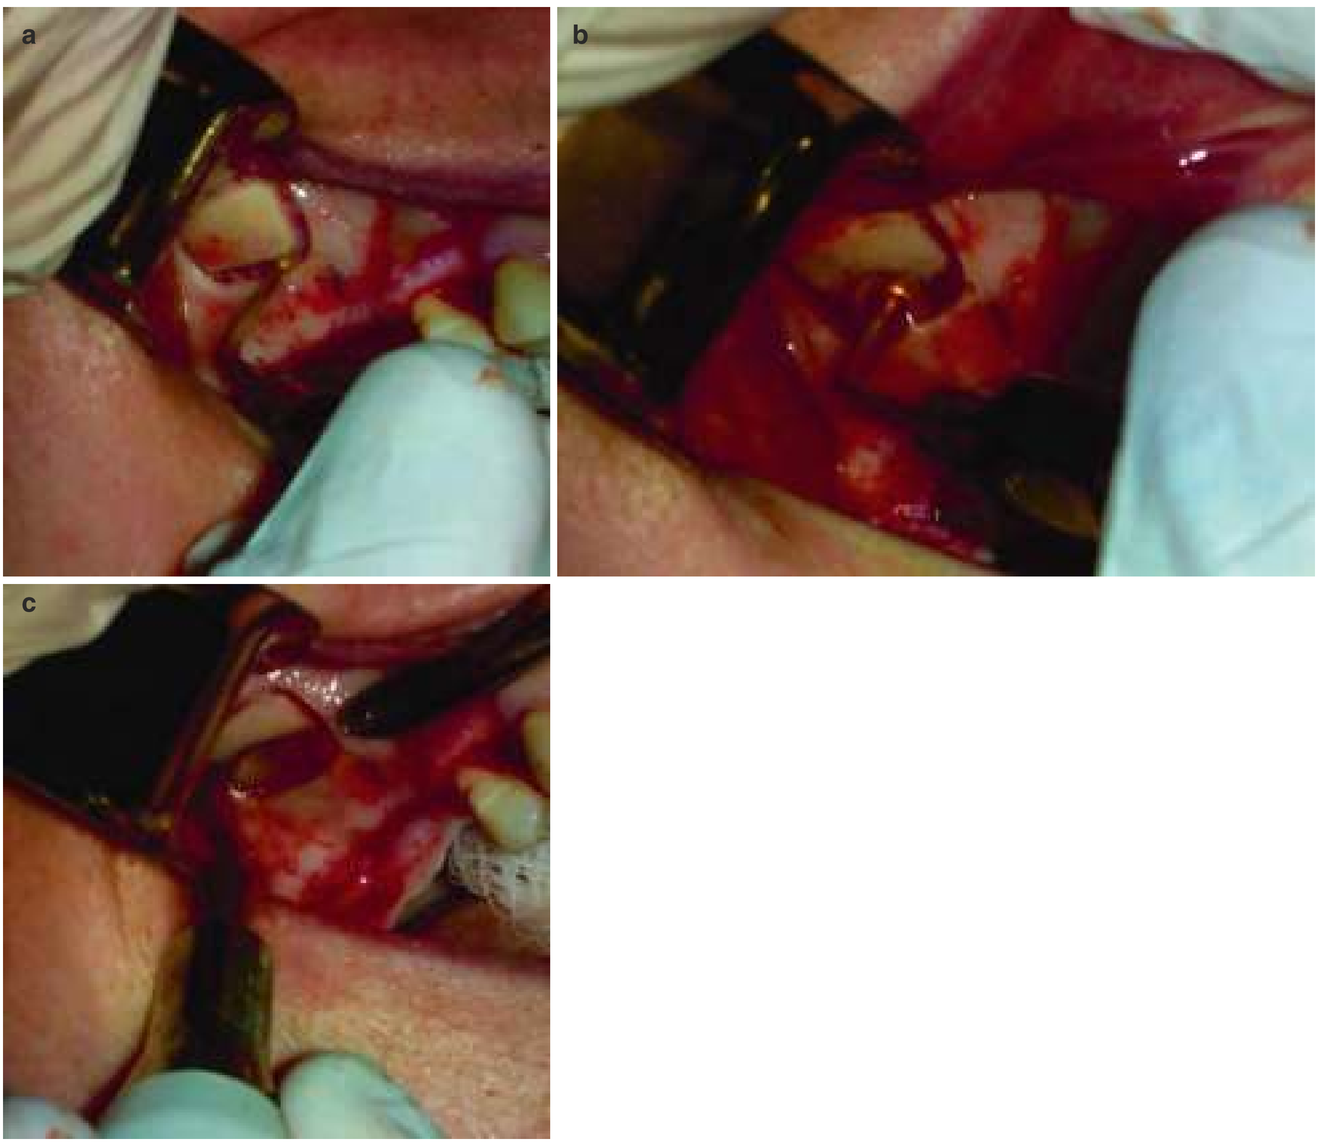

Fig. 40.2 (**a**) Piezosurgery insert used to perform outline of the lateral wall osteotomy to thin the wall. (**b**) Blunt piezosurgery insert used to infracture the window wall and initiate the separation of the schneiderian membrane from the sinus wall. (**c**) After the lateral sinus wall osteotomy completed, membrane separation initiated a third insert shaped as an elevator used to continue the separation of the membrane to create required space for the bone graft for augmentation

anatomy with decreased chance of membrane perforation.

- Sinus membrane separation: Most commercially available piezosurgery devices have special inserts that make the separation around the perimeter of bony window easier and decrease chance of tear or perforation during the manual lifting process.

40.5.2.2 Implant Site Preparation

Implant site healing and ultimate osseointegration of implants is negatively influenced by the high temperatures created during site preparation. Results of an in vitro study done by Heinemann et al. in 2012 on porcine jaws comparing piezosurgery, Sonicflex®, and rotary instruments showed the highest temperature rise with use of piezosurgery, although the trabecular bone and osteocytes were still intact [19]. On the contrary, a recent randomized, controlled clinical trial by Da Silva Neto et al. in 2014 compared implant stability at various times postoperatively in osteotomies performed by conventional rotary instruments versus piezosurgery devices, and found implant stability to be higher with Piezosurgery [20]. The use of piezoelectric devices facilitates the use of selective enlargement of only one socket wall and Vercellotti called this: “differential ultrasonic socket preparation.” [4].

40.5.2.3 Alveolar Ridge Splitting

Ridge-splitting techniques for alveolar augmentation is indicated when there is adequate height of bone for implant placement but inadequate ridge thickness. The conventional ridge-splitting procedure uses chisels, rotary instruments, or saws, all of which have a high risk for damage to soft tissue, undesired propagation of the osteotomy and bone fracture, as well as prolonging treatment time due to the need for second-stage surgery to place the implants. (Fig. 40.3a, b) With use of piezosurgery, one can decrease the chance of the damage to adjacent structures during the osteotomy as well as reduce the risk of bone thermonecrosis, while simultaneously providing better control of propagation of the ridge split osteotomy. Although ridge splitting was traditionally used in the maxillary arch, piezoelectric bone surgery allows ridge expansion even in highly mineralized tissues like the mandible with ease [21, 22]. Blus et al. conducted a study on ridge splitting for more than 200 implants placed in 57 patients and reported 96.5% success rate with a 36-month follow up [23].

40.5.2.4 Lateralization of the Inferior Alveolar Nerve

In order to place implants in atrophic edentulous mandibles, IAN lateralization can be used as an alternative to bone augmentation procedures (Fig. 40.4a–c). Bovi, in 2005, first reported a technique for IAN mobilization with simultaneous implant placement utilizing a piezoelectric device. He reported that IAN mobilization with a piezoelectric device minimizes the risk of irreversible damage to the IAN and enables the surgeon to make a smaller bony window, which, in turn, decreases overstretching of the mental nerve [24]. In an in vitro study, Metzger compared transposition of the IAN with use of a piezoelectric device versus conventional burs. His study also supported the lower rate of nerve injury from use of piezosurgery [25].

40.5.3 Bone Graft Harvesting

For bone augmentation, bone grafts in the form of chips or blocks can be used. Bone chips are primarily indicated in guided bone regeneration where the stabilization of the graft is not an issue, such as multiwalled defects. On the other hand, when the bony defect is large or stabilization is diffi-

Staged Ridge Split Procedure in the Management of Horizontal Ridge Deficiency Utilizing Piezosurgery. *Journal of Maxillofacial and Oral Surgery, 15*(4), 542–546 (Springer)

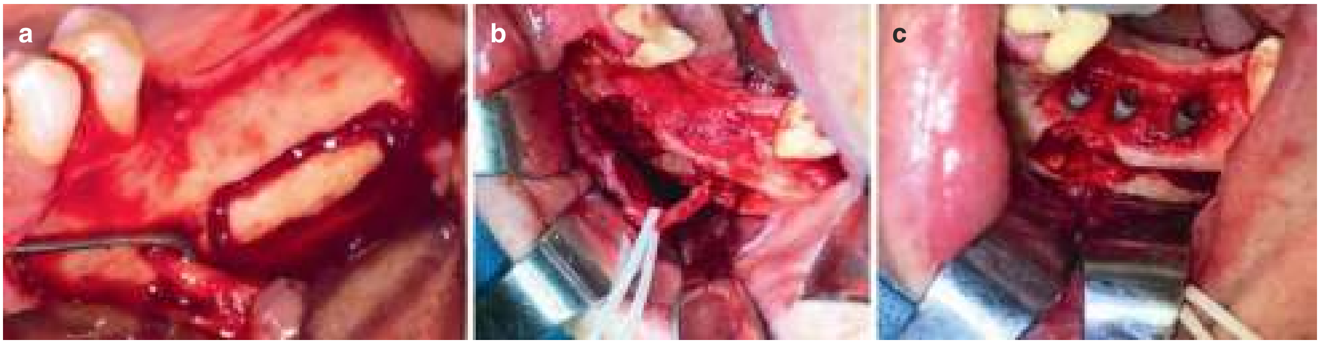

Fig. 40.4 (**a**–**c**) Inferior alveolar nerve (IAN) lateralization for placement of implant

cult, block grafts must be utilized to augment vertical or horizontal dimension. Piezosurgery is used for harvesting all types of bone grafts, including autologous free block grafts, microvascular free flaps, and bone chips.

For example, piezosurgery is commonly used to harvest mandibular ramus block grafts. This requires use of two types of piezosurgery inserts. One is the standard saw-shaped right angle insert, which is used in an area, which can be viewed directly to make the depth cut and vertical cuts, while a second, dual-angled, insert is used specifically to make the inferior horizontal bone cut. In bone graft harvesting, piezosurgery allows better visibility, precise cuts, and good adaptation of the grafts along with better survival of bone cells. In a study by Happe in 2007 on 40 patients, bone grafts harvested from the mandibular ramus by piezosurgery resulted in 93% uneventfully healed donor sites and 96% uneventfully healed graft sites [26]. There was also minimal resorption of the graft. Shaping of block grafts can be better controlled with piezosurgery, although this can take longer than rotary instruments. In microvascular free bone flaps harvested with piezosurgery, the surgeon can decrease the chance of injury to the vascular bundle along the surface of bone. With the use of piezoelectric surgery, the clinician can cautiously osteotomize the fibula or other bone without any periosteal/pedicle dissection. In addition, the piezoelectric method also allows shaping and handling the pedicle while it is still attached to the donor site.

40.5.4 Orthognathic Surgery

Piezoelectric devices are increasingly being used in orthognathic surgery due to its precise cutting and lower risk of damage to adjacent teeth and nerves. Landes et al. performed a large study on 90 patients in whom orthognathic surgery was performed with piezosurgery. This study demonstrated decreased blood loss compared to conventional surgery but no significant difference in surgical times. Lefort I osteotomy only required the use of chisels in about 33% of cases [5, 27, 28]. In the same study, among patients who underwent bilateral sagittal split osteotomy (BSSO), inferior alveolar nerve sensitivity at 3-month follow up was retained in 98% of the cases, compared with 84% after conventional BSSO (Fig. 40.5). When performing surgically assisted rapid maxillary expansion (SARME), the advantage of using piezoelectric surgery is that it minimizes potential damage to the descending palatine artery while separating the pterygomaxillary junction, the nasopalatine artery while making the midline maxillary cut, and it lowers indirect thermal damage to the bony surfaces and adjacent structures, including teeth [29].

40.5.5 Aesthetic Facial Surgery

Conventionally, chisels are used for osteotomy of the lateral nasal bone during rhinoplasty, which transmit significant force to the surrounding soft tissues in a blind manner, and increases the risk for bleeding from injury to the adjacent vasculature. A study done by Robiony et al. assessed use of chisels versus piezosurgery and found a decreased risk of injury to adjacent soft tissues with use of piezosurgery. Use of chisels also may create inaccuracy due to blind use and the unguarded nature of the instrument. On the other hand, use of piezo will not incur this issue and gives the operator more control and accuracy [30].

40.5.6 Distraction Osteogenesis

Distraction osteogenesis (DO) is indicated when there is a need for significant amounts of bone augmentation or lengthening, or when the soft tissues that cover the bone will not

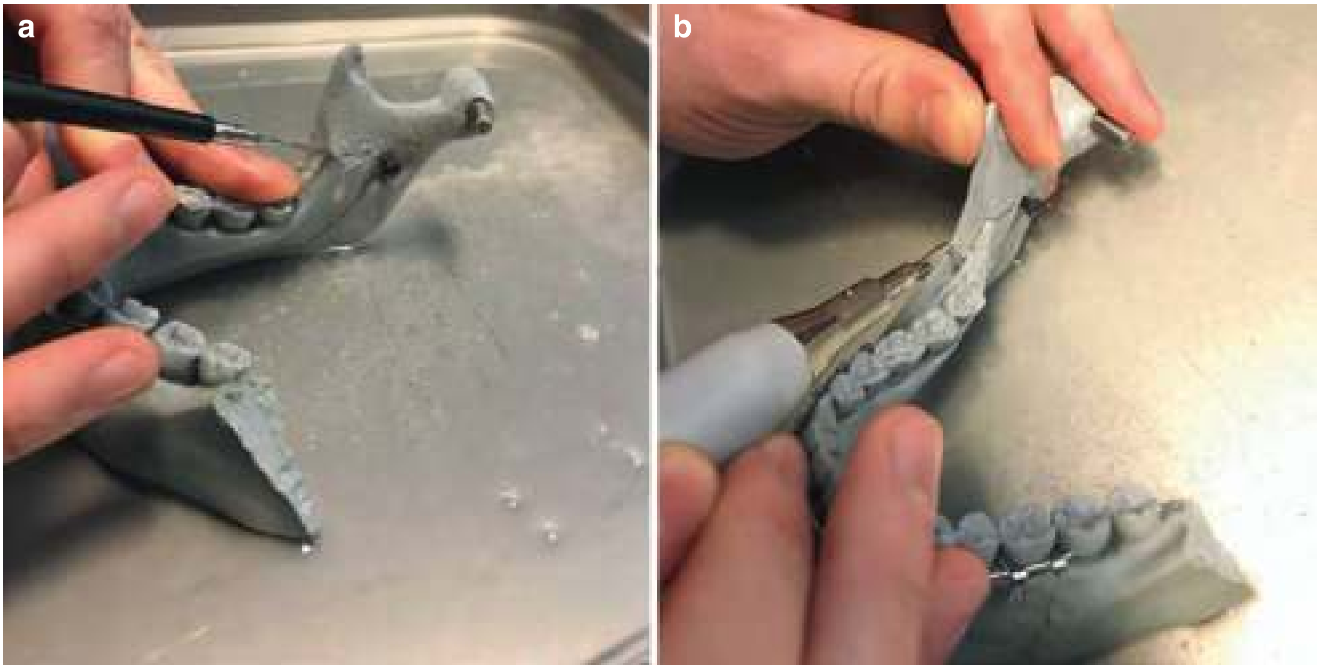

Fig. 40.5 (**a**, **b**) Orthognathic surgery using Piezo. Figure shows steps in a BSSO. Variations in the blade design can be used based on desired osteotomy

allow for osseous augmentation. The use of piezosurgery permits the initial osteotomy to be made delicately and accurately while minimizing injury to the soft-tissue flap and surrounding hard tissue, allowing maintenance of the vascularity needed for successful new bone formation [31]. Distraction Osteogenesis (DO) can be used for distraction of either the alveolar bone or the basal jawbone. DO with a piezoelectric device ensures the preservation of original bone structures, specifically the cancellous bone, which favors the healing process due to its high healing potential. In a recent article, DO with microdistractors using a piezoelectric device has shown favorable results in patients with Pierre Robin Sequence [32].

40.5.7 Temporomandibular Joint Surgeries

Osteotomies and osteoplasty in the temporomandibular joint (TMJ) region involves risk to the facial nerve as well as major vessels such as the internal maxillary artery and the masseteric artery. Due to anatomical complexity, the use of conventional bone-cutting tools such as burs and saws may put these vital structures at risk of injury or permanent damage. Given the advantages of piezosurgery as discussed previously in the chapter, its use in this specialized surgery is reasonable and advisable. In 2014, Anson Jose observed less bleeding along with minimal postoperative complications while treating TMJ ankylosis with piezosurgery [33].

40.5.8 Inferior Alveolar Nerve Preservation

The IAN is at risk whenever there is the need to extract impacted mandibular molars, enucleate large cysts, or remove benign mandibular tumors. In 2009, Dr. Kagan Degerliyurt presented an article describing a procedure called the “bone lid technique,” which is performed by using a piezosurgery device when there is a definitive risk of damage to IAN [34, 35].

40.5.9 Trauma

Piezoelectric devices can be used for reconstruction in multiple trauma cases, such as comminuted frontal bar fractures, to cut and shape the inner table of a calvarial bone graft, to osteotomize a healing fracture while reducing the chance of adjacent tissue injury. Using piezosurgery in post-traumatic cases can help preserve bone, protect adjacent soft tissues, decrease blood loss, improve visibility, and ensure a better overall outcome [36].

40.6 Conclusion

Piezosurgery is a promising surgical tool for safe and effective use in various surgeries. For an oral and maxillofacial surgeon, piezosurgery allows safer and effective osteotomy or osteoplasty compared to conventional rotating instruments such as burs and saw blades, even in complex anatomical areas. Over the past decade, it has not only been increasingly used in OMFS but has been adapted for use in neurosurgery, orthopedic surgery, and otorhinolaryngology. In addition to the surgical advantages, it helps the patient by reducing procedural stress, postoperative swelling, pain and overall improves the surgical experience. The major drawback of piezosurgery is the lack of efficiency or cutting speed, which can be balanced by improved clinical outcomes. Future generations of ultrasonic devices may bring about better efficiency and ultimately replace all conventional cutting tools.

41 Computer-Assisted Navigation Surgery in Oral and Maxillofacial Surgery

Shintaro Sukegawa and Takahiro Kanno

41.1 Introduction

The anatomy of the oral and facial region is complex, having many vital organs and structures, including an intricate network of blood vessels and nerves as well as the brain, eyes, nose, and vital teeth. Plain radiography can be used for screening because of its simplicity, but it cannot characterize detailed anatomical relationships. Currently, imaging diagnosis must be performed with computed tomography (CT) and/or magnetic resonance imaging (MRI) before surgery to characterize the surgical area and surrounding anatomical structures. Recent developments in imaging technology have allowed for rapid processing and visualization of significant amounts of data yielded from a variety of digital imaging modalities. Prerequisites have been established for three-dimensional (3D) visualization as well as programs for the computer-assisted 3D planning of surgical procedures, and these image sources are now available to assist the surgeon in the operating room [1].

Today, surgeons can use computer-aided design and computer-aided modeling (CAD/CAM) software to assist with the planning and implementation of complex maxillofacial surgical procedures [2]. CAD/CAM software allows the clinician to import two-dimensional (2D) CT data in DICOM format (Digital Imaging and Communications in Medicine) to a computer workstation and create accurate 3D representations of the facial skeleton and related soft tissues. The data can then be used either to print a stereolithographic (STL) model or for virtual manipulation of the generated 3D model by segmentation, reflection (mirroring), insertion, or repositioning of 3D objects for treatment planning [3].

S. Sukegawa
Division of Oral and Maxillofacial Surgery, Kagawa Prefectural Central Hospital, Takamatsu, Kagawa, Japan

T. Kanno (✉)
Department of Oral and Maxillofacial Surgery, Shimane University Faculty of Medicine, Izumo, Shimane, Japan
e-mail: tkanno@med.shimane-u.ac.jp

Stereolithographic 3D models are useful for maxillomandibular reconstruction indicators such as

1. A guide for plate adaptation.
2. Planning bony osteotomies.
3. Planning for graft or flap placements.
4. Surgeries involving jaw repositioning.
5. Construction of patient-specific custom implants (PSI).

Not only are they useful in visualizing and planning, but also for providing haptic support to the surgeon for perceived excellent tactile feedback during virtual surgery. They also prove to be very useful in creating a more predictable workflow for the intended surgical intervention. Unfortunately, there is no single prediction method where the surgical plan as performed on the model can be directly transferred to the patient.

Computer-assisted surgery (CAS) uses data from image processing, and can be divided into two major categories:

1. Computer-assisted presurgical planning.
2. Intraoperative navigation.

Computer-assisted presurgical planning involves preoperative surgical simulation using physical or virtual 3D images or models, and helps the surgeon to appreciate the underlying skeletal anatomy in a more precise manner. The application of preoperative surgical simulations is being used in the field of dental implantology for determining the appropriate positions and sizes of implants as well as evalu-

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_41

ating and planning for bone augmentation when needed, and in the field orthognathic surgery for assessing the amount and direction of movement of the jaws.

The process of intraoperative navigation was developed to improve the sequence of "diagnosis-surgical planning-surgery," allowing surgeons to accurately visualize the positions of surgical instruments and guides in real time on a display of patient CT and/or MRI data. Intraoperative navigation systems integrate diagnostic imaging with the actual surgical field, allowing simultaneous visualization of the surgical site and the analogous image counterpart with the help of a sensor that enables more precise access and manipulation for areas with sensitive anatomy. These navigation systems have now evolved greatly to minimize invasiveness while improving accuracy. The development of intraoperative navigation surgery has enabled improvement in execution and predictability for greater precision during oral-maxillofacial surgery.

This section presents an overview of currently available navigation systems and their applications, focusing on clinical utility and solutions they offer for problems and challenges in the field of oral and maxillofacial surgery.

41.2 Medical Navigation Technology

"Navigation-assisted surgery" is a broad term and can be interpreted in various ways.

This is most usefully represented by three questions: "Where is the anatomical target in our patient?", "How can we reach our target safely for our patient?", and "What is our current anatomical location?".

Besides these questions, navigation-assisted surgery may also be used as an "information center" to provide surgeons with accurate and efficiently retrievable information. Navigation systems used for surgery are very similar to a global positioning system (GPS), as is commonly found in automobiles.

It comprises three principal components: (1) a localizer, which is analogous to a satellite; (2) a "hand-held" probe, which corresponds to the track waves emitted by the GPS unit; and (3) the CT scan data of the patient, which is analogous to a road map.

Intraoperative navigation systems were initially developed for use in neurosurgery, but they are now commonly used in surgery of the craniomaxillofacial region due to their high accuracy and reliability [1, 4] (Fig. 41.1).

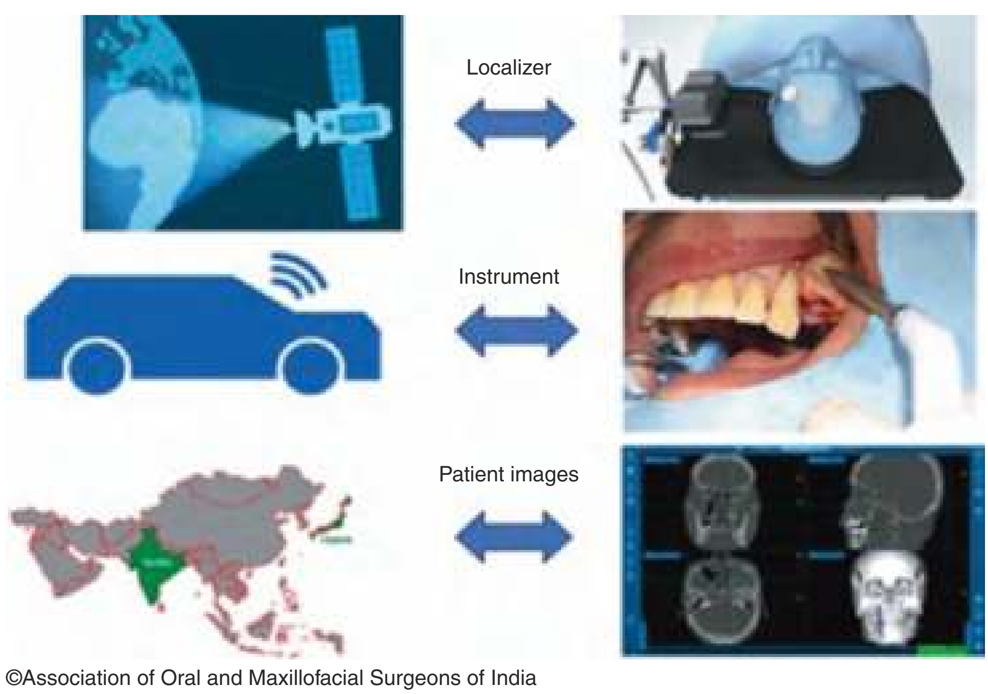

Fig. 41.1 Components of a surgical navigation system. A surgical navigation system is comparable to a global positioning system (GPS) as is commonly used in automobiles, and is composed of three primary components: a localizer, which is analogous to a satellite in space; an instrument or surgical probe, which represents the track waves emitted by the GPS unit in the vehicle; and a CT scan data set, which is analogous to a road map

41.2.1 Differences Between Optical and Electromagnetic Tracking Systems

Two main technologies are currently available for intraoperative navigation, including optical and electromagnetic (Fig. 41.2), and they share the same function. However, they use very different technologies to relay position information to the surgeon. Two major components of the optical navigation system are measured using an infrared camera. These include the position of the reference frame, which is the optical point of reference for navigation and is also called the patient tracker, and a surgical probe with light reflectors. This enables the position of the surgical probe to be displayed on the CT or MRI image in real time. Care should be taken to ensure that both the tracker and the probe are detected by the infrared camera of the navigation system to track the instrument position within the surgical field [5]. By contrast, the electromagnetic system utilizes electromagnetic fields and reference points on a patient borne device, along with a wired instrument for the surgeon to manipulate within the surgical field. The system functions by creating a magnetic field of known intensity and then using microsensors in key instruments to allow the system to determine where the instrument is located relative to the patient's anatomy [6]. In contrast to an optical system, an electromagnetic system does not require a clear line of vision between the IR camera and the sensors, allowing equipment and objects to be placed between the sensors and the IR camera. However, the accuracy of this system is compromised when using ferromagnetic instruments.

41.2.2 Registration Techniques

Registration is the task of obtaining the mutual transformation matrix by calculating the relationship between the coordinates of the actual patient space and the coordinates of the medical image. In other words, this procedure involves the alignment of the patient and the image, and it is the most important process when performing surgical navigation.

> Registration techniques are categorized into two major types: (1) marker-based [7] and (2) marker-free [8] (Fig. 41.3).

In the marker-based technique, registration requires identifiable markers to be placed within preoperative images that can be easily detected on the patient during the surgery. These markers include dental splints [9], skin adhesive reference markers, and bone-implanted screws [10]. In contrast, the marker-free technique is based on the patient's regional anatomy. This can be performed by registering easily identifiable soft tissue or bony structures on the patient's preoperative scans. Another technique for marker-free registration is laser surface scanning, which is used to match random points on the surface of facial skin to corresponding points on CT or MRI images. More recently, hybrid registration combining methods have been used that combine point registration and surface registration [11].

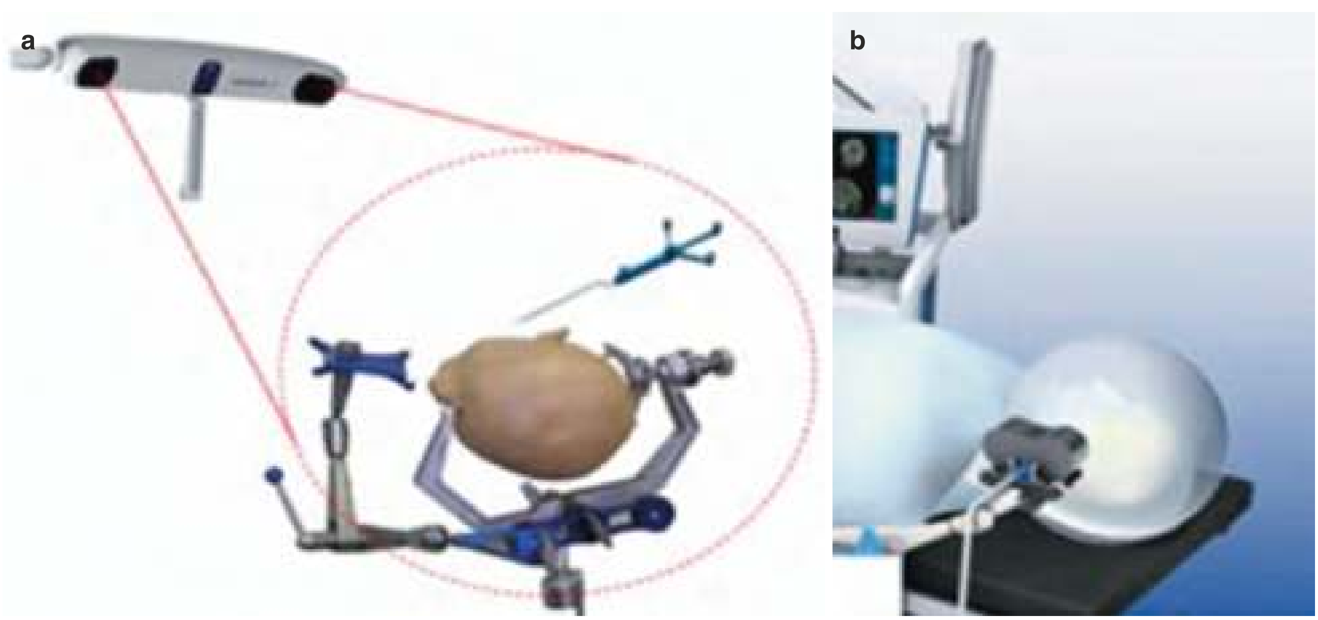

Fig. 41.2 There are two main types of navigation systems currently available: (**a**) optical and (**b**) electromagnetic systems

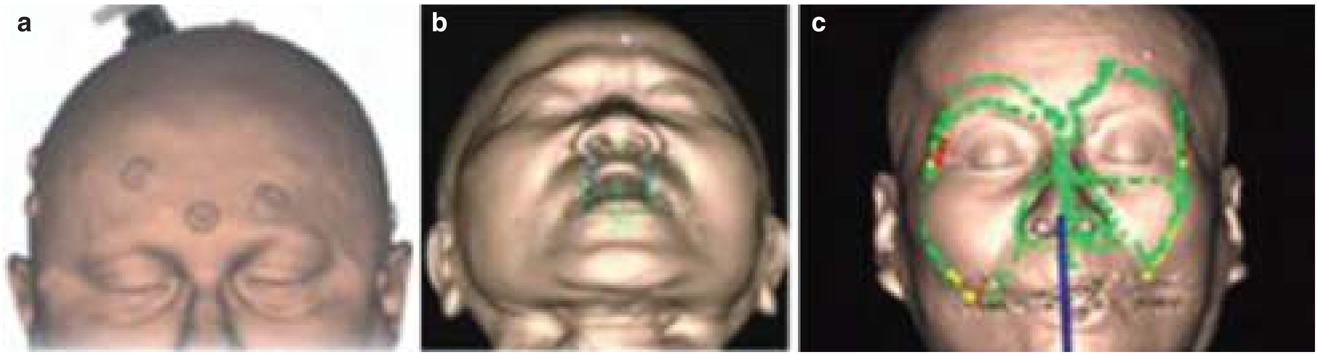

Fig. 41.3 Registration techniques for navigation preparation can be categorized into two main groups: marker-based and marker-free. Marker-based registration requires markers that are apparent on preoperative images and that are easily detectable on the patient during the procedure, such as (**a**) skin adhesive reference markers or (**b**) a referencing dental splint (**c**) Marker-free registration relies on the patient's craniomaxillofacial anatomy. Laser surface scanning is applied in a distinct marker-free registration technique, where random points on the facial skin surface are matched to corresponding points on the soft tissues in preoperative computed tomography/magnetic resonance imaging (CT/MRI) images

41.2.3 Application to Oral-Maxillofacial Surgery

41.2.3.1 Application to the Maxilla and Midface

The use of navigation systems significantly improves the degree of intraoperative precision and accuracy that can be predictably transferred from the planning stages to the actual surgery. However, navigational accuracy is limited by the type of system used, the method of procuring imaging data, and the intraoperative synchronization of the imaging data with the patient's actual position. The systems currently in use for maxillary and midface surgery are relatively reliable, as most have been modified from their neurosurgical counterparts [12]. Because the maxilla and midface are immovable, unlike the mandible, the position of the skull relative to the reference is stable, and the registration procedure directly reflects this. Therefore, navigation-assisted surgery is the best option at the maxilla and midface.

41.2.3.2 Application to the Mandible

The use of navigation systems is not currently approved for mandibular surgery. This is due to the nature of the mandible to move on its joint (Fig. 41.4), resulting in the registration not being reflected accurately in the navigation of the mandible. However, it may be possible if the position of the mandible is held identical to its intraoperative position during image acquisition.

At present, solutions exist for the application of navigation systems to mandibular surgery. One such option is the use of a dynamic reference frame mounted to the mandible that enables the continuous tracking of mandibular movement during surgery [13]. This method utilizes a sensor frame and mandible/teeth supported markers for the direct tracking of the mandible during surgery. This permits free intraoperative movement of the mandible. The second option is to maintain an immobile intercuspation position, such as using a maxilla-mandibular fixation to maintain intraoperative synchronization [14]. Unfortunately, this is impossible to achieve in most intraoral procedures. Therefore, a third strategy has been developed in which the mandible is placed in a reproducible position against the maxilla using an occlusal splint. This method appears to produce no additional error.

41.3 Clinical Significance in Oral and Maxillofacial Surgery

There are numerous clinical applications for CAS and intraoperative navigation in oral and maxillofacial surgery. This is reiterated by literature support available over the last decade supporting its use.

41.3.1 Application for Oral-Maxillofacial Trauma

Computer-based surgery is a rapidly emerging approach used in some surgical disciplines, and can be used both as a research tool and to improve healthcare. Computer-based surgery, in combination with the use of a navigation system, has been shown to reduce overall operation time in complex anatomic areas, such as maxillofacial trauma surgery (e.g., orbital trauma reconstruction surgery), making surgery more reliable. Using 3D models based on CAS is suitable for preoperative preparation of reconstruction material for bone defects caused by trauma. On the other hand, navigation surgery is most suitable for intraoperative anatomical evaluation [15]. By combining these techniques, safer and minimally

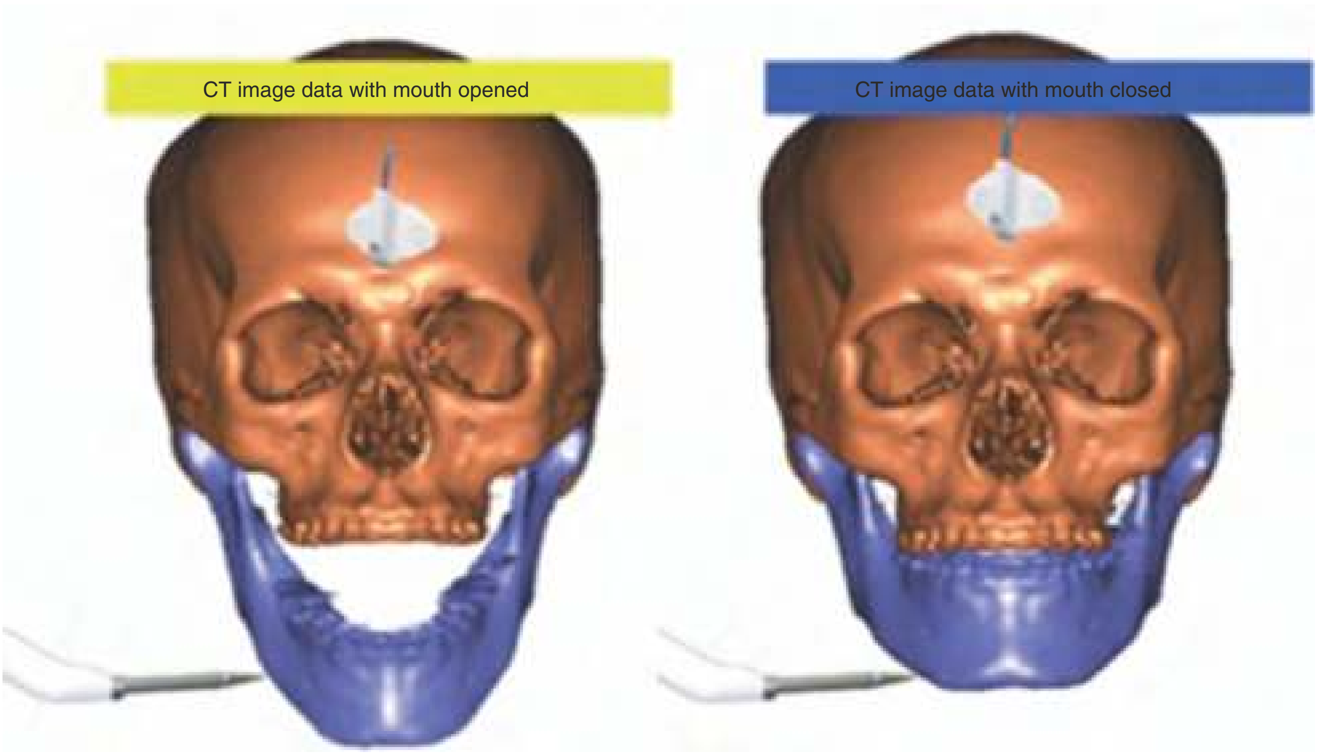

Fig. 41.4 The positional relationship between the reference and the target becomes unstable due to the free mobility of the mandible. If the mandible were maintained in an identical position during image acquisition and the surgical procedure, then all structures within the image could be fixed in an identical position, thereby ensuring the accuracy of the navigation surgery

invasive surgery is possible. Maxillofacial trauma may be an important indicator suggesting the use of navigation systems (Figs. 41.5, 41.6, 41.7 and 41.8). Unilateral midfacial and orbital trauma surgery may also be indicators, and are normally treated with open reduction and fixation with navigation assistance.

The largest sample sizes for navigation surgery were found in the field of craniomaxillofacial trauma, offering significant positive results for orbital fracture treatment through navigation-assisted surgery. Midfacial trauma, and particularly unilateral midfacial trauma, was most common example of maxillofacial trauma available in the literature. Some of these reports described the treatment of patients with delayed zygomatic fractures requiring osteotomies to reposition the abnormally healed bones. This results in added complexity for the surgeon due to the lack of known anatomical landmarks. He et al. presented a protocol for the creation of artificial landmarks on the surface of the zygoma [16]. The technique involved the registration being performed with rigidly fixed, light-reflecting spheres placed on the patient's skull. Subsequent soft tissue surface scanning was performed using a laser pointer to complete the process.

Another challenging facet of oral and maxillofacial surgery is the management of orbital fractures. This can prove to be demanding even for the most experienced of surgeons. Literature indicates that intraoperative navigation is a very useful tool in post-traumatic orbital reconstruction. Another rising trend is the use of patient-specific implants (PSIs). A recently published literature also discusses the use of PSIs with navigation guidance [17]. A control group was treated with navigation using prebent titanium mesh. Several significant factors were reported favoring the study group. PSIs are poised to make a significant change in the management of orbital trauma.

Innovations such as intraoperative navigation and computer-assisted surgical planning have been shown to improve the efficacy, accuracy, and predictability of surgical procedures. The 3D reconstruction abilities of software could be used to virtually display the patient's anatomy throughout the case, allowing for stereotactic navigation. During the surgery, the intraoperative navigation system helps surgeons to control the positions of implants or of repositioned bone, and assists in verifying the final location. A navigation system enhances the surgeon's ability to measure the extent of resection and to confirm the orientation of bone grafts used for reconstruction. Using this approach, it is possible to minimize the human error factor by increasing the adherence to a pre-

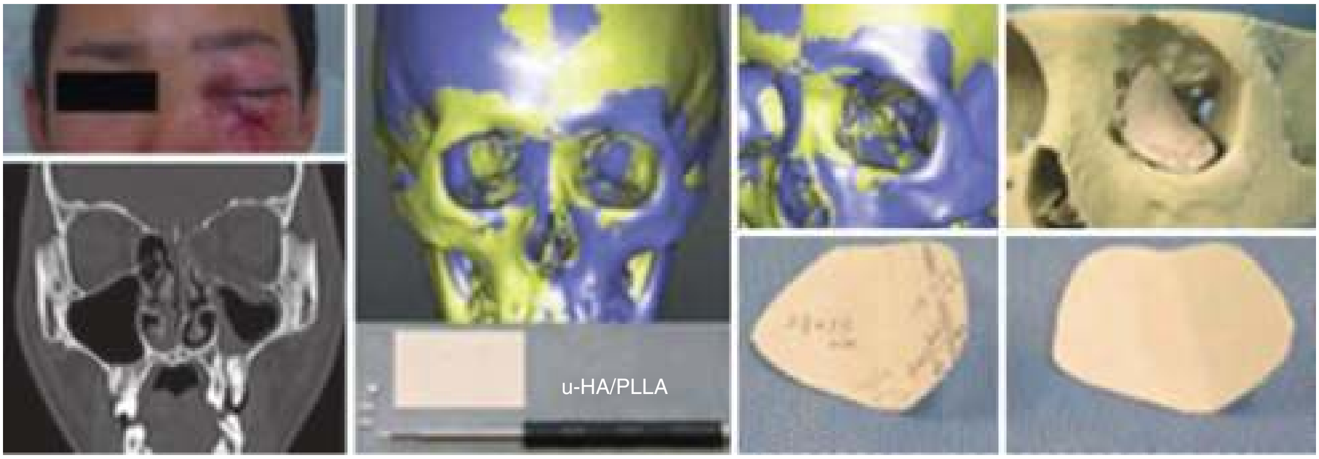

Fig. 41.5 A 17-year-old male undergoing a large orbital floor to medial orbital fracture reconstruction. Surgeons first created a three-dimensional model that was mirrored by CAS, and determined the angle and form of reconstruction material using third-generation bioactive/bioresorbable materials, the SuperFIXORB-MX® (OsteotransMS®) system; TEIJIN Medical Technologies Co., Ltd, Osaka, Japan, according to the shape of the orbits to be reconstructed

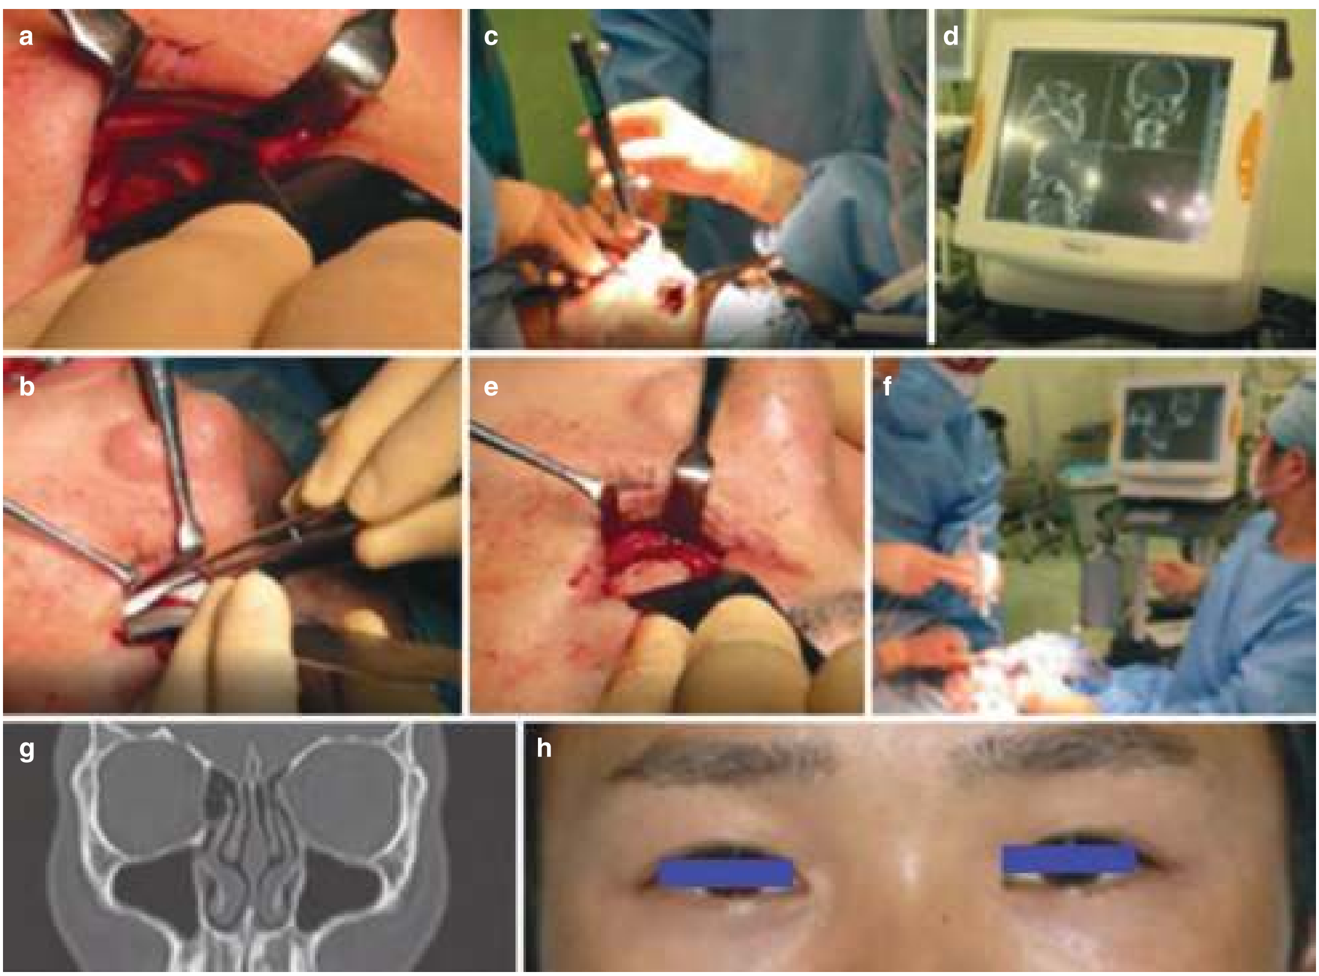

Fig. 41.6 (**a**–**h**) A 17-year-old male undergoing a large orbital floor to medial orbital fracture reconstruction. Navigation will determine the exact intraoperative anatomical form. Reconstruction material before CAS was positioned at the reconstruction site. We then confirmed the exact position of the reconstruction material and reconstructed the orbital shape using the navigation system

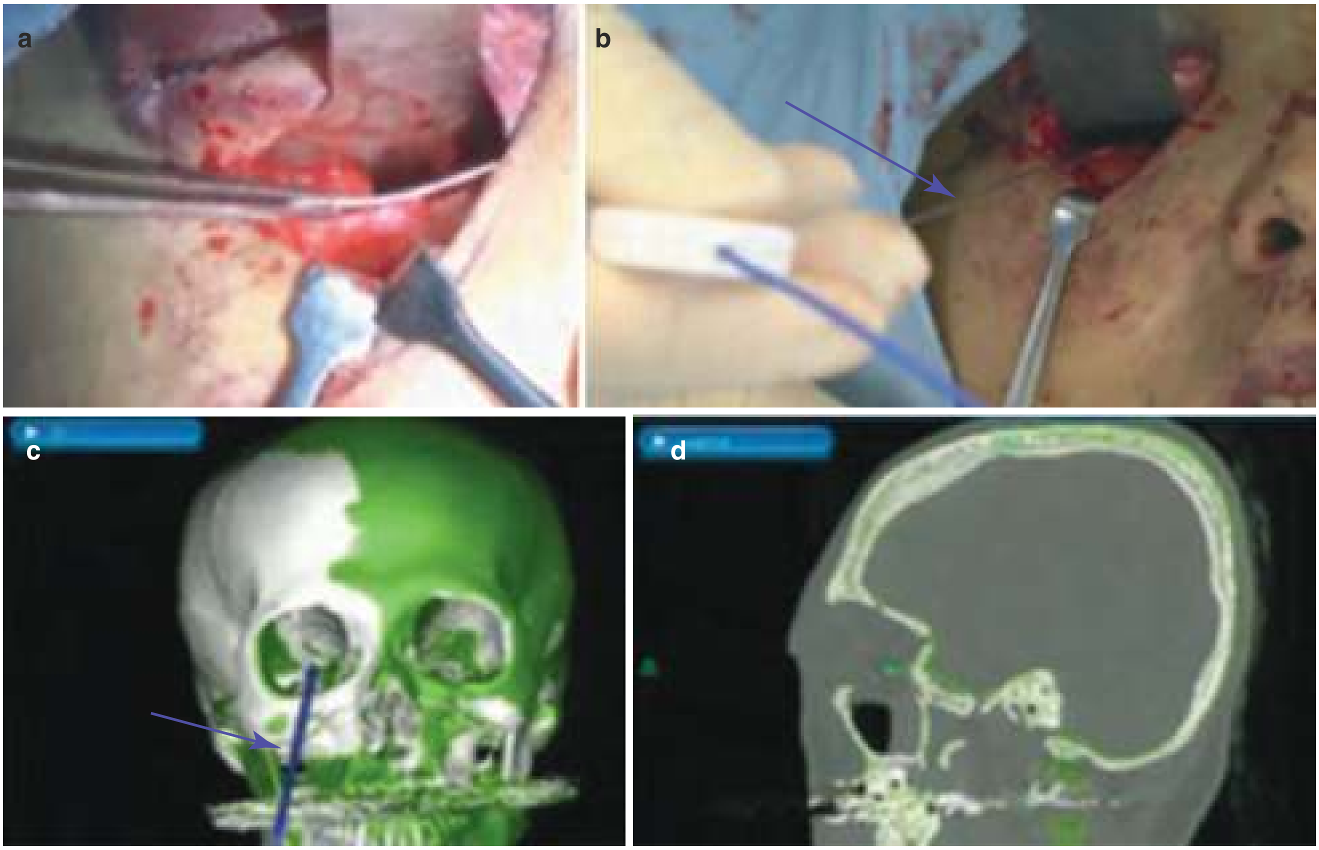

Fig. 41.7 (**a**) The bioresorbable mesh plate was positioned to support the orbital globe. (**b**) The reconstructed site was confirmed to match the mirror image using a tip pointer with a navigation system. (**c**) Intraoperative navigation system screenshot showing a multiplane view of the position of the surgeon's navigation probe in relation to the orbital floor defect region at the time of localization. (**d**) Shows the reconstruction plan image, created using the mirroring technique

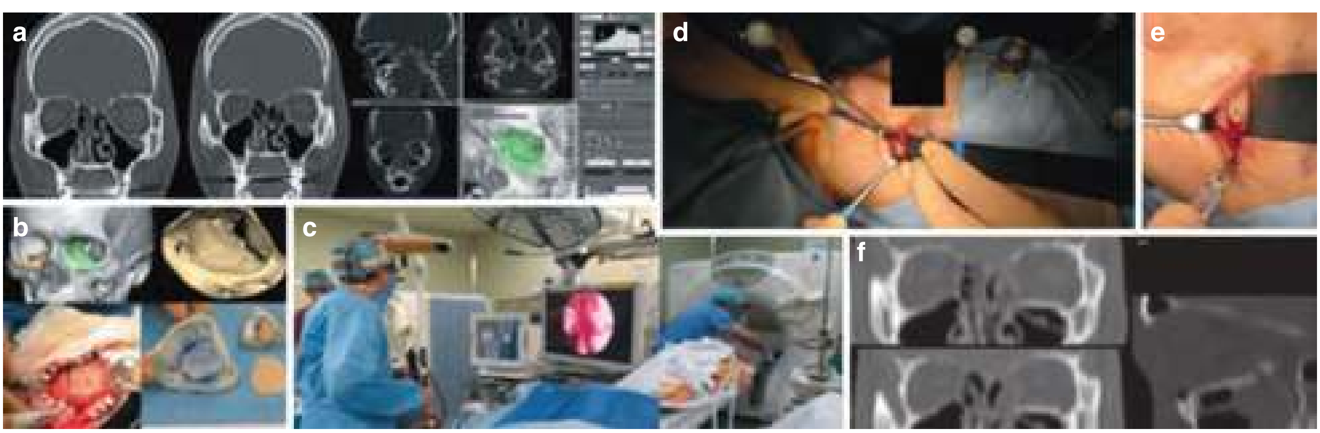

Fig. 41.8 (**a**, **b**) A 33-year-old male undergoing a nasoorbitoethmoidal (NOE) and maxillary fractures open treatment, including a large orbital floor to medial orbital walls fractures reconstruction. We, maxillofacial surgeons, first created a three-dimensional (3D) precise preorbit to orbital groove model that was mirrored by computer-assisted simulation, and determined the anatomical form of reconstruction for autogenous bone harvested from calvaria using Piezosurgery® according to the 3D shape of the orbits to be reconstructed (produced by Yasojima Proceed Co., Ltd. Osaka, Japan). Navigation will determine the exact intraoperative 3D anatomical form. (**c**) The fractured deep medial orbital wall was precisely reduced under an endoscopic-assisted navigation-guided surgery by otorhinolaryngology-head and neck surgeons. (**d**, **e**) We then reconstructed the large orbital floor and confirmed the exact position of the autogenous calvarial bone for accurate reconstruction of the orbit using the navigation system, followed by fixation using titanium screws. (**f**) The use of intraoperative CT in the hybrid operation room can provide rapid CT data during surgery for the final 3D confirmation of complex orbital reconstruction cases

operative plan. Furthermore, this also helps in reducing the incidence of postoperative complications due to improperly positioned or oriented bone grafts, plates, or fixation screws. Virtual surgical planning (VSP) combined with 3D printing technology has improved surgical efficiency and precision through the generation of 3D surgical models, implants, and guides [18]. This increases the number of indicators suggesting the use of VSP by the surgeon, as it offers additional tools in preoperative planning and intraoperative decision making. Both VSP and 3D models may be used to plan the optimal reconstruction material in terms of the volume, shape, and dimensions required. They can also be used to produce templates for resective surgery to accurately demarcate the boundaries for resection and/or to plan more efficient and accurate reconstructive strategies. A further advantage of using 3D models is a reduction in total operative time and the elimination of potential complications from prolonged surgery.

41.3.2 Application for Oral-Maxillofacial Tumor/Cancer

Computer-assisted navigational surgery is a proven method for reducing operating time and increasing reliability in complex surgical procedures of the infratemporal fossa and the periorbital region [19] (Fig. 41.9). Navigation-assisted surgery was introduced in the field of oral, head, and neck tumors more than 20 years ago. The use of navigation in the management of benign and malignant lesions is discussed later.

Malignant lesions of the head and neck have a high rate of recurrence (25–48%). Tumor control essentially depends on the extent of the tumor, its location, and the margins of resection, with the latter being a very important prognostic factor in cancer surgery. Feichtinger et al. [20] used navigation systems to evaluate the resection margins in the treatment of six patients with carcinomas in the nasal cavity, maxillary sinus, and oral cavity. In four patients, further resection had to be performed after an assessment with a navigation system

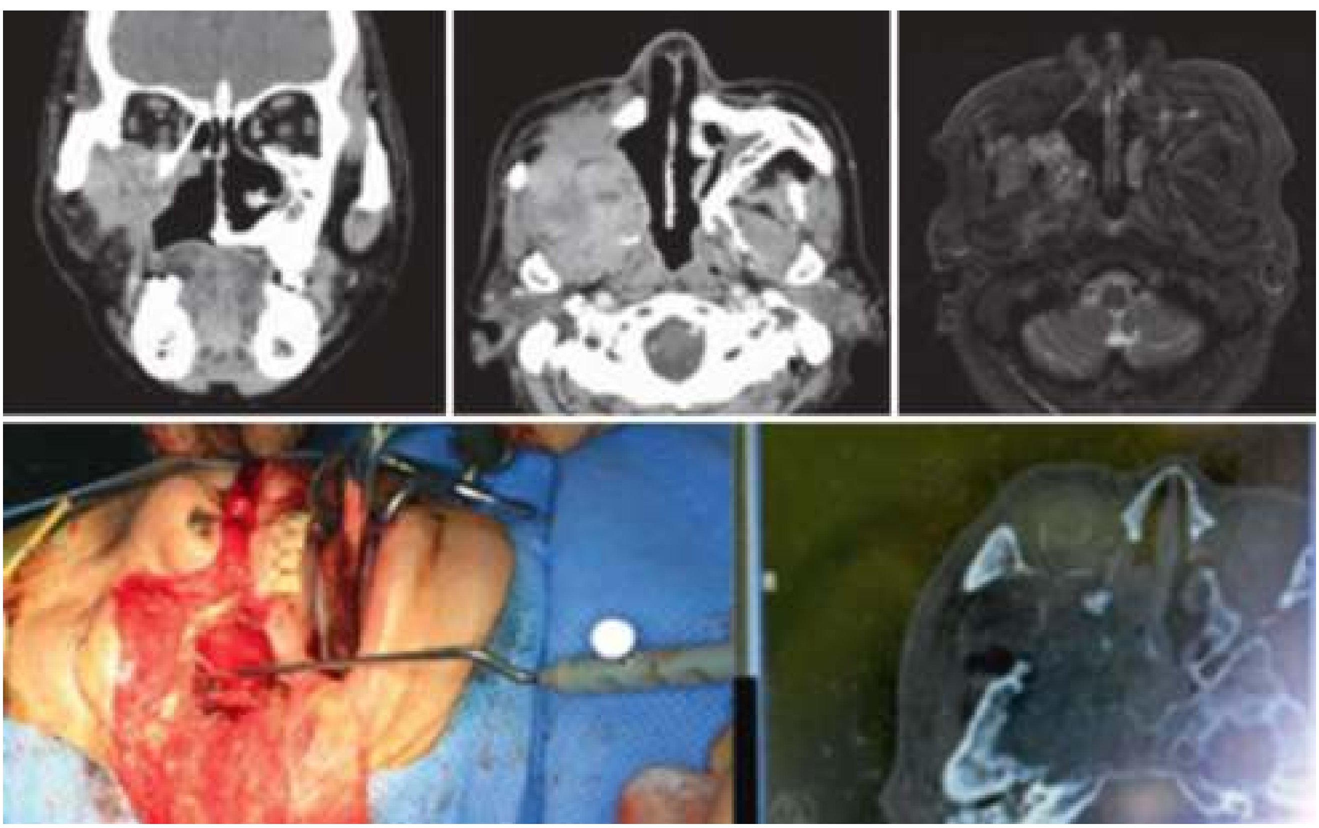

Fig. 41.9 A 79-year-old male with recurrent ameloblastoma of maxilla-infratemporal fossa. Because of the complexity of the local anatomy, tumors in the infratemporal fossa present a challenge to oral and maxillofacial surgeons. Recurrent malignant tumors in this area are particularly difficult to resect because scars from previous operations may dislocate important structures. A navigation technique has been introduced to resect infratemporal fossa tumors and was successfully applied for the resection of recurrent malignant tumors. The visible navigation during surgery could increase the accuracy and safety of the operations and enhance surgeon confidence

using positron emission tomography (PET)-CT scans proved the initial resection to be unsatisfactory. This demonstrates that navigation surgery based on PET-CT image fusion is an excellent tool for improving the local control of advanced head and neck cancer.

Navigation-assisted surgery has also been successfully used in the management of benign tumors of the maxillofacial region [21]. This was performed with features such as mirroring and side-to-side comparisons, and was applied with successful results. Use of customized hydroxy-apatite prosthesis with pre-embedded titanium implants was used for reconstruction. Optimal positioning is secured using navigation. Some interesting techniques for reconstruction are discussed now.

It is important to remember that navigation is an excellent tool when it comes to its use in the skull base [22], the midface [23], and the neck [24]. However, its use in mandibular tumors is limited due to the possibility of changes in the spatial orientation of the lower jaw, as described earlier.

41.3.3 Application for Orthognathic Surgery

The primary determinants of success in orthognathic surgery include an accurate diagnosis, meticulous treatment planning, and the ability to transfer the plan precisely to the patient intraoperatively. In earlier years, this was performed by a process of model surgery in a laboratory using articulators on plaster casts, which were then transferred to the patient using acrylic splints during the surgical procedure (Figs. 41.10 and 41.11). The procedure was error prone at multiple levels within the sequence. Literature reports an error of up to 5 mm using this type of treatment sequence. With the advent and routine usage of CAD/CAM technology

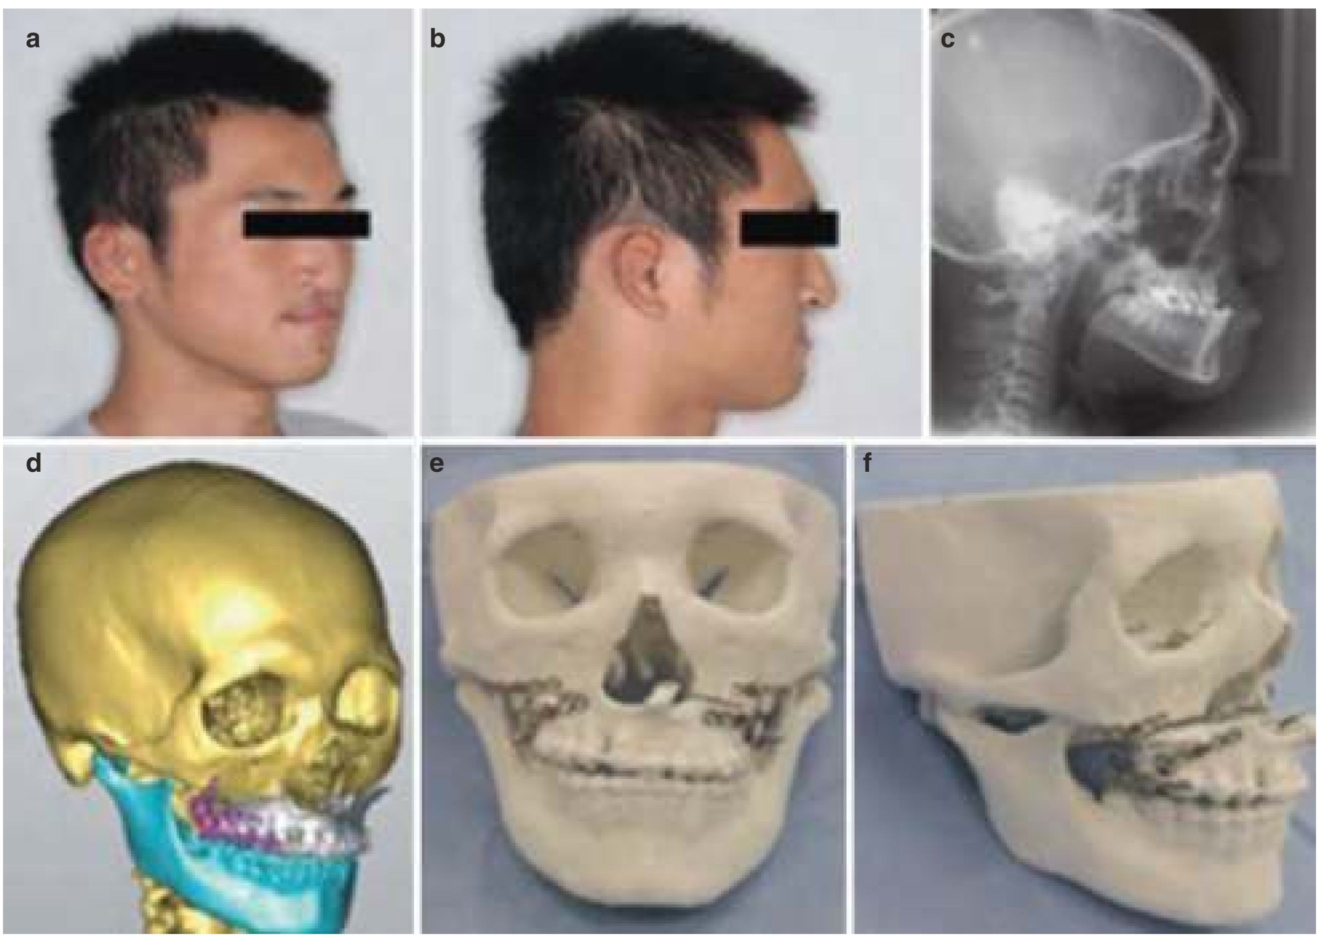

Fig. 41.10 Optimal treatment planning and preparation using 3D models. CAS for cleft lip and palate-related severe maxillary hypoplasia deformity patients using maxillary distraction osteogenesis. (**a**–**c**) A 17 year old male undergoing maxillary distraction for cleft-related midfacial retrusion. (**d**) Detailed computer simulation for maxillary distraction surgery in a patient with severe maxillary hypoplasia deformity was used to determine the optimal treatment plan, such as the distraction direction and degree of advancement. (**e**, **f**) A 3D printed skeletal model was used to prepare for a maxillary semi-custom-made distractor setting with fabrication

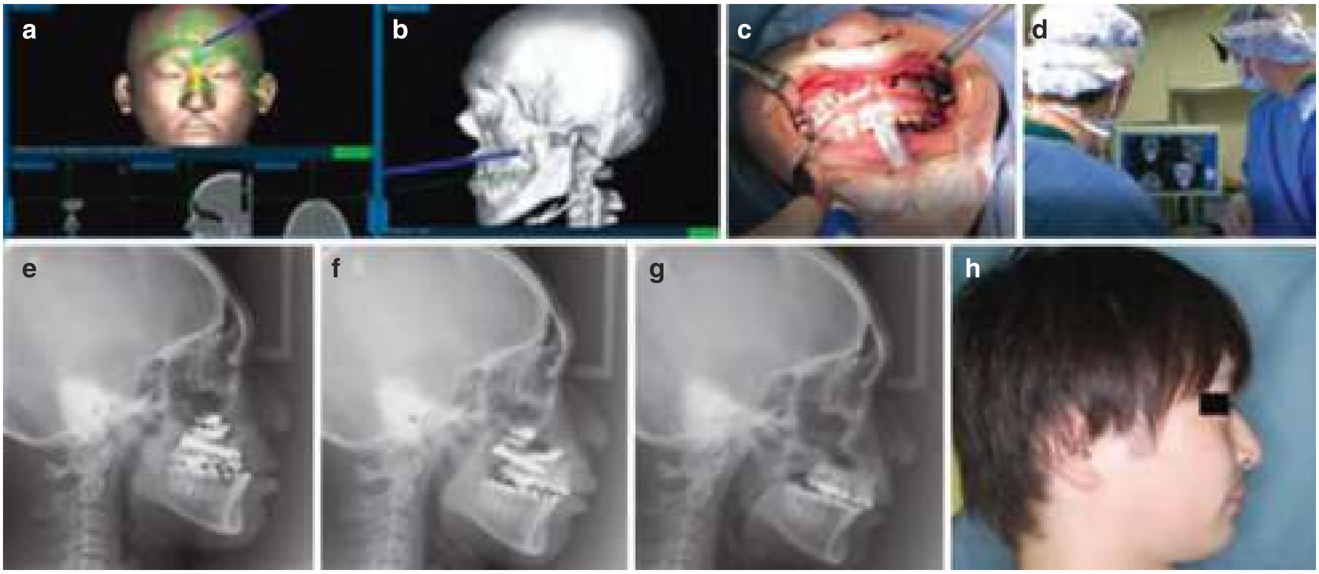

Fig. 41.11 A 17-year-old male undergoing maxillary distraction for cleft-related midfacial retrusion. (**a**–**d**) Accurate transfer of the treatment plan to the patient in the operating room was acheived. Using the navigation system, precise placement of the maxillary distraction planned preoperatively at the set position was performed. The surgeon then confirmed the same distraction direction that was preoperatively planned by the intraoperative navigation. (**e**–**g**) Shows the radiographs during and post treatment. (**h**) Shows the final post surgical result of the patient

and virtual surgical planning, the workflow of treatment planning in orthognathic surgery has undergone a paradigm shift. The conventional workflow of model surgery and splint fabrications is slowly paving the way for VSP and custom printed 3D splints and guides.

Although the degree of inaccuracies associated with treatment planning is reduced using this approach, certain drawbacks such as autorotation of the mandible and lack of control on the vertical position of the maxilla are still prevalent.

> There are three methods by which CAS is used in the practice of orthognathic surgery: (1) using real-time intraoperative guidance with surgical navigation for the repositioning of the maxilla and mandible; (2) use of 3D printed cutting guides for precise osteotomy and repositioning, with or without customized 3D printed osteosynthesis plates; and (3) the use of wafer-less surgical planning where the printed implant doubles as both a cutting guide for the osteotomy and as the fixation devices. Many clinical studies have evaluated the efficacy of these methods with promising results.

Mazzoni et al. were the first to report the use of intraoperative navigation in orthognathic surgery, in 2010 [25]. They calculated the overlap error to assess the accuracy of the technique after surface matching the virtually planned model and the postoperative CT scan. The accuracy was reported for the entire facial skeleton, rather than for each component individually (maxilla, mandible, chin), with a mean match error for each patient ranging from 0.28 to 1.99 mm. Repeatability (<2 mm) in the face area ranged from 77.5% to 96.2% between patients, with a mean reproducibility of 86.5%.

Zinser et al. published a clinical controlled trial study in 2013 that compared the navigation technique with conventional technique, using 3D surgical guides and intermaxillary splints [26]. The highest accuracy for transfer of the maxillary plan to the patient was observed when a 3D surgical guide was used, and no significant linear differences between the planned virtual model and the postoperative results were present in any direction. The navigation technique only showed a significant mean linear difference in the vertical dimension, and differences in angulation were not significant in either group. In contrast, significant linear differences were shown for the classic intermaxillary splints between the planning results and the actual results in the sagittal and vertical dimensions. Differences in plane angulations when using an interocclusal splint were also significant. The usefulness of navigation-assisted surgery for orthognathic surgery was supported based on previous reports.

Published literature demonstrates that all studies have met the 2-mm success criterion, which refers to a maximum difference of 2 mm between the virtual planning performed and the actual surgical outcome. Zinser et al. reported the only prospective controlled clinical trial comparing CAD-CAM splints, navigation surgery, and intermaxillary splints for the transfer of maxillary planning [26]. The CAD-CAM splints, patented by the authors, were used for maintaining the mandibular condyles (TMJ) in their centric relation. Mandibular positioning still poses a challenge during orthognathic surgery, with none of the solutions having attained "gold-standard" status.

An important clinical limitation for the use of navigation is the increase in operating time [27]. Though there is ample support for increased accuracy levels with the use of navigation, the prolonged operating time still remains a deterrent for the routine use of intraoperative navigation in orthognathic surgery. A recent study indicates that dynamic navigation systems have an entry error of approximately 0.4 mm [28] and an angular deviation error of approximately 4° [29]. Further technological developments can be expected in the field of orthognathic surgery, and an appropriate update for surgeons is required.

41.3.4 Application for Preimplant Bone Augmentation/Dental Implants

Loss of teeth and supporting structures is a common occurrence in the field of oral and maxillofacial surgery for patients who have suffered extensive alveolar bone defects caused by cysts, tumors, facial trauma, or severe periodontal disease [30]. Comprehensive reconstruction methods, including rehabilitation with multiple dental implants, are commonly required to restore function in these patients.

Issues like atrophic jaws, where dental implants cannot be placed due to the loss of bone corpus, are managed by regenerative procedures. Although bone augmentation at the mandibular posterior area is important for occlusion reconstruction using dental implants, it is difficult due to anatomical limitations arising from the inferior alveolar nerve (IAN) and the mandibular bone. However, bone augmentation at the mandibular posterior area can be performed safely and reliably using CAS with 3D modeling and navigation systems (Figs. 41.12 and 41.13).

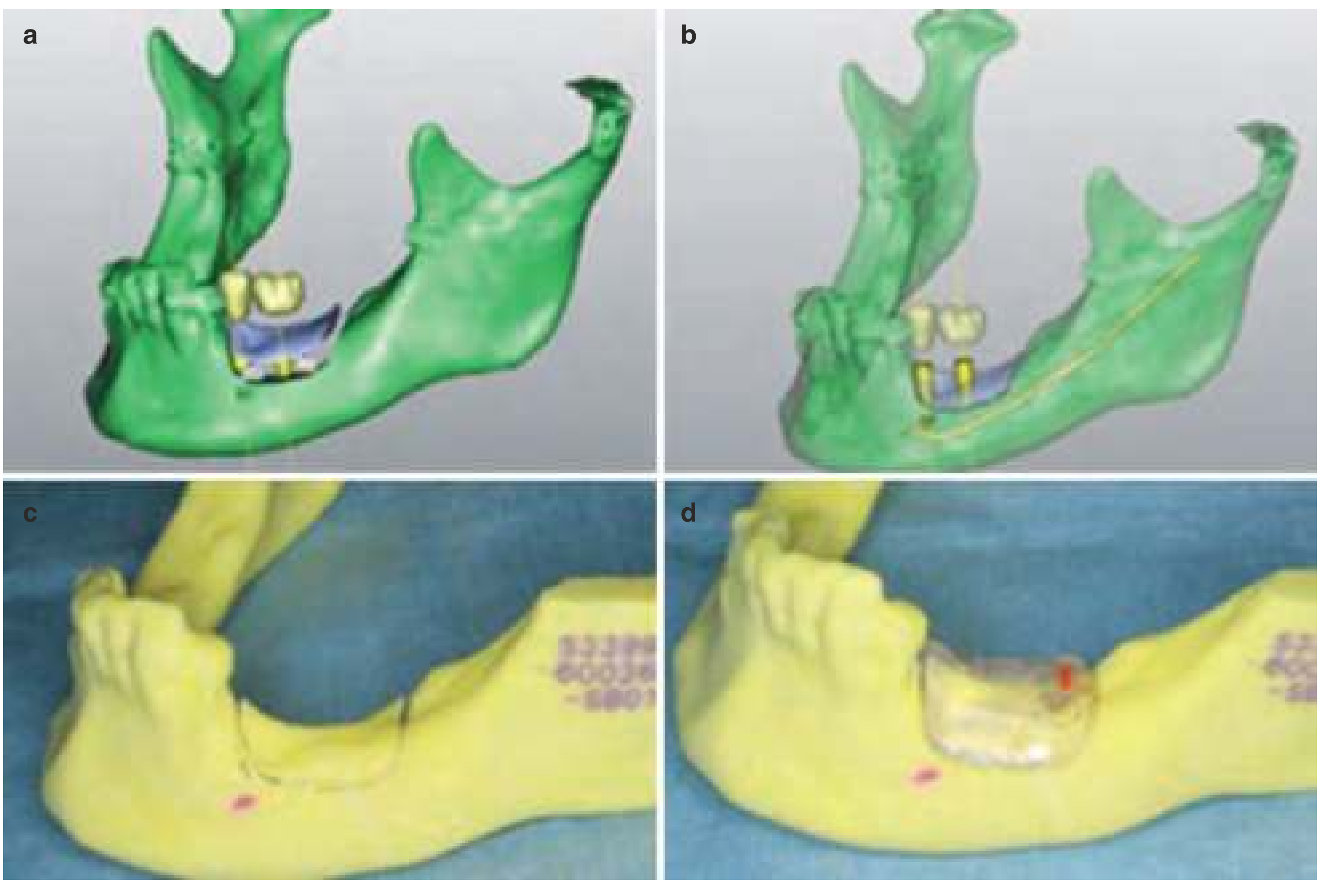

Fig. 41.12 (**a**–**d**) Computer simulation based on preoperative CT data will determine the bone augmentation method for implantation. In this case, we chose bone augmentation using the sandwich technique. The necessary bone augmentation volume and position of the anatomically important inferior alveolar nerve (IAN) were confirmed using computer simulation. Based on this information, we will determine a safe bone cutting line. Surgeons then created a surgical guide using a 3D model based on simulation

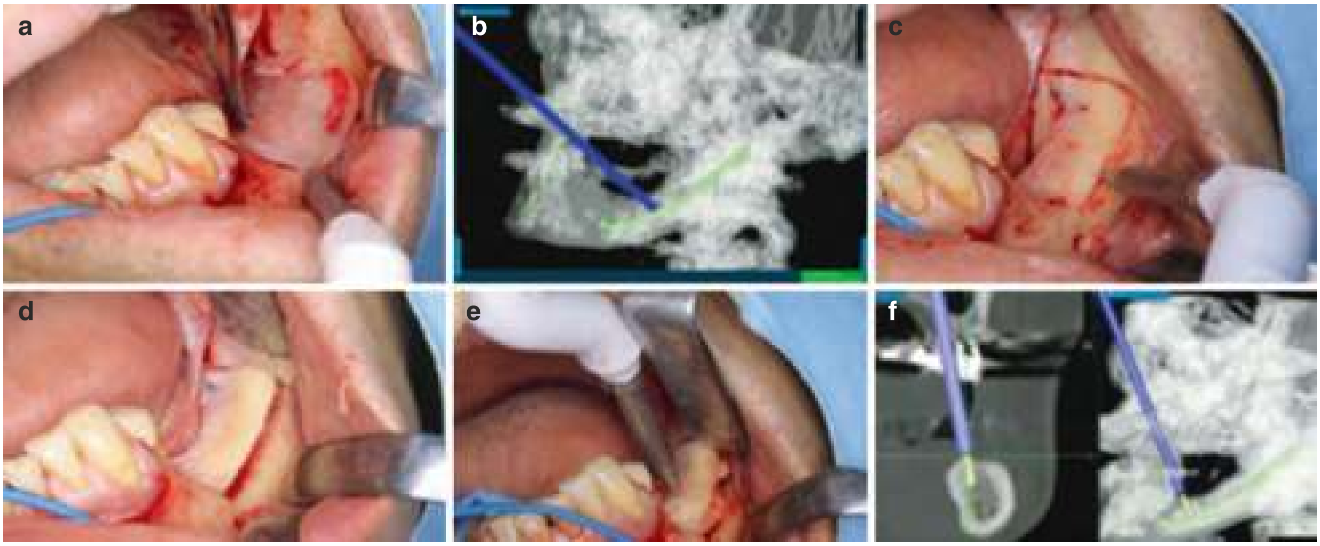

Fig. 41.13 (**a**–**d**) This is a continuation of Fig. 41.12. While confirming the position of the IAN in real time based on intraoperative navigation, the surgeon cut the alveolar bone with reference to the surgical guide created before surgery. (**e**) The surgeon then inserted autologous bone taken from the donor and increased the alveolar bone vertically. The most important goal in this surgery is to acquire alveolar bone height as planned before surgery. (**f**) The bone height can be confirmed in real time based on intraoperative navigation

Traditionally, implants have been placed freehand or with the use of laboratory-fabricated guidance stents. The use of CT-guided 3D printed stents with coordinated drill sequencing has minimized errors to a level of less than 2 mm for crestal and apical deviations, and to less than 5° in angulations. Dynamic navigation systems use a time-effective method to accurately place implants with equivalent implant placement error. Currently the Image-Guided Implantology system (Navident; HERMANS Corp., Tokyo, Japan) is the only dynamic image navigation system (DINS) available for in-office dental procedures in Japan. Its counterpart in the United States is the passive optical dynamic navigation in implantology (X-Nav Technologies, Inc., Lansdale, PA, USA).

> Navigation in dental implantology can add the following advantages: (1) precise depth control and reduced risk of IAN damage [31]; (2) help in planning for flapless surgery or limited flap elevation surgery with reduced postoperative morbidity [32]; and (3) accurate spacing and implant angulation compared to using a freehand approach.

The use of virtual implant planning and intraoperative navigation allows for prosthodontic and surgical coordination due to its planning accuracy and implementation in actual surgical scenarios.

Dynamic navigation methods have similar advantages, including high accuracy, time- and cost-effectiveness, minimally invasive techniques, and flexibility in changing the implant size, system, and location during the surgical procedure [33]. An additional advantage is comfort provided the surgeon in the form of posture, facilitating reduced bending of the neck and back. For example, dynamic navigation allows implant placement for patients with a limited mouth opening, or requiring an implant at a second molar site with reduced access, by relying on a navigation screen to guide the drill sequence without direct visualization of the patient's mouth.

41.3.5 Clinical Applications for the Removal of Foreign Bodies

Retrieval of foreign bodies in the craniomaxillofacial region is often extremely dangerous due to the proximity to various vital structures within a limited anatomical space [34]. This may be made more complex by the presence of deep foreign bodies secondary to severe trauma such as gunshot wounds or blast injuries, which significantly alter the anatomy. Precise location of the foreign body is the first step in the retrieval process, and this may be accomplished with preoperative scans and 3D image rendering. The intraoperative step is next, and is more challenging, as the exact location of the foreign body within the surgical field must be ascertained. Traditional methods utilize a stereotactic "double needle" method with venipuncture needles for triangulation

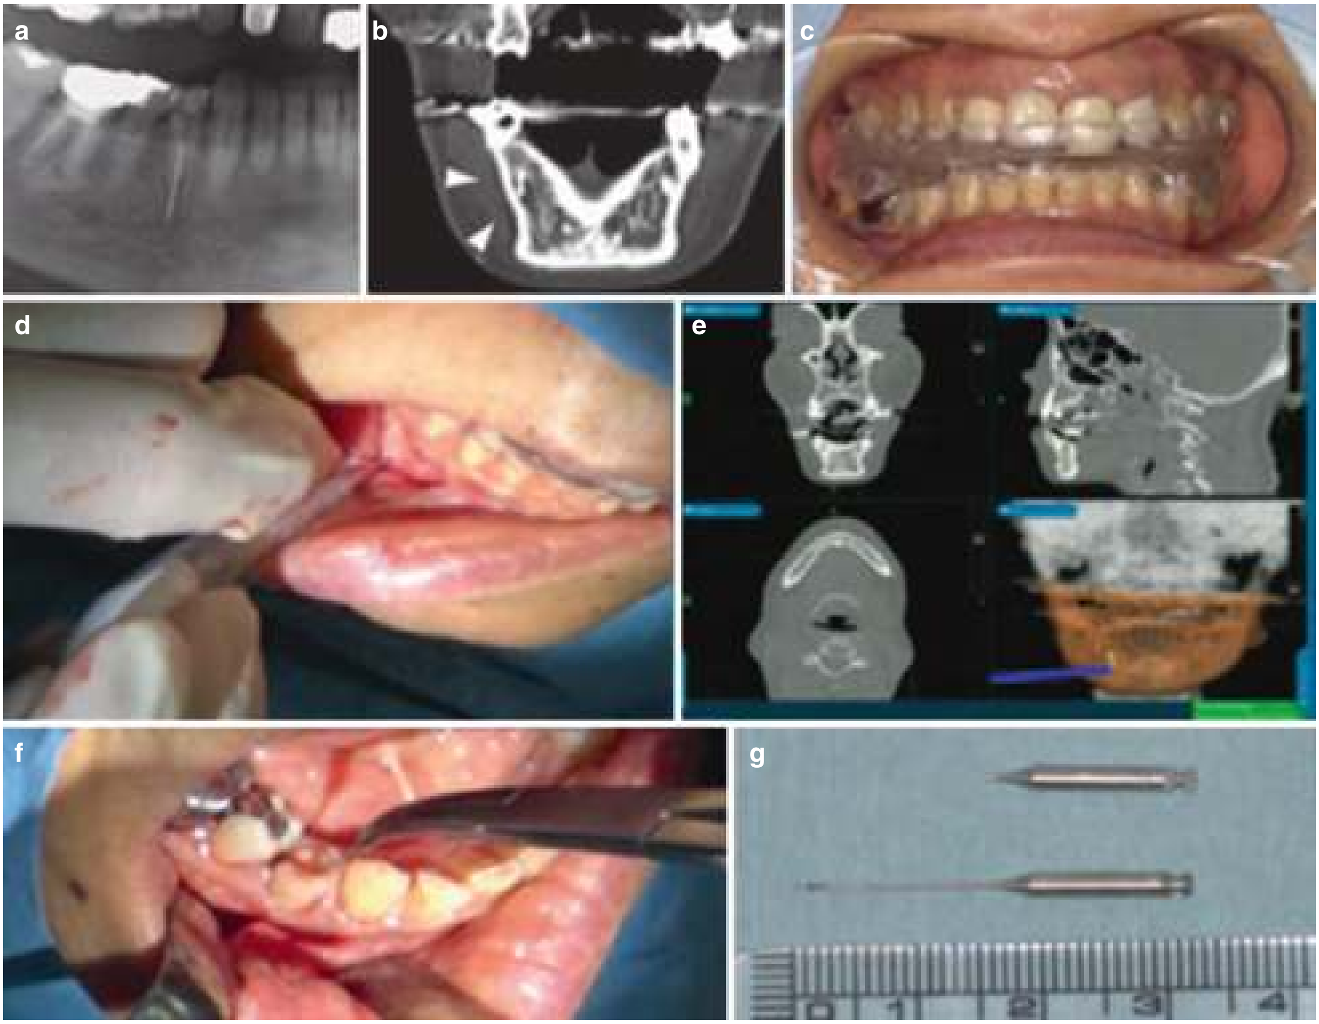

Fig. 41.14 (**a**–**g**) A 65-year-old female with a foreign body due to dental instrument breakage in the mandible, occurring during an endodontic treatment for a restorative dental procedure. (**a**, **b**) Fracture of root canal instruments, with a fractured piece protruding beyond the apex, is a troublesome incident during endodontic treatment. Locating and retrieving these objects represents a challenge for maxillofacial surgeons because they are difficult to access due to the proximity between the foreign body and vital structures. Using the navigation system for mandible treatment is difficult as the mobile nature of the mandible complicates its synchronization with the preoperative imaging data during surgery. (**c**) The broken dental instrument was removed using a minimally invasive approach with a surgical navigation system and an interocclusal splint for stable, identically repeatable positioning of the mandible. (**d**, **e**) Based on the 3D position of the navigation probe, a location that best approximated and the most anterior extent of the fragment was selected. (**f**) A minimal vestibular incision was made at this location, a subperiosteal reflection was performed, and the foreign body location was confirmed using the navigation system. (**g**) The instrument was carefully visualized and extruded from the apical to the tooth crown side and was then removed using mosquito forceps through the medullary cavity of the crown side of the tooth

of the foreign body using plain radiographs [35]. This involved the two reference needles being sequentially placed until both met the foreign body on radiographs. Through blunt dissection, one of the needles is made to contact the foreign body and locate it. It is important to understand that it may be difficult to distinguish small changes in position on plain radiographs. The use of C-arm digital fluoroscopy was a significant advancement for this method, providing rapid radiography [36]. However, as with plain films, fluoroscopic images are 2D, which imposes limitations when locating objects in a 3D space. The use of intraoperative ultrasound imaging has also been proposed to localize foreign bodies. However, the precision involved in positioning may be questionable, and its use in the oral cavity may also be limited by the size of the instrument.

Intraoperative navigation systems could allow a foreign body to be accurately located in 3D space; these systems are very effective for removing a foreign body during facial surgery [37] (Figs. 41.14 and 41.15). One limitation of navigation is the incapability of the system to account for

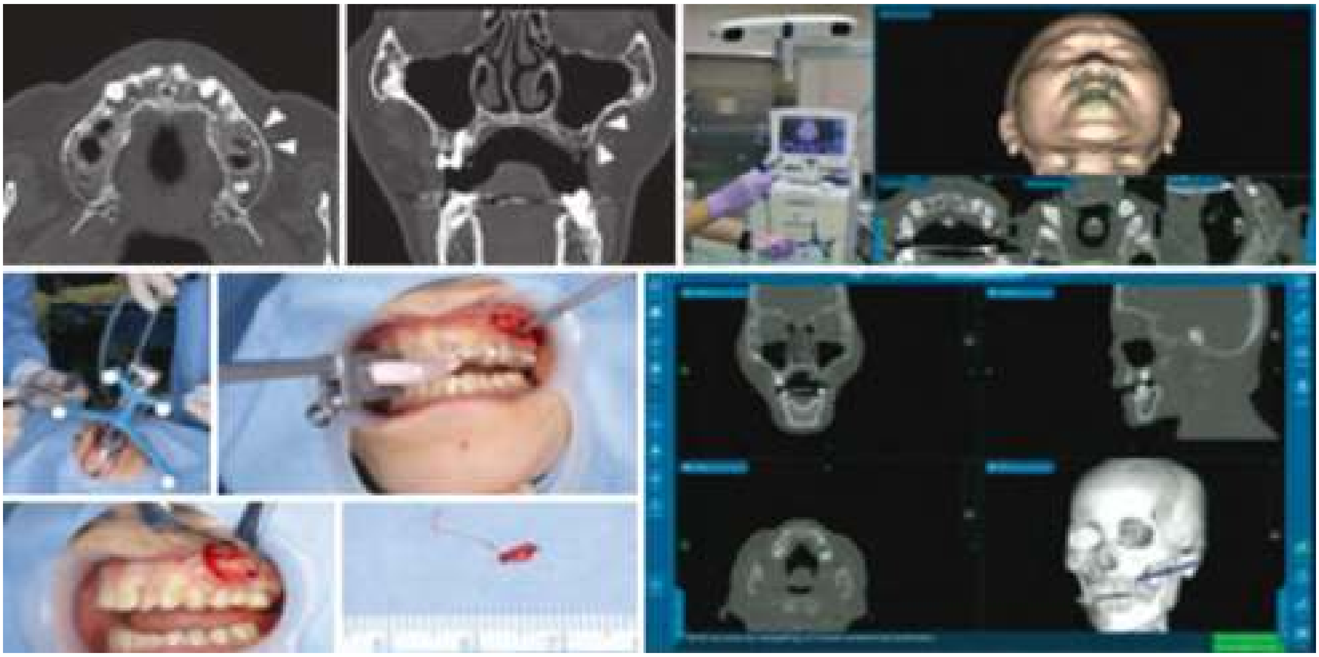

Fig. 41.15 A 78-year-old female with a small foreign body in the maxilla. Accurate determination of the position of the foreign body in the maxillofacial region can be challenging. This may be due to a small-sized foreign body or a limited inflammatory response. Navigation systems are helpful in identifying the location of the foreign body, determining the optimal approach, and performing the surgical procedure using a minimally invasive surgical strategy. In this case, registration could be reliably performed before surgery using an optical navigation system that facilitates the process, utilizing splints with embedded reference points. This method can decrease the operation time

intraoperative soft-tissue changes. The use of navigation techniques superficial tissues or to minimize soft-tissue manipulation may help us overcome this to an extent.

41.3.6 Application for Dentoalveolar Surgery

Dynamic computer-based image navigation technology is a good method for increasing accuracy while minimizing the invasiveness of surgery. It has the additional advantage of real-time access to intraoperative radiographs, which enable us to perform complex dentoalveolar procedures with relative ease. Currently, the Image-Guided Implantology system (Navident; HERMANS Corp.) is the only dynamic image navigation system (DINS) available for in-office dental procedures in Japan. This is an ultraviolet-based optical system, which was approved by the US Food and Drug Administration for the placement of dental implants. However, its use for other dentoalveolar procedures is not approved. Its advantages in the field of dental implantology have already been discussed earlier. The use of dynamic navigation when applied to complex dentoalveolar procedures, such as the surgical removal of third molars, is similar to its use for dental implants, helping the surgeon prevent inadvertent damage to key structures like the IAN, roots of adjacent teeth, or the lingual plate of the mandible [38]. Common indications for the use of navigation in dentoalveolar surgery include third molar extractions and the location and extraction of supernumerary [39] or malposed teeth (Fig. 41.16), as well as teeth, which get iatrogenically displaced into the sinus, the sublingual pouch, or even the infra temporal fossa.

The use of CAS in oral and maxillofacial surgery has been enhanced with the increasing availability of CBCT. This in turn has promoted the use of Dynamic Image Navigation. As described earlier, the use of DINS during surgical extraction improves visualization of the regional anatomy, preventing or minimizing complications secondary to dentoalveolar surgery. In addition, improved instrument control allows for reduced bone removal, minimization of the surgical access size, and an overall reduction in the morbidity of the procedure. As discussed earlier, this technology also allows for improvement of the ergonomics involved during the surgery. Lastly, dynamic guidance can serve as an effective teaching tool for young surgeons by displaying the surgery and the locations of vital structures on screen.

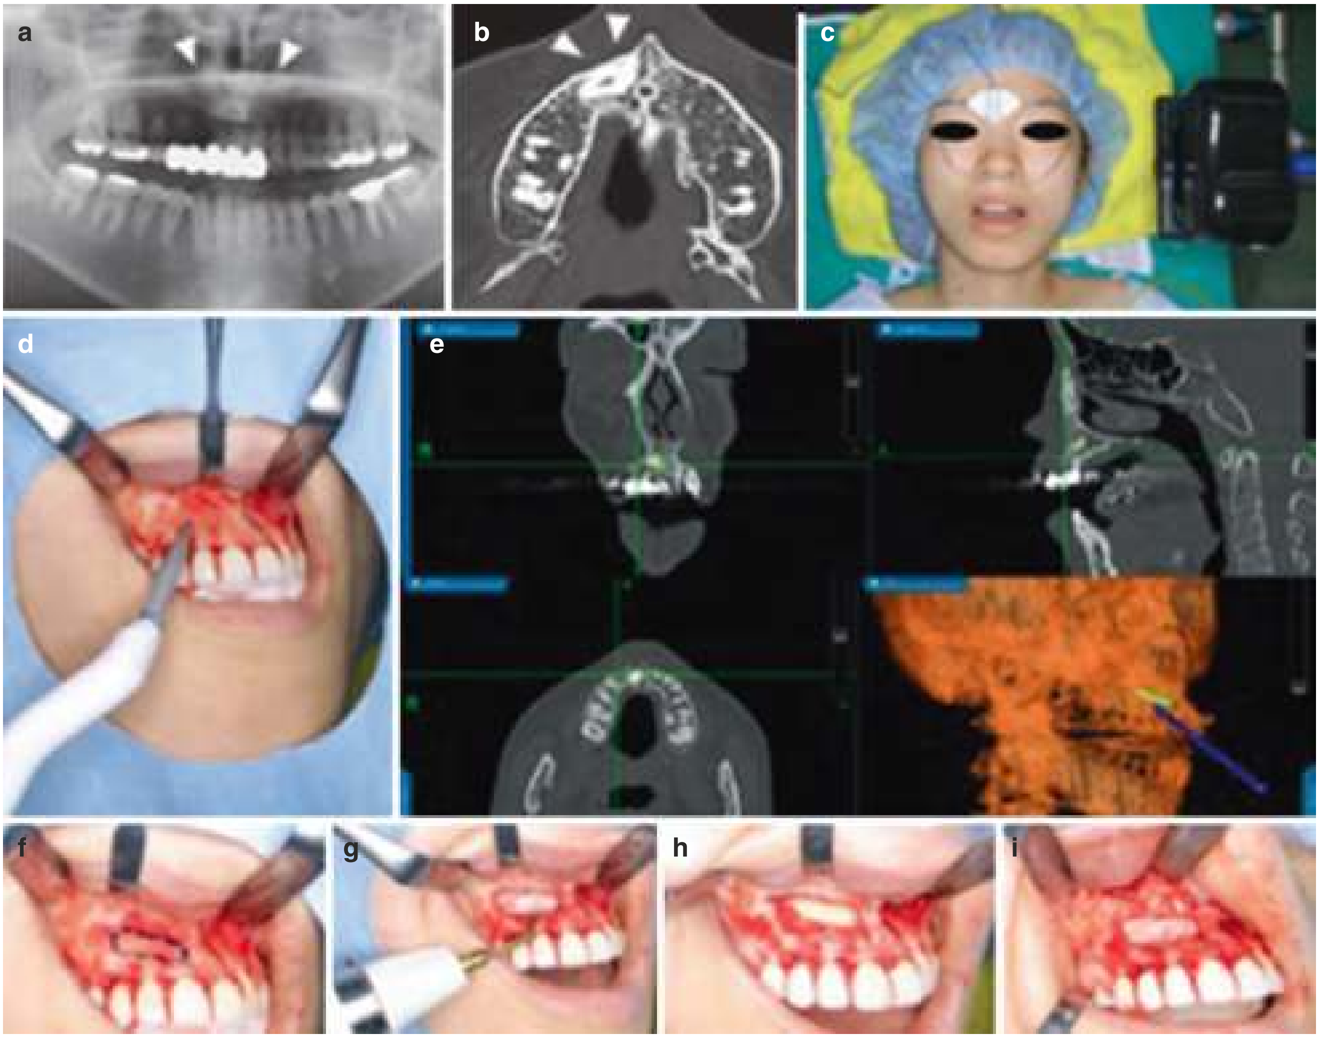

Fig. 41.16 (**a**–**i**) A 24-year-old female with an impacted maxillary canine tooth. Bone lid surgery involves cutting a window into the cortical bone and removing a portion thereof; this portion is subsequently returned to its original position at the end of surgery. Bone lid surgery is a minimally invasive technique designed to avoid secondary large bone defects during osteotomies. However, because jaw bone lesions are completely covered with cortical bone, it can be difficult to accurately determine the position of the lesion from the outside. As a potential solution, we used navigation-assisted bone lid surgery. Using navigation, surgeons could confirm the state of the impacted tooth and surrounding tissue from above the covered bone. We were also able to establish a safe and reliable bone cutting line. In addition, the removed cortical bone was returned to the same (i.e., presurgical) position. Navigation-assisted bone lid surgery for the removal of impacted teeth increases surgical accuracy, minimizes invasion, and allows the bone to be returned to its original position (**a**, **b**)-pre operative OPG and CT (**c**–**e**)-shows intra operative navigation. (**f**) outline of canine marked (**g**, **h**) impacted canine being removed (**i**) the bone lid placed back in position

Wang reported the following advantages of surgical navigation in complicated extractions: (1) localization of teeth for accurate access planning and minimal bone removal; (2) differentiation of impacted teeth from erupting tooth germs; (3) ensured transfer of the preoperative plan to the surgical procedure; and (4) the marking of safety margins while preserving adjacent structures, to avoid complications [40].

41.3.7 Application for Temporomandibular Joint and Skull Base Surgery

The TMJ and surrounding anatomy, including the skull base, are extremely complex and require a cautious approach during surgery. Intraoperative navigation can play an important role for surgeries such as the removal of an ankylotic bony mass, tumor resection, and gap arthroplasty [41]. Successful treatment outcomes have been reported by studies for the use of navigation assistance in unilateral surgery for the TMJ. Other publications report that navigation is helpful and increases safety in TMJ surgery. A recent publication used navigation to compare prospectively treated groups of patients with recurrent malignant tumors of the infratemporal fossa. Although the results are not independently significant, they yielded a benefit to the navigation cohort. The authors concluded that surgeon confidence and safety during the operations improved, but the navigation system alone did not determine patient outcomes.

Management of tumors at the skull base or of end-stage degenerative TMJ disorders requires thorough knowledge of the regional anatomy and precise 3D planning of the resection margins with attention of vital structures in the immediate vicinity (Fig. 41.17). The location, invasion, and extent of the tumor are key determinants in deciding the surgical approach. In the past, malignant tumors that had infiltrated into the infratemporal fossa or the middle of the skull base were considered inoperable due to the compromised access and inability to achieve predictable tumor control or hemostasis.

The use of surgical navigation for skull base surgery offers the following advantages: (1) ensuring safer and quicker skull base access through a dynamic display of the precise operating site and the extent of bone drilling, thereby significantly reducing intraoperative risk; (2) mapping the anatomical structures and important landmarks such as the foramen ovale and rotundum; and (3) the incorporation of allied imaging modalities, such as 3D CT angiography and MRI, into the intraoperative navigation planning, increasing our understanding of the skull base anatomy and the internal carotid artery region.

As surgery of the skull base is not affected by the shifting brain, use of navigation in this field is more precise than in other neurosurgical procedures. The use of a navigation system for the resection of tumors of the skull base or of TMJ lesions increases surgical predictability while reducing the surgical duration.

41.3.8 Other Applications

Another application of intraoperative navigation is in surgery for the management of Eagle's syndrome, which may be due to the elongation of the styloid process of calcification of the stylomandibular ligament [42]. This condition involves a group of symptoms, including throat pain and foreign body sensation on the affected side, reflex otalgia, head and neck pain, and hypersalivation. Surgical treatment was indicated for patients with no symptomatic improvement following conservative treatment.

The surgery may be performed by two different approaches: (1) transcervical and (2) transoral. The cervical approach provides better surgical exposure of the area, but has the major disadvantage of an external incision. The transoral approach is cosmetically favorable, and is more commonly used. However, this approach offers very limited access. This may affect the management of intraoperative complications, including hemorrhage or difficulty in identifying the styloid process. Several methods have been advocated recently to overcome these problems. One report suggests an endoscopically assisted transoral approach for achieving better exposure and visibility of the field. Another method proposes a combination of piezoelectric surgery and surgical navigation for a transcervical approach to remove the styloid. This technique offers a safe and effective method for the treatment of Eagle's syndrome (Fig. 41.18).

41.4 Recent Advances

41.4.1 Navigation Using Intraoperatively Updated Images

The accuracy of surgical navigation in recent years has been augmented by the induction of intraoperative imaging modalities like the intraoperative CBCT, C-arm, and O-arm systems [43]. These offer intraoperative multiplanar reconstruction capabilities, which enable the improvement of surgical outcomes in demanding surgeries such as surgery of the orbital walls. Furthermore, the popularization of hybrid operating rooms (Fig. 41.19) equipped with both intraoperative imaging and navigation systems has revolutionized surgery of the maxillofacial region. It is now possible to continuously update intraoperative images to determine the best sequence to follow during surgeries (Fig. 41.20). The effectiveness of a navigation system using intraoperative CT images has been already demonstrated in orthopedic surgery and maxillofacial operations, which involve bone movement, such as trauma surgery and orthognathic surgery. Intraoperative CT images have allowed for rapid intraoperative evaluations, which when coupled with surgical navigation, may allow for performing more complicated maxillofacial surgery with increased accuracy.

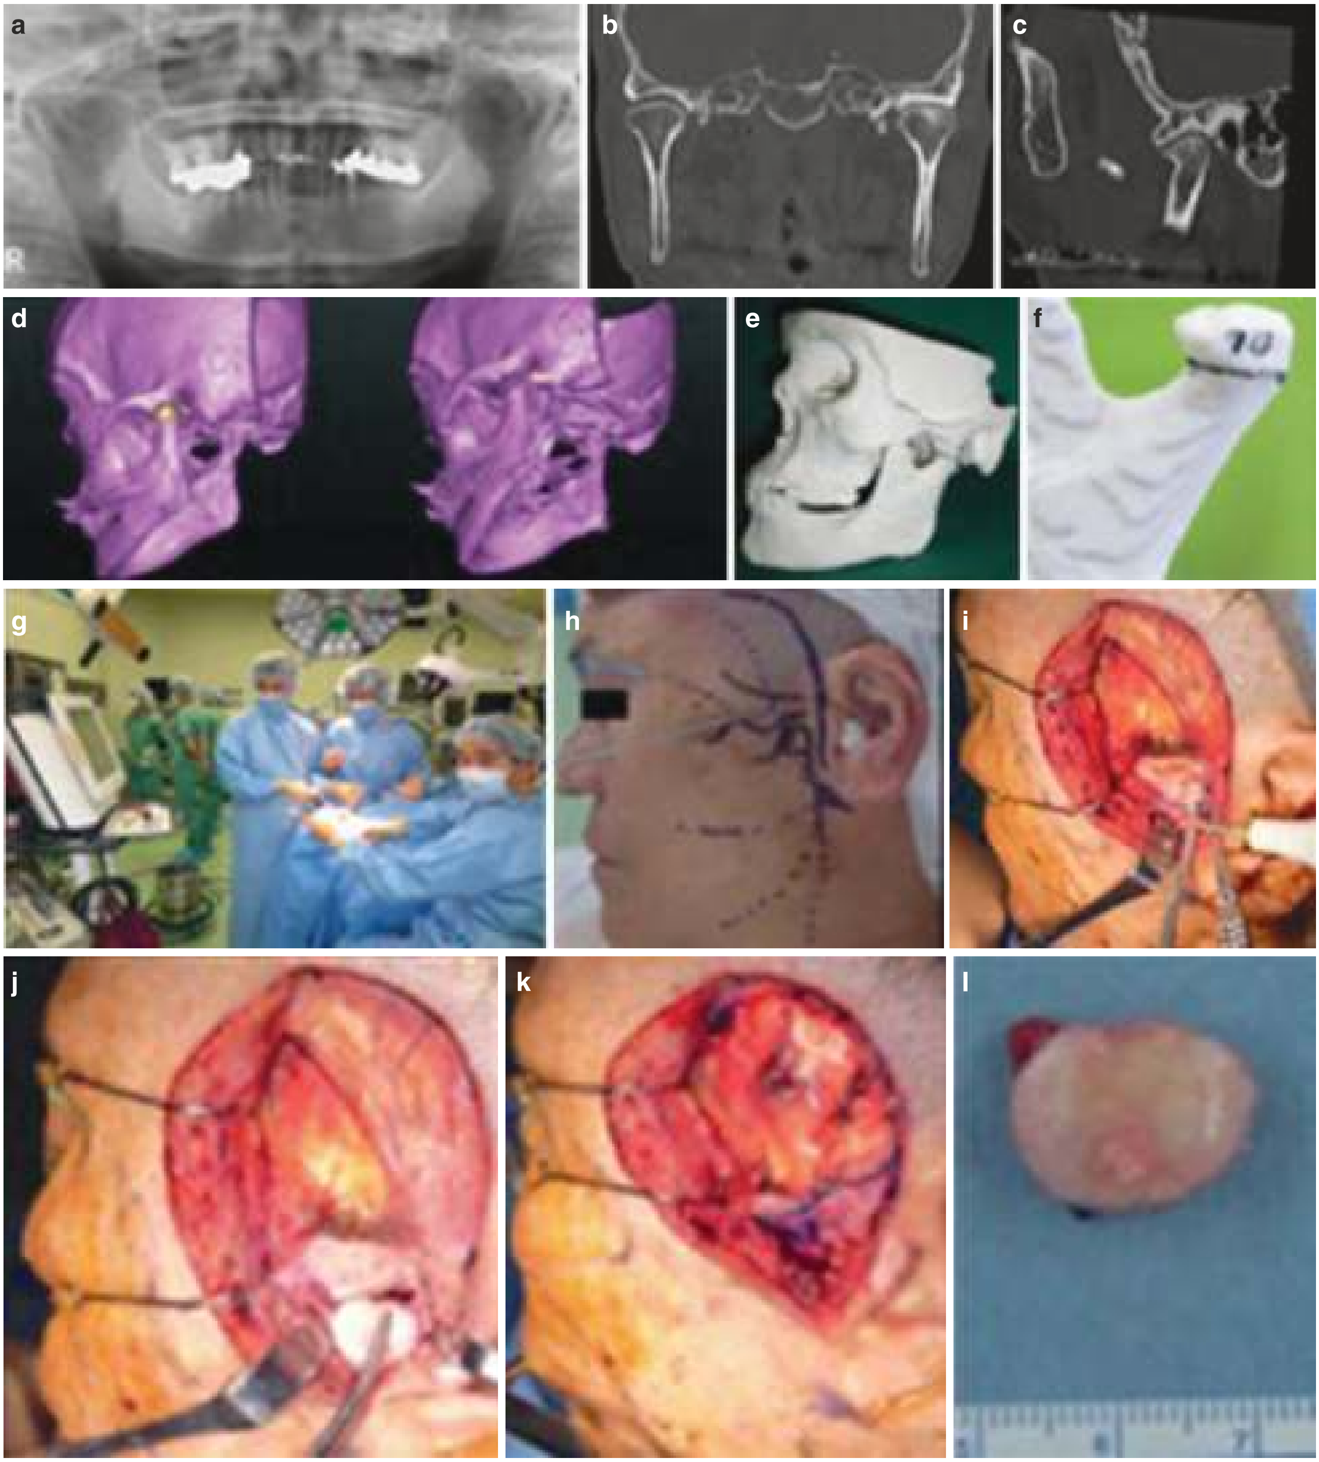

Fig. 41.17 A 70-year-old female with temporomandibular joint (TMJ) ankylosis. Ankylosis surgery is used for gap arthroplasty and mobilization of the joints. (**a–c**) However, removal of the bony ankylosis and creation of a gap between the ramus of the mandible and the base of the skull can be difficult because of the size of the ankylosis and the anatomy on the inner aspect of the mandible. Virtual planning is useful in conjunction with surgical navigation to remove the ankylosis. (**d**) First, a computer simulation based on preoperative CT data was performed for the virtual surgery. (**e**, **f**) Once the virtual surgery was completed, templates were constructed using rapid prototyping techniques from the virtual plan and applied at the time of surgery to facilitate the bony cuts. (**g**, **h**) Using the intraoperative navigation system, the surgeon can see the medial aspect of the mandible on the navigation station CT and protect important structures on the medial side. (**i–l**) This visualization prevents significant bleeding from the vessels on the medial side of the mandible and prevents penetration into the middle cranial fossa during release of the ankylosis. The temporalis flap was used for prevention of reankylosis

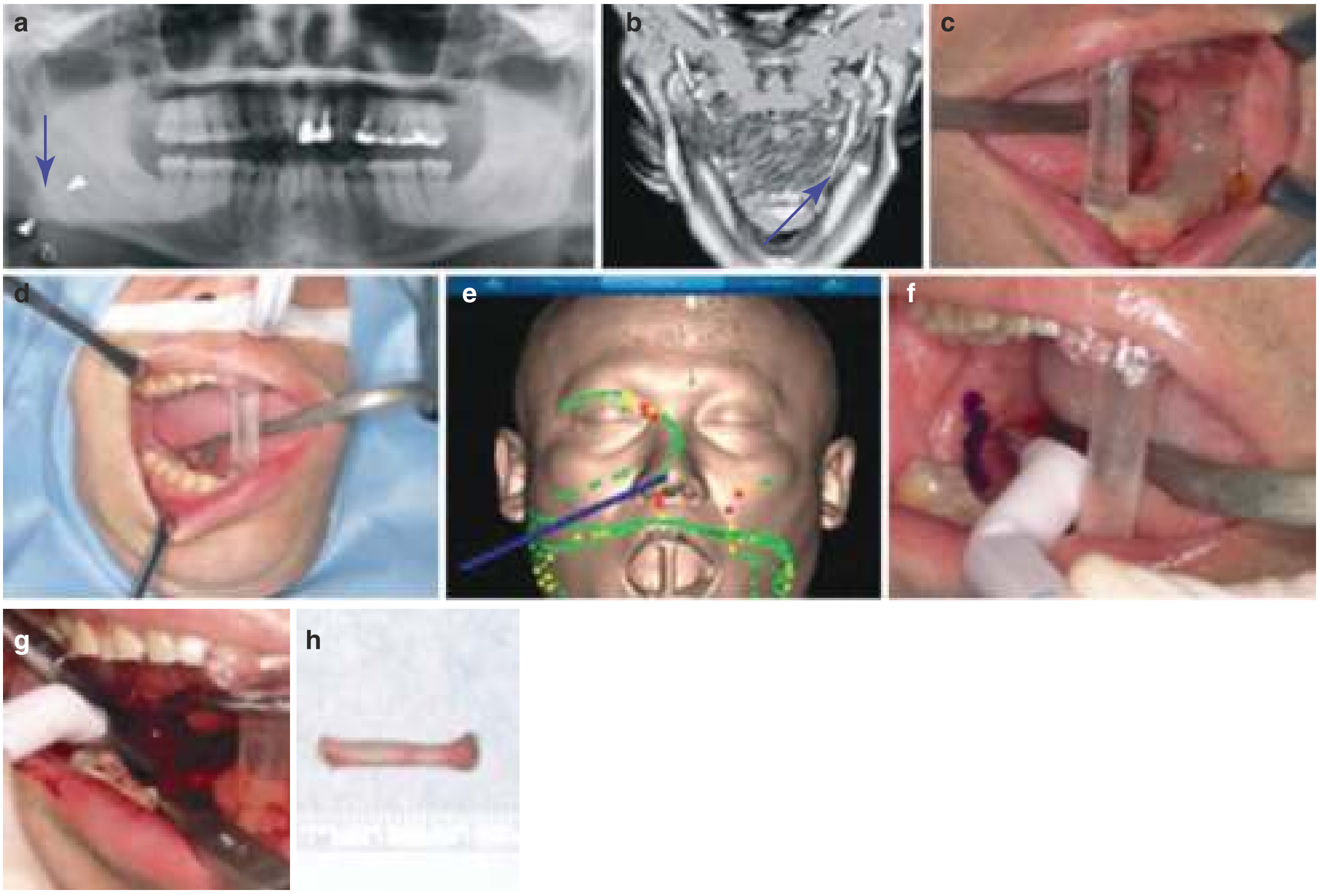

Fig. 41.18 (**a**, **b**) A 45-year-old male with elongated styloid process syndrome (Eagle's syndrome). A minimally invasive approach with an intraoperative navigation system was used. (**c**) Preoperative preparation involved a custom interocclusal splint to produce the mouth opening conditions required during surgery. In this case, since the transoral approach was employed, it was important to reproduce the same mouth-opening conditions when obtaining the preoperative images required during surgery, because the position of the styloid process and the blood vessels may change depending on the position of the mandible during the mouth opening. Since it is difficult to implement the locational findings from the preoperative imaging data while performing surgery owing to the mobile nature of the mandible, a custom interocclusal splint for repeated maximum opening in the same mandibular position, while enabling surgical access, was used. (**d**) The patient was taken to the operating room, where the custom interocclusal splint was reinserted. (**e**) To perform patient-to-CT and MRI data registration, the instrumentation navigation probe was used to trace the reference array and soft tissue landmarks of the face. (**f**) Using the 3D position of the navigation probe, the location of the elongated styloid process was identified. (**g**, **h**) After confirmation of the resection location via the transoral approach, the styloid process was dissected using piezoelectric surgery. Follow-up examination showed an uneventful recovery with no associated complications. (The resection of the styloid process using an intraoperative navigation system and a custom interocclusal splint during a transoral approach, together with a piezoelectric cutting device, is safe and effective for the treatment of Eagle's syndrome)

41.4.2 Wearable Mount Display for Navigation-Assisted Surgery

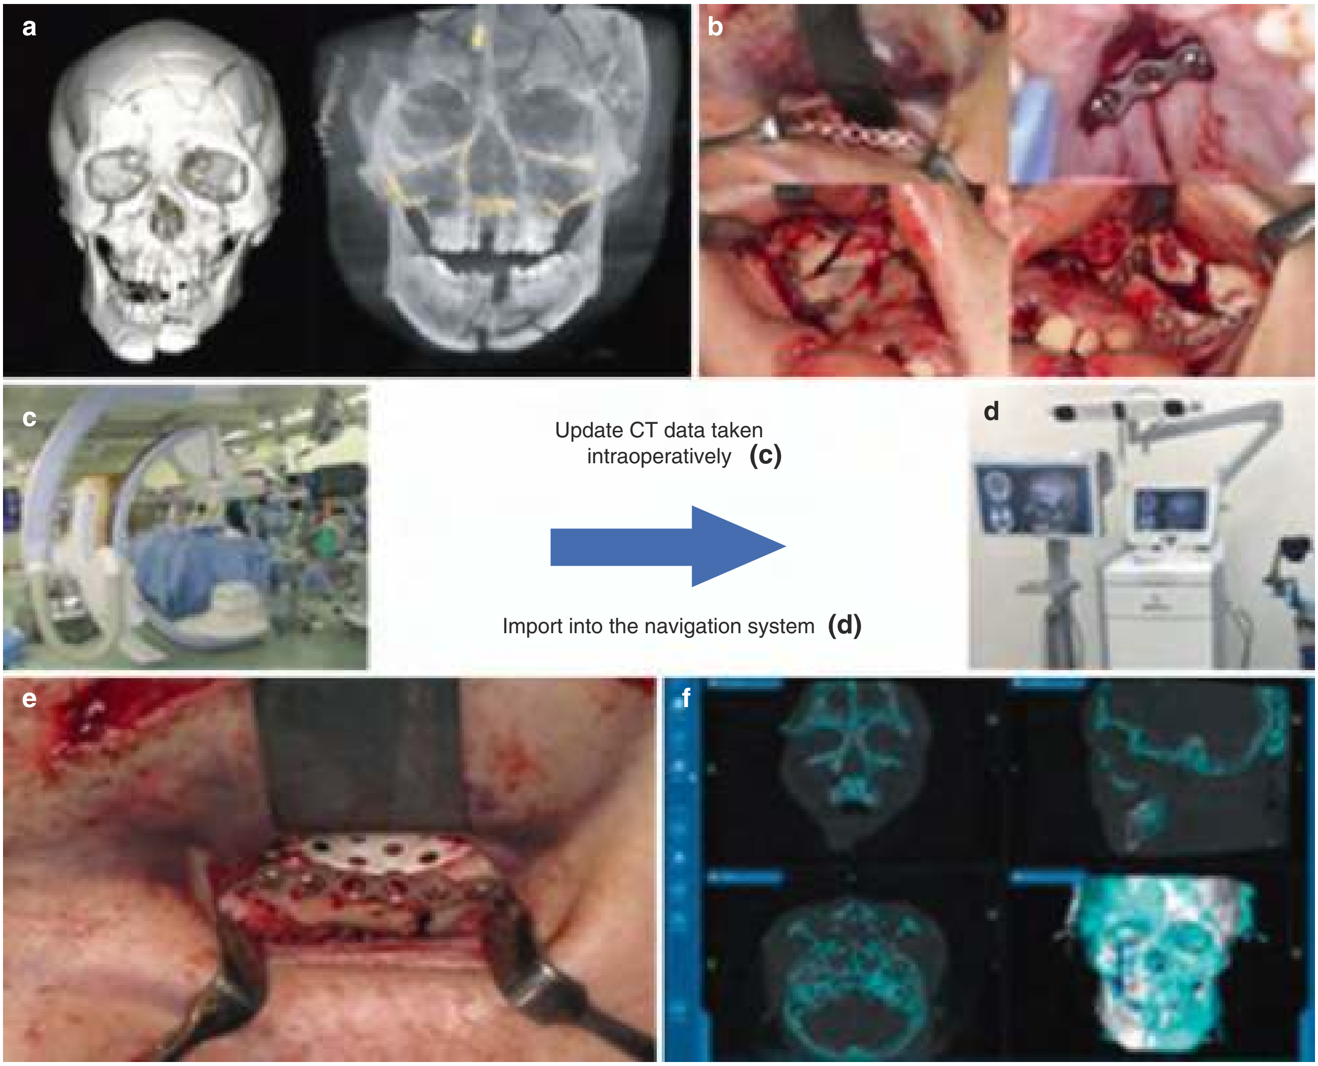
Although intraoperative navigation yields helpful information on anatomical features, it is used in conjunction with a monitor. Generally, the direction of the monitor from the surgeon and operator is different from that the surgical field. Therefore, to see the navigation image, the surgeon and the operator must look up, which is stressful for the operator. It is important to minimize muscle tension and allow the surgeon to perform the operation in a

Fig. 41.19 A hybrid operating room is a surgical theater equipped with advanced medical imaging devices, such as fixed C-arm and angiographic systems. Intraoperative CT imaging is convenient because the CT is installed in the hybrid operating room. Furthermore, recent advances in technology have made it possible to edit and use images simultaneously with intraoperative CT imaging

relaxed position. Moving the head to look at the monitor can result in considerable misalignment of the eye-hand-target axis during task execution, significantly affecting postural comfort and interventional safety. In recent years, head-mounted display monitors have been developed to address this problem. Such wearable displays can provide high-quality images [44]. Using a head-mounted display monitor, surgeons can finish the surgery without moving their head to check the navigation image. The head-mounted device also allows both the surgeon and the assistant to view both the navigation image and the surgical field without interrupting the flow of surgery. This contributes to rapid surgical operation, resulting in minimally invasive surgery. Navigation-assisted surgery with a head-mounted display is a revolutionary technique. In the future, head-mounted displays will be wearable devices that promote the use of navigation (Fig. 41.21).

41.5 Conclusions and Perspectives

CAS and navigation offers significant improvements in patient orientation and safety in every facet of maxillofacial surgery. Ranging from precisely planned orthognathic procedures to the removal of foreign bodies requiring



©Association of Oral and Maxillofacial Surgeons of India

Fig. 41.20 (**a**) A 19-year-old male with a complex facial fracture and orbital fracture. Navigation surgery is difficult to apply for treating a complex facial fracture with orbital fracture. (**b**) Since reconstruction of the buttress of the facial bone is performed prior to the treatment of the orbital fracture, preoperative CT data and the actual state of the facial bone are different. Therefore, a navigation system using preoperative CT data cannot be employed. (**c**) Using CT data obtained after facial fracture reduction, (**d**) it is possible to use a navigation system reflecting the updated patient condition. The use of CT in the hybrid room can provide rapid CT data during surgery. (**e**) The orbital floor defect has been repaired. (**f**) Post operative CT showing the accurate reduction of fractures

extremely flexible surgical options, and from minimally invasive dental implantology procedures to radical tumor resections of the skull base, they have made their mark improving procedure safety, predictability, and accuracy of surgery while also improving options for intraoperative adaptations. In the future, the application of CAS is expected to further reduce operative risks and surgery time, accompanied by a considerable decrease in patient stress.

Navigation systems are effective for delicate and accurate oral and maxillofacial surgery and neurosurgery, as well as for otolaryngology and orthopedic surgery. In the future, we expect to develop more convenient and reliable navigation systems using new technologies and devices.

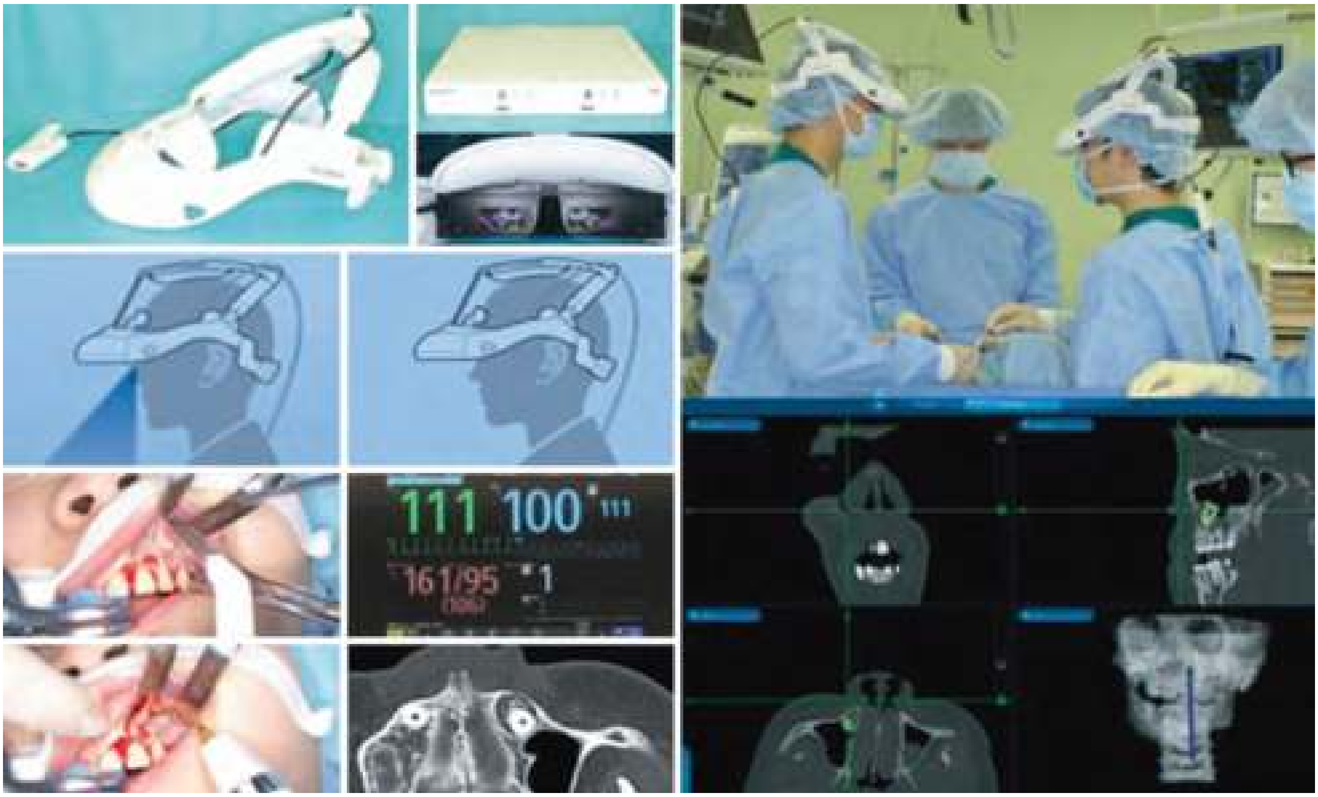


Fig. 41.21 The head-mounted display can provide high-quality images with wearable technology. The head-mounted display unit was composed of a head-mount image processor unit (HMM-3000MT; Sony Corporation, Tokyo, Japan) and a head-mounted display monitor. Although the navigation system provides helpful information, it is used in conjunction with a monitor. Generally, the direction of the monitor differs from the surgical field. Therefore, to see the navigation image, the surgeon and the operator have to look up, which is stressful for the operator. Using a head-mounted display monitor, we could finish surgery without moving the head position. The surgeon must perform not only the surgery but also intraoperative systemic management. Multimodality patient information is important in such cases. Multimodality medical information fusion and processing have been developed in recent years. This head-mounted display system allows the integration of preoperative radiological findings with monitoring of navigation images and patient vital signs. Using the head-mounted display system, the surgeon can see multiple images in one view using a split screen, regardless of the head position. This technology facilitates safe surgical management with the navigation system

Part XIV

Practice Management in Oral and Maxillofacial Surgery

42 Human Factors Recognition to Enhance Team Working and Safer Patient Care

Peter A. Brennan and Rachel S. Oeppen

42.1 Introduction

Human error and organisational mistakes are a significant cause of morbidity for patients. It is important to recognise and address human factors (HF) in the context of our own performance optimisation, enhancing team working to improve patient safety, and better working lives for clinicians across surgery and medicine.

Medical errors are usually multi-factorial rather than the direct fault of any one individual. Organisational issues, poor team working and other HF are often at the root of many incidents and errors. The Surgical Checklist produced by the World Health Organization (WHO), and aviation-styled communication training initiatives have been advocated to optimise surgical performance by reducing human fallibility and misinterpretation between team members. Brief and debriefing processes and other performance improvement practices have been positively rated when incorporated into healthcare. Ergonomics and other factors such as stress and fatigue, emotional status, hunger, dehydration and situational awareness can all lead to human error, but these are often under-appreciated and in some cases even disregarded.

The aims of this chapter are to raise colleague awareness of both individual human factors and those relevant to organisations and to highlight relatively simple methods to actively reduce error in healthcare.

42.2 The Scale of the Problem

Over 70% of plane crashes are due to a human mistake rather than a failure of the aircraft itself. Issues with communication can occur in up to 80% of air disasters. Recognition of factors leading to human error, including tiredness, stress, and repetitive tasks, and an acceptance that a certain degree of failure is almost inevitable, has improved air safety. These factors are being increasingly recognised by healthcare professionals [1]. The American Institute of Medicine report entitled "To Err Is Human" published in 1999 and subsequent work has found death from preventable medical errors, with those in surgery second only to medication errors as the most common reasons for death from medical error [2]. Recent estimates place avoidable patient deaths in USA hospitals at over 400,000 per year, with preventable harm in the top three causes of death [3].

While the authors were not able to source any statistics for the Indian sub-continent, death in UK hospitals from medical error is estimated to be about 4000 per year, with a disproportionate amount of harm caused by errors in surgery. To put this into context, this would be the equivalent of more than one A320 fatal airbus (Fig. 42.1) crashes occurring twice a month. Incidentally, the A320 is the aircraft involved in the widespread media coverage after an emergency landing on the River Hudson in January 2009 by Captain 'Sully' Sullenerger, subsequently dramatized in the well-known movie, Sully. Despite the WHO checklist, which is widely used throughout the modern world, the number of 'never events'—those that should never happen, including wrong site surgery and retained instruments or swabs—is increasing [4]. Although doctor-induced mistakes are quite rare, a near miss occurs far more commonly in the hospital environment. An investigation and detailed cause analysis following any incident can help organisations learn, prevent and reduce the chance of such errors occurring again in the future.

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_42

Fig. 42.1 The flight deck of an Airbus A320 being configured for departure

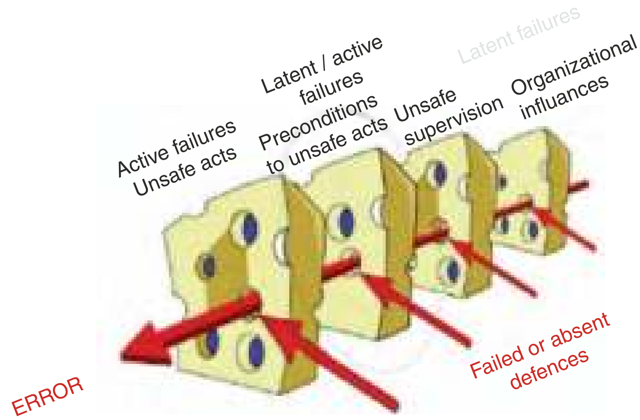

Fig. 42.2 Schematic representation of the Swiss cheese model of human error. Each of the cheese slices acts as a barrier to an error occurring with the final chance for stopping the error being the elimination of the unsafe act itself. Error has its origin in organisation influences (latent failure) and those caused by individuals and teams (active failures)

42.3 How Do Human Errors Arise?

Recognition and understanding of those relevant HF involved in potential error is vital for improving patient safety. These factors include fatigue and tiredness, stress, communication style, effective team working, and good leadership. The well-known 'Swiss cheese model' of error (Reason [5]) is illustrated in Fig. 42.2. Organisational failures contributing to medical error could include pressures on individuals to meet hospital targets, having too many patients on an operating list than is deemed safe, too many patients in an outpatient clinic, working very long hours without taking a break or being expected to operate the following day after having being disturbed overnight with on-call emergencies.

42.3.1 Senior Management Support Is Essential in Helping to Reduce Medical Error

Senior management commitment is essential in ensuring safety across any organisation. An open culture has to be key in any hospital agenda and strategy. Poor leadership together with a 'blame culture' led to more than 35 deaths in the Bristol paediatric cardiac surgery service. As a result, a large number of changes were implemented to limit future preventable surgical incidents. Pilots, aircraft ground engineers and other aviation safety staff are encouraged to actively question any safety issues related to their aeroplane, and their employer must investigate concerns, even if this means stopping a flight from taking off. In healthcare, we should be following this safety model with higher hospital management and surgical team leaders creating a safe environment to report and action possible error. The surgical team has to endorse the use of evidence-based best practices, including use of the WHO Surgical Checklist, avoiding human error traps (Table 42.1) and early identification of those situations in which harm or error is more likely to occur (Table 42.2).

Table 42.1 Avoiding human error traps

• Read out WHO Checklist with active participation of all team members. Engage with it as if your own life or limb depended on getting it right
• Ensure staff communicate well with each other
• Use briefing/debriefing to improve team working
• Limit avoidable distractions and any interruptions during essential parts of an operation (same as sterile cockpit in aviation).
• Promote use of positive two-way communication.
• Ensure 6–8 h of sleep, regular physical activity and adequate nutrition and hydration before starting surgery.
• Look out for each other as part of the team.
• Ensure you take regular breaks and eat and drink often during the day.
• Recognise when something doesn't seem right in yourself.
• Do not assume physically uncomfortable postures unless absolutely necessary. Adjust equipment, table for the comfort of you and your team.

Table 42.2 Take special care—recognise situations in which error/harm is more likely

• Site- and side-specific procedures
• Staffing limitations high turnover rates
• Changes in physical environment
• Changes in staff/scheduling
• Staffing limitations
• High staff turnover
• Significant changes in life situation of team members—divorce, death in family
• Special patient factors, e.g. Jehovah witness unable to accept transfusion, obesity

While a surgeon's life or limb is not at stake during an operation (unlike an air disaster when a mistake made by an airline pilot might result in the death of all those on board, including the crew), the psychological effects of a major surgical incident or error can be devastating to both individuals and teams [6].

42.3.2 Human Factors That We Should Be Thinking About

There are many personal human factors that can cause error, including tiredness and fatigue, nutritional status, anger and stress, multitasking and loss of our own situational awareness. However, all too often as individuals we sometimes imagine that these factors do not apply to us, and therefore we might choose to ignore them (such as missing lunch, working for many hours without taking a break) significantly raising the risk of patient harm and potentially damaging our own health and well-being.

42.3.2.1 Fatigue and Tiredness

These are known in aviation and other high-risk organisations (HROs) as significant factors that can cause human error. As a result, strict guidelines have been put in place in these HRO, with for example flight crews only being working a defined number of hours in any given month. Many airlines have a policy in place to make sure that one pilot is as refreshed as possible for the most dangerous aspects of flying such as the landing. Intense concentration can only be maintained for about 20–30 min. For example, one pilot will take over the actual landing when the other has done the first-stage descent. The effect of these personal factors in surgical performance is less understood than in aviation though tiredness will affect decision making, as well as doing complex tasks. Situational awareness will also be affected even if surgeons behave as if they are immune and operate for many hours without taking a break. The ability for sleep deprivation to degrade performance is dramatically under-estimated by healthcare providers [7].

With reference to the Swiss cheese analogy, tiredness, emotional factors and stressful surgery can all align together to raise the risk of serious error. Table 42.2 shows some of these high-risk situations. Good communication and team working and the ability to question decisions with a phrase such as 'can I check that I've got this correct' can be useful. Other phrases like 'I am not happy' and 'I am going to take over' can also be used in situations where an error might happen.

42.3.2.2 Nutritional Status and Hydration

These factors significantly affect HF and our performance in a demanding operating room setting. Even modest levels of dehydration are known to impair cognitive function and performance [8]. Meals that contain protein, carbohydrates and fats such as those derived from olive oil, fish and avocado as well as certain nuts are considered to be best for optimal nutrition. Simple sugars (such as chocolate bars) and processed food do not readily support long-term concentration and the endurance that is needed in the operating theatre [8].

The authors recommend taking a short break of 10–15 min every 2–3 h when at work, especially if performing complex tasks or surgery. Of course, the procedure can continue if there is suitable expertise within the team, but each team member should plan to take a regular break, which can be staggered. Even a short time spent away from operating can help provide a fresh outlook, improve morale, and enable a toilet and food/water break. Recovery is aided through regular sleep, which is positively linked to healthy eating and drinking. Certain nutritional supplements may also support performance [9].

42.3.2.3 Stress and Emotions While We Are Working

Emotional and psychological issues can affect performance. While these emotions can often be hidden, a trigger or so-called sentinel event that results in upset or even anger can occur, during times of high mental workload or in those stressful situations that we all will be familiar with. Many of us will have witnessed others (or ourselves) having an emotional outburst, including shouting at other team members. During these events, error is much more likely to occur. In these situations, visible anger usually results from additional hidden factors that others do not see in the so-called anger triangle (Fig. 42.3).

A simple thing to remember, **HALT** (Table 42.3), reminds us of sometimes overlooked personal issues and to ensure we stop to take a break. The importance of a short rest cannot be emphasised enough if it is safe, especially when these HALT

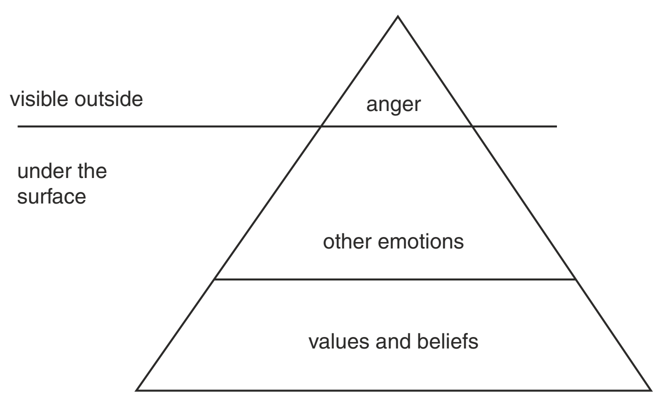

Fig. 42.3 Anger triangle: many emotions may be hidden from others until a sentinel event causes an outburst of anger. During this time, error is much more likely

Table 42.3 Try to stop or inform a member of the team when experiencing or witnessing these HALT factors

H	Hungry
A	Angry or anxious
L	Lonely or late
T	Tired

issues becomes apparent, and may prevent something serious from occurring.

Management strategies such as increasing our own emotional awareness and learning how to deal with personal stress may also be useful.

Effective communication with the rest of the team and questioning decisions where there might be some doubt by saying something like 'can I check that I have got this right?' is paramount. Other words such as 'I'm not happy' and 'I'm going to take over' can also be used in situations where potential errors are deemed more likely.

42.4 What About WHO and Other Checklists and Team Working Dynamics on Surgical Performance?

The WHO Surgical checklist has resulted in significant decreases to post-operative mortality and morbidity on a worldwide scale, yet errors persist and recur. While checklists, including WHO's, cannot address all aspects of medical and surgical practice, good team working with effective briefing can help to optimise team performance. There are many situations in surgery and other medical specialities when mental or physical workloads increase suddenly or dramatically (for example, during complex microvascular reconstruction) and these can have an adverse effect on performance. In such cases, team dynamics and an understanding of each individual's role within the wider team are crucial. Airlines enforce a 'sterile cockpit' policy in which noise is kept to only essential conversation below 10,000 ft (during high-risk procedures such as landing and take-off) and only essential conversation relating solely to procedure is permitted. The sterile flight deck concept is being advocated for reducing error in anaesthesia and surgery [10]. This should be discussed with all team members at the pre-operative briefing so that all know the need to stop non-essential communications at certain times. Poor team working has had tragic consequences on many occasions. In one well-known UK case (Elaine Bromiley), the airway was lost following induction of anaesthesia for a routine ENT procedure. The anaesthetists made repeated attempts to secure an airway, and had 'tunnel vision' about this rather than seeking assistance from surgeons or others for an emergency needle cricothyroidotomy.

Ancillary staff were well aware of the patient's prolonged hypoxic state but felt reluctant to assert themselves or state the need for alternative intervention. No individual took a leadership decision role and the team did not have designated roles during a difficult airway situation. As a result, the patient died when she could so easily have been saved. Lack of leadership, poor communication, inability to challenge hierarchy, and many other HF failings were to blame for this tragedy.

Effective team working is also valuable in promoting a sense of shared responsibility for patient safety. Team performance is often improved when front line staff actively monitor important performance criteria such as blood loss, regular swab counts, and needle and instrument checks.

The WHO checklist and other team tools have helped with theatre safety; however, never events still continue to occur [4]. Much more is needed around safer team interactions. The team brief, coupled to a debriefing after the day's operating, can enhance patient care, team working and feeling valued by all.

Airline pilots discuss the 'what if?' scenario in pre-flight briefings and know who will be doing what if something doesn't go well (Fig. 42.4). Some clinicians even go as far as to ask team members 'how could we kill this patient today?' Table 42.4 summarises items that could be included in a good briefing and debriefing. The nominated team leader can summarise what has been discussed and repeat back as necessary to confirm to everyone that there is shared understanding. We also suggest monitoring each other for signs of loss of situation awareness as well as looking for features of tiredness and fatigue.

An open culture and respect by all team members are crucial for better team working and enhancing patient safety. Even the most inexperienced pilot will question decisions of senior Captains without fear. While a hierarchal gradient between trainees and their boss is needed, this should be sufficiently flat to allow and encourage them to speak up when something does not seem right. At all times, this needs to be done in an environment where there is no fear of retribution for speaking up about something that may appear trivial.

This concept is important in the team brief so that students, trainees, and nurses all feel valued. We need to be aiming for a 'smooth and enjoyable flight' in our workplaces, even if the view isn't as exciting as from the flight deck.

42.5 Situational Awareness

An important HF principle is recognising and understanding how we relate and behave and how changes over time. Surgeons can sometimes develop tunnel vision during long procedures. This can be confounded by indicators that they recognise confirm their behaviour, and thus may need to rely

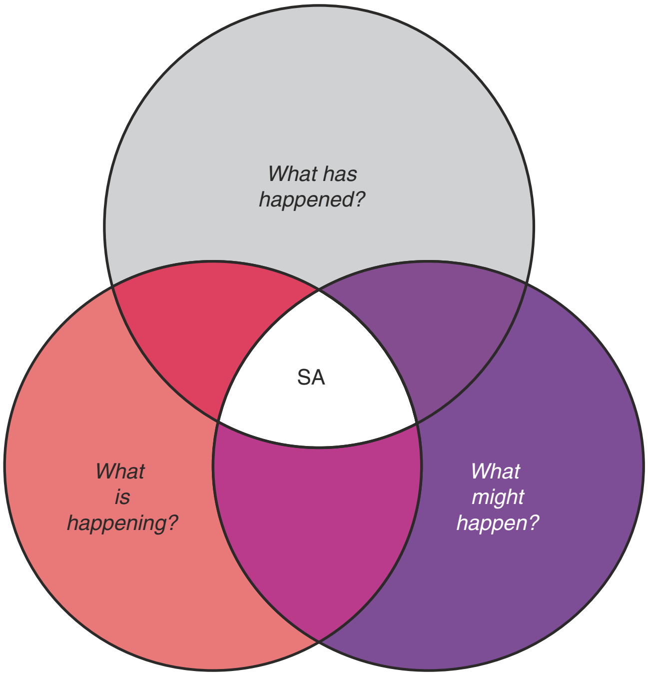

Fig. 42.4 The three key elements that comprise situational awareness (SA)

Table 42.4 Things to consider at a team brief

A well-prepared team knows their role, looks out for each other and helps all to feel valued.
Briefing
Introductions, transparent culture, 'anyone can speak if concerned'
Team working and leadership
Identify major parts of surgery and who is going to do what
Ask 'What am **I** going to do if something goes wrong?'
Situation awareness—how can I intervene when something doesn't seem quite right
Decision-making skills
Debriefing
• What went well today? • One thing I (we) could do more of? • One thing I (we) could do less of? • What will I (we) do differently next time? • Saying 'Thank you' to everyone

on other team members to identify a problem. Losing track of time is one factor, which can lead to catastrophic consequences as highlighted by the Elaine Bromiley incident mentioned earlier. An otherwise competent team lost their situational awareness as critical minutes passed by during failed intubation attempts. Her husband Martin (airline pilot) knew about the same tunnel vision from a fatal plane crash, where a prolonged attempt to troubleshoot a landing light warning and a crew member's failure to assertively communicate led to the plane running out of fuel.

A lack of situation awareness causes many diving accidents. Recognising it for ourselves is important for developing surgical skill and where possible stopping what we are doing when things do not seem quite right. A well-briefed team will be able to recognise at a much earlier stage when something is not quite right [11].

A simple diagram showing the three key components of situational awareness is shown in Fig. 42.4.

42.6 HF Training When Not in the Operating Theatre

Technology developments have led surgeons to perform increasing minimally invasive procedures. Physicians also do more invasive procedures such as interventional radiology (IR), percutaneous coronary techniques and gastrointestinal endoscopic surgery. The lessons learnt from surgery and team briefs, WHO checklists and other HF training initiatives should be applied to other parts of the hospital.

Medicine is a challenging activity and patients are far more complex than aircraft. Greater control is needed wherever possible to minimise the risk of harm to others as a result of human error. HF training can readily be taught across medical practice leading to widespread improvements in safety. It is clear that any HF training includes important safety concepts, including better communication in teams, a culture of open reporting without blame, regular safety briefings and leadership skills. Aviation-based 'Crew Resource Management CRM' training has improved reduction in wrong site surgery. Hospitals need to recognise that they can influence attitudes, culture and values towards patient safety. HF training is simple, cost-effective and deliverable way of getting all staff members involved.

42.7 Conclusion

HF and better team working, as well as commitment towards continual performance improvement, are increasingly recognised as essential aspects of patient safety. Despite this, serious medical errors have not been abolished. Many errors can be prevented by recognising and using simple measures in our clinical practice. An appreciation of those factors that affect each of us as being potential contributors to error is a great step towards improving safety for our patients.

We believe and advocate that HF training is essential for medical staff as it is for airline employees. Since the introduction of compulsory HF training in the early 1990s, there has not been a single death on a UK-based airline due to human error in more than 3 billion passenger journeys. An individual would have to fly every day for 38,000 years before experiencing a human error–related aviation catastrophe. Surely we owe it to our patients to do everything we can to improve their safety too?

43 De Novo Practice of Oral and Maxillofacial Surgery

Srinivas Gosla Reddy and Avni Pandey Acharya

43.1 Introduction

The exhilarating and exciting emotion of starting your own practice can also be a daunting experience to a freshly passed out maxillofacial surgeon. Student loans taken during the course of one's studies also play a significant role in determining one's ability to take on any additional financial burden.

As oral and Maxillofacial surgery is a bridge between medicine and dentistry, there is a continual national debate regarding the need to pursue a dual degree. The option to pursue a condensed medical degree as part of the current syllabus is still not available in India. Thus, new residents should always strive to do additional training [residency, fellowship and diplomas] in their fields of interest to expand their expertise prior to starting their own set-ups [1]. It is a well-known fact that it is easier to gain knowledge and skills during the starting of one's career rather than later in life. The goal is to aim high by keeping one's feet grounded in the soil of academics.

The fire of determination and passion should always be kept alive in order to truly succeed and excel in our field. The truly successful surgeon is the one who has thrived against all the odds and taken advantage of every opportunity that has come his or her way. This chapter aims to guide the freshly passed out maxillofacial surgeon regarding further avenues of learning and about the establishment and expansion of one's surgical practice.

43.2 Professional Skill and Learning

For the freshly passed out maxillofacial surgeon, the option of acquiring financial stability always appears alluring. However, it is a well-known fact that enhanced surgical skills and strong academic knowledge cannot be traded for the financial gains obtained by prematurely starting one's surgical practice. Thus, it is always advisable to pursue additional training in the form of a fellowship, residency or diploma in one's area of interests [2, 3]. This trend will help the surgeon establish a niche practice where they specialize in a particular domain of oral and maxillofacial surgery, which eventually leads to improved surgical results and credibility for our profession. This kind of surgical practice will also help to create an edge over the plastic surgeon and the otolaryngologist and establish a distinguishable specialty offering an unequivocal service to patients. Despite the prevailing circumstances governing one's decision to enter practice immediately or continue training, everyone will eventually contribute to the OMFS field with their skills and knowledge.

Laskin [4] made an organized attempt to tackle this problem by dividing the scope of oral and maxillofacial surgery into three categories: areas of expertise, competence, and familiarity. To be addressed as an oral and maxillofacial surgeon, one needs to include the areas of expertise and competence in their work profile.

- Areas of expertise include oral pathology/oral medicine, dentoalveolar surgery, implantology, pre-prosthetic surgery, and maxillofacial traumatology.
- Areas of competence involve orthognathic surgery, temporomandibular joint surgery, and local reconstructive surgery.
- Areas of familiarity are cleft lip and palate surgery, regional reconstructive surgery, oncologic surgery, craniofacial surgery, and cosmetic surgery.

The first step in learning a skill is to know how a skill is learned. Educationists have constructed many models attempting to outline the learning process. The most widely accepted was first documented by Noel Bunch and was subsequently re-worked by Abraham Maslow (Figs. 43.1 and

43.2). In the beginning, a student is in the 'unconsciously incompetent' phase. An undergraduate dental student in their third year would have no idea about administering local anaesthesia. After working on the skill for some time, they move on to the 'consciously incompetent' phase. Here, they have attempted different ways of anaesthetizing teeth and are now keenly aware of the various ways to give local anaesthesia along with their shortcomings in certain regional nerve blocks.

Most of our trainees will arrive somewhere between these two steps of knowing what they can and cannot perform. Educators must help them overcome their limitations. Once they are aware of their shortcomings, they can actively begin to correct them. With practice and appropriate teaching, they move to the third level of being 'consciously competent'. Here, the trainee can perform every step of local anaesthesia along with variations of different techniques. However, the steps require focus and assiduousness. Now, he or she would be considered as a competent surgeon who can practice independently although lacking in instinctiveness. As learning advances, with years of handwork and practice, they will reach to the concluding stage, 'unconsciously competent'. Now the local anaesthesia can be given while listening to music or talking to patients or colleagues [5].

The obstacle to a meticulous 'ability preparation' is that most of our instructors perform numerous components at an unknown and advanced skilled dimension, while the students are frequently unmindful of numerous components of what they have to learn. The individuals who have overlooked the subtleties of an expertise are entrusted with showing people who don't know about what abilities they are unequipped for performing. The initial step for an ace instructor is to perceive that the educator and understudy live at inverse finishes of the authority. Perception, readiness, practice and tolerance are the key components of learning in any skill [6].

43.2.1 Kolb's Learning Cycle [7]

David Kolb is renowned in educational circles for his Learning Style Inventory. In Kolb's speculation, the drive for the headway of new thoughts is given by new experiences. "Learning is the technique whereby data is made through the difference in comprehension" [7]. Kolb's experiential learning style theory is conventionally addressed by a four-stage learning cycle in which the understudy contacts all of the bases (Fig. 43.3). Along these lines, everyone responds to and needs the improvement of a wide scope of learning styles.

Here are brief depictions of the four Kolb learning styles:

- *Diverging (feeling and watching—CE/RO)*

These individuals can take a gander at things from alternate points of view. They are touchy. They want to observe as opposed to doing, tending to accumulate data and use creative ability to tackle issues. They are best at reviewing solid circumstances from unique perspectives.

Kolb called this style 'separating' in light of the fact that these individuals perform better in circumstances that require thoughts, for instance, conceptualizing. Individuals with a wandering learning style have wide social premiums and like to assemble data.

They are keen individuals, will in general be inventive and enthusiastic, and will be solid in expressions of the human experience. Individuals with the veering style like to work in gatherings, to tune in with a receptive outlook and to get individual criticism.

- *Assimilating (watching and thinking—AC/RO)*

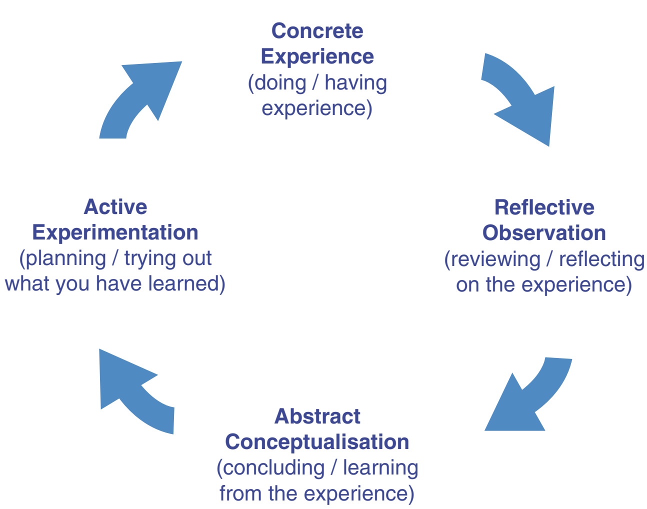

Fig. 43.3 Kolb's Experiential learning cycle

The Assimilating learning inclination is for a compact, sensible methodology. These individuals require clear clarification as opposed to pragmatic chance. They exceed expectations at seeing wide-going data and sorting out it in a reasonable coherent configuration.

This learning style is essential for viability in data and science vocations. In formal learning circumstances, individuals with this style incline toward readings, addresses, investigating diagnostic models, and need room to thoroughly consider things.

- *Converging (doing and thinking—AC/AE)*

Individuals with this combining learning style can tackle issues and will utilize their figuring out ability to discover answers for reasonable issues. They lean toward specialized assignments and are less worried about individuals and relational angles.

Individuals with a combining learning style are more pulled into specialized errands and issues than social or relational issues. A meeting learning style empowers expert and innovation capacities. Individuals with a meeting style like to try different things with new thoughts, to recreate, and to work with handy applications.

- *Accommodating (doing and feeling—CE/AE)*

The Accommodating learning style is 'hands-on' and depends on instinct as opposed to rationale. These individuals utilize other individuals' examination and want to take a viable, experiential methodology. They are pulled in to new difficulties and encounters. They usually follow up on 'gut' nature as opposed to sensible examination.

Individuals with an obliging learning style will in general depend on others for data than complete their own examination. This learning style is common inside the all-inclusive community. To become familiar with specific, careful abilities, an understudy needs to go intensively through every one of the styles of learning. First, we have to observe, think and feel pursued by experimentation on models to learn the aptitude to do medical procedure on humans.

43.2.2 Transformative Learning Way

Transformative learning is the procedure by which we digest and decipher data based on our own encounters to date, to deal with ace Surgical aptitudes. This can be seen in a case of a boss helping a careful student with his or her first case. One of the key issues is for the chief to be accessible if for no other explanation other than to counsel, whenever required, and guarantee that things go easily. Grown-up students need to realize that they have the director's certainty and support and that they will be permitted to extend their range of abilities to attempt to take care of any issues they may experience, before the chief strides in.

The following enquiries of destinations and points can give understanding into the learner's self-appraisal capacity or trainee's self-assessment:

- Pre-employable appraisal or Pre-operative assessment
- Discourse of case, history, examination and examinations to date.
- Discourse of the means of the activity and who will attempt which part—the director ought not to set suddenly exclusive requirements, just what is sensible to accomplish for the dimension of the student.
- Conceivable complexities and their goals
- Armamentarium.
- Consent
- Break process

43.2.3 Intra-operative Educating

- The student endeavours to pursue the pre-operative plan and, if there is a deviation, guarantees to take assent from the supervisor.
- The supervisor controls through the central specialized advances and focuses on technical steps and gives assertion for leading following the next stage, simply after fruitful fulfilment of past advances.
- The teacher gives prompt input on what is being progressed admirably and what should be possible in an unexpected way.
- The chief considers enabling the student to accomplish more on the off chance that they are advancing admirably and exhorts them in like manner.

The teacher must attempt to 'dominate', if important to help the patient yet this positively doesn't imply that boss should hinder in each progression and make the student uncertain.

Post-operative questioning

This can begin to happen as the student is concluding the case; however, a few learners may discover this diverting, which may hamper their execution.

The chief should plan to question in a peaceful domain.

- Ask the student how they think they went, invigorate reflection and show general tenets; help them survey their execution; investigate ways they can set a few objectives to help address insufficiencies
- Provide explicit instances of how the student could have performed better. An administrator may figure the learner progressed nicely, yet on the off chance that they don't convey, the student may feel that some perspective was not progressed admirably. Strong correspondence is critical [8].

43.3 Career Goals

Oral and maxillofacial surgery gives a wide range of alternatives from a conventional private minor oral surgery practice to specialist maxillofacial surgery in trauma, temporomandibular surgeries, orthognathic surgeries, implantology, oncology, aesthetic surgery and cleft and craniofacial surgery [9]. The following are the alternatives, which can be taken by a newly passed oral and maxillofacial surgeon:

- *Associateship*—The possibility of associateship with an officially settled practice is by all accounts extremely appealing. By joining a specialist set-up, one stays away from the numerous costs and unpleasant circumstances involved in setting up one's own practice. However, one should make sure to join the right specialist practice. There is a lot of contrast between a specialist that genuinely needs a partner and a specialist that may need a partner for increasingly narrow-minded reasons. The practice may not have enough volume to support two specialists and the senior associate may. In this situation, the new specialist may be in charge of creating the new referrals. This can be a troublesome circumstance. In addition, one may anticipate that as the new associate one should take an excessive measure of call, see all patients with insurance formalities and not take an interest in the 'great cases'. Additionally, the desires of the senior associate might be farfetched and a lot of additional fault may be put on the new junior associate. Before getting engaged with any of the associateship, the term and conditions ought to be clear in the pre-legally binding stage [10].
- *Scholastics and Research*—Teaching is one of the alternatives for a specialist who has the enthusiasm to educate the new batch of upcoming surgeons. It is one of the best ways to remain connected with your field. There are many institutes looking for youthful surgeons with a keen interest in academics, research and administrations [11].
- *Organization*—Being a manager includes leading, managing, overseeing and supporting health care departments or associations to accomplish their pre-set goals. With the opening of a several corporate hospitals, administrators with a medical background are most desirable for such roles. The size, intricacy and mission of various healthcare organizations (hospital systems, academic medical centres, practice groups, insurance companies) require assistance from experienced specialists with fluctuating roles [12].

- *De novo Practice*—Opening one's own OMFS office from the ground up is an extremely tough task that is not for the weak hearted. It has been rightly said the war field ought not be entered without a weapon and thus one need to be confident in their surgical skills and also have a basic understanding of the administration involved with running one's own practice [10].

43.4 De Novo Practice

43.4.1 Requirements

- *Surgical Skills*: Never accept surgery as an easygoing endeavour and always keep the patient's prosperity over any of your own advantages. It is important to develop surgical skills early on in one's career as it is these skills that will carry you forward throughout life. However, one should also make an effort to get the right opportunity
- *Site or place of your practice*: Selection of the place where you will set up your centre is the first and most basic decision that one comes across. Choosing a location that has a geographic advantage [as in easily accessible via adequate public and private transport] and has an adequate population to support your practice is essential. Demand and supply also needs be considered when choosing your location. Too many competing specialists in the vicinity will definitely make attracting patients difficult. However, it must be said that the eventual fate of a practice depends on the surgical skills and services offered by the surgeon in charge. Lastly, the spot ought to be close to the living arrangement of the surgeon in case of a medical emergency [13].
- *Accounts or Finances*: It is prudent to begin a project of such magnitude with your financial capacity in mind. Very few specialists manage to acquire stipends during their residency programs and hence are not well acquainted with handling funds. One should avoid large and unnecessary expenses in the beginning. However, this does not mean that one should skip on the basic requirements for starting a well-equipped practice. Expansion, modernizing and incorporation of advanced technology into the practice must be kept as a long-term step wise plan. The computations of property expenses [rent/lease/loan], staff salaries, equipment costs, sterilization and biomedical waste management ought to be dependably considered in evaluating the finances [14].
- *Framework*: The rooms required in an OMFS workspace are as follows: reception room, business zone, financial zone, exams rooms, operatories, x-ray zones, research centre space, staff lounge, specialist's private office, restrooms, medicinal gas space, mechanical space, sterilization space, recovery space and storage space [10].
- *Marketing strategy*: Health care associations actualize business techniques through projects and administrations, and achievement relies upon program structure and execution. Beginning a business adventure without an arrangement is out and out welcoming a fiasco and human services is no exemption for this standard. Since we are specialist co-ops, we ought to dependably remember that this field is certifiably not a "high pay" creating field except if we are managing corporate divisions. That is the reason why practical objectives ought to be set to keep ourselves as well as other people away from the rat race of cash. This positively doesn't imply that you ought not dream about a sensible way of life.

43.4.2 Types of Practice

There are four different ways by which medical practices can be organized:

(a) *Sole Proprietor*—This is for the specialist who already has a foundation of maxillofacial surgical or other medical service organizations running in the family. The choice appears to be practical for the surgeon who has full control of his financial assets and is as of now experienced in the field [15].
(b) *Organization or associateship*—If you have fellow medicos who are of the same or diverse fields and are prepared to create a combined practice with you, then it is the most reasonable choice. Always scrutinize your colleagues before entering into such arrangements. The success of this arrangement relies upon mutual trust for each other. It is also necessary to discuss all the terms and conditions [expenses and division of profits] before entering such an arrangement.

Additionally, you can work under the umbrella of some settled specialist and eventually move toward becoming a partner in the not-so-distant future [15].

(c) *Corporate segment.* Joining corporate hospitals or chains is also an alternative. The hustles of marketing, equipment, and location can be obliterated. However, corporate hospitals today are keen on hiring well-settled specialists as patients are hesitant being treated by novice surgeons [15].
(d) *Trust or NGOs*—These organizations are created to help unaffording individuals for treatment. One cannot expect great monetary benefits from a trust or NGO. However, there is a feeling of fulfilment of helping other people. There are a few associations in and outside India, which raise funds for such organizations. A point worth noting is that there are numerous specialists who are working free of charge under such associations while simultaneously obtaining their standard pay elsewhere [15].

43.4.3 Qualities Needed

43.4.3.1 Strategic Planning

Due to the contingent nature of the decision of essential structure be it sole owner or in affiliation, Strategic arranging is required. It is a definite methodical report demonstrating the manner in which it intends to advance from its present circumstance to the ideal future situation [16].

The SP procedure is isolated into progressive stages. The writing gives diverse names to unmistakable stages yet we are adopting established strategy, distinguishing five values simultaneously. The Mission, Vision and Values ought to be institutionalized amid the underlying stages.

- Mission
- This mission characterizes the general motivation behind the association, the objective customers, the administrations offered, its distinctive highlights, the geological territory in which the centre works, and occasionally the manner in which it works (quality, morals, productivity, and so forth.).
- Vision
- The vision displays the future picture. The substance of the vision ought to uncover what the human services association explicitly tries to be later on.
- Qualities
- Qualities are the arrangement of standards, rules and social viewpoints administering the Hospital Organization (HO) and deciding their institutional conduct. They comprise the association's moral code that gives it its 'spirit' and 'character'. These qualities foresee a particular reaction by the HO when a circumstance emerges that must be quickly settled.

43.4.3.2 Technique Formulation

The accompanying five phases ought to be considered

- *First Stage: Analysing the External Environment*
- This examination generates data on those difficult to change external variables that can affect the association. This involves patients and contenders.
- Patients: The place that you will eventually set up should have a geographic advantage with the right patient demographic. All too often, a specialist will begin their facility in a distant, underdeveloped and immature zone due to the dread of rivalry. It is a well-known fact that a specialist practice survives on referrals and not only on walk-in patients.
- Contenders: Good work and identity are significant in keeping an edge over your rivals. Endeavour to build up your individual character, as far as work and morals are concerned, should be made.
- *Second Stage: Analysing the Internal Environment*
- This investigation generates data on everything pertinent that has/can and is happening inside the set-up. This investigation centres around three distinct angles:
  - Resources: It incorporates individuals, monetary spending plans, consumable and non-consumable supplies and their level of obsolescence.
  - Licensure—Legal parts of drug store, radiations, and different licenses with respect to specific region ought to be taken already relying upon the standards of the region.
  - Analysis of clinical and research work, action and spending plan ought to dependably be kept aside [16].
- *Third Stage: The SWOT matrix*
- When the outside and inside examinations have been finished and coordinated, the vital arrangement directing gathering will have an abundance of thoughts regarding conceivable vital activities that could be tended to in the arrangement. Then, the issues distinguished in the examination are characterized into four classifications to comprehend what to do and in what request. This is the SWOT investigation, an abbreviation framed from qualities (S), shortcomings (W), openings (O) and dangers (T), which orders the consequences of the examination.
- Every one of the outcomes, notwithstanding grouping them with SWOT criteria, can be weighted as far as significance or relative power (high, medium, and low; +, ++ or +++, and so on.). It permits the arranging group to build up a positioning, with the most vital components positioned in the principal position, situated to key priorities [17, 18].

TOWS Matrix Analysis

The TOWS Matrix is aimed at developing strategic options from an external-internal analysis. TOWS idea is firmly identified with SWOT investigation. Whereas SWOT Analysis starts with an internal analysis, the TOWS Matrix starts the other way around, with an external environment analysis; the threats and opportunities are examined first. As indicated by H. Weihrich (1982) [19], Dangers, Opportunities, Weaknesses, Strengths (of the association) ought to be examined in a specific order, as a critical thinking succession during the time spent on the procedure plan. To streamline, let's use TOWS examination in beginning an oral and maxillofacial medical procedure set-up:

Inner Strengths: The accompanying could be qualities of the endeavour:

- Proficient abilities of the head picked up by changed associations, confirmations and courses
- Focal Location of the set-up
- Access to demonstrated plan of action

- Relationship with other dental and restorative fields to give all administrations under one rooftop
- The individual variables of the specialist like family foundation, past experience, unique intrigue, administrative and specialized abilities, self-assurance, inventiveness, creativity and eagerness to go for broke

Inward Weaknesses

- less familiarity with the field of Oral and maxillofacial medical procedure
- Constrained patient base if there should arise an occurrence of elite oral and maxillofacial practice
- Understanding paying limit
- Issue of staff wear out

Individual shortcomings (inside negative factors or challenge) like deficient abilities, terrible work propensities or attributes like poor relational abilities, poor systems administration, ineffectual authority characteristics, absence of specialized mastery, absence of IT information, absence of comprehension of statistical surveying, absence of promoting skill and so on because of which wrong choices are generally taken.

The following stage is the planning of TOWS 'Matrix of key' choices, which empowers determination of supportable, open door, simpler, and quantifiable results. '*Inward'* are the shortcomings and qualities and '*outer'* are the dangers and shortcomings. Four quadrants with various vital circumstances are created as pursued:

S-O—How can the organization employ the expertise of its own professionals to respond to the needs of centres? By partnering up, the organization can convince the institutions that there is enough capacity, knowledge and experience to train young people to independent professionals at all levels of surgery.

- *SO circumstance—maxi-maxi system.* This circumstance compares to the maxi-maxi methodology whereby it is conceivable to have solid extension and broadened advancement. In such cases, if the cost is utilized as to prepare individuals and keep them on minimal effort at first to give complete consideration by the prime specialist will prompt bringing down of beginning costs. Along these lines, more income is produced amid starting days just to have the capacity to rise as market pioneer.

S-T—How can the organization use its skilled staff to compete with cheaper workers employed by competitors? A smart approach for the organization would be to communicate to the outside world that their staff has accredited diplomas and that it's important for health care centres to comply with legal requirements and safety standards.

- *ST circumstance—maxi-little system*. The wellspring of troubles in development and improvement are ominous outer conditions (predominance of dangers) like a lot of swarming of good oral specialists in the zone, or patients paying limit is low, and so on. The procedure should utilize vast interior qualities in endeavour to defeat dangers from environment. The technique of reaching and catching patient ought to be connected through free camps, minimal effort medications contrasted with encompassing zones and catching exchange out specialists. On the off chance that the ability of the prime specialist is awesome, settle on troublesome cases left by different specialists with the dread of disappointment. In addition more up-to-date methods and medical procedures ought to be aced by the specialist in such cases.

W-O—How can partnerships with other centres help the organization to improve itself and put more effort into patient acquisition? By presenting itself as an accredited apprenticeship provider, the organization will put itself on the market again and its shows that adapt to changing times and wants to offer different kinds of treatments.

- This circumstance has more vulnerabilities—shortcomings, yet its condition gives more open doors like less number of oral specialists in the town and so forth. The procedure ought to incorporate the utilization of these chances while decreasing or amending shortcomings inside. Executing the arrangement step by step is required in such cases. The emphasis ought to be on improving the patient experience by great work by prime specialist, less staff and nearly not all that extravagant set-up amid introductory stage. Along these lines, cost cutting should be possible successfully without settling on the treatment plan. As the patient information and OPD increments, further advances can be taken for extension.

W-T—How can the organization better position itself in the market and thus reduce the threat posed by competitors? By presenting itself as an accredited apprenticeship provider, the organization can claim that they are a serious competitor and can possibly offer healthcare services by apprentices at reduced rates, with the work still being done by the prime specialists.

- WT circumstance—smaller than usual little methodology. This circumstance is without any advancement openings. It works in antagonistic situations, and its potential for change is little. It doesn't have huge qualities, which could withstand dangers. Scaled-down smaller-than-expected technique comes down to a negative rendition of the shut down or in idealistic circumstance—to take a stab at survival keeping in mind the desire of restoration. Advertising is the key in such cases alongside advancement of uncommon careful just as relational abilities of the prime specialist. Additionally, creating specialty brands are of significance as the abilities are not present with basic maxillofacial specialists. These brands include clefts, oral oncology, all out TMJ substitution and so on [17].

- *Fourth Stage: Strategic Alternatives*
- Equipped with this arrangement of recommendations, the vital arrangement controlling gathering starts a procedure, which orders them into characterized territories of activity. These zones of activity are additionally at the same time distinguished and named relying upon the kind of recommendations they contain [16].
- *Fifth Stage: Strategic Areas and Objectives*
- Now, it is prudent to adjust the procedure definition created, to check whether in reality a methodology exists by asking the accompanying inquiries:
  - Does the plan give a key suggestion that will lead the setup to a truly remarkable position thinking about the challenge?
  - Does it offer an incentive in an alternate manner?
  - Are the key decisions that have been made substantial in the long haul?

On the off chance that there are negative answers, the detailing ought to be looked into to check whether, rather than shaping a key arrangement, an arrangement has been made with a progressively restricted scope [16].

43.4.3.3 Operational Planning

The point of operational arranging is to make the arrangement totally explicit, viable and unmistakable. The Operation destinations unite the accompanying attributes:

- They must have a fixed length, in every case under 1 year. Middle-of-the road objectives can be built up to be completed in various stages after some time.
- They ought to be evaluated. To follow their level of consummation, pointers that measure this are oftentimes required.
- They ought to challenge and keep the association in a condition of alarm so as to accomplish them.
- As a capability to the previous, the Operational goals ought to be feasible.
- Each objective must have an assigned individual in control, who truly has the ability to change the execution of the unit or subunit.
- Each Objective must have a cost doled out to its usage, with the end goal that the all-out expense of all the goals is equivalent to the absolute expense of the key arrangement.
- Each Objective must have the financing and different assets (staff time, gear and so forth.) important to accomplish the goals.

When all the OOs are detailed, the execution has to be incorporated with that of the others inside a course of events of activities that incorporates every one of them and gives an outline of the connections, timing and succession of errands, just as the joined endeavours that the HO needs to perform at each stage.

43.4.3.4 Assessment of Results

Auspicious evaluation of results ought to be done, which is dependent on development of number of patients, nature of administrations, nature of medical procedure, income age and work fulfilment. This should be possible by figuring the development charge. Arbitrary overviews on the web or discontent ought to be finished with the assistance of patients to keep up the pace of association and know the dimension of fulfilment of the patient with the health care providers, i.e. the head and the staffs. Likewise, number of patient waiting ought to dependably increase steadily for a feasible growth [16].

43.4.3.5 Marketing Oral and Maxillofacial Surgery [20]

- It is a must that both the specialist and the staff also show consideration for the patient's needs and have a humble attitude. This will go a great length in gaining the good will of the patient and word-of-mouth referrals.
- Utilizing online marketing tools through advertisement and social networking are slowly becoming a must for every new practice.
- Showcasing your work in study clubs, get-togethers and association conferences will also make fellow medicos aware about your abilities.
- You can publish in the neighbourhood newsletters through knowledgeable articles with respect to your field.
- Conducting free camps for check-ups with the neighbourhood non-profit associations can also help showcase your aptitudes.

43.4.3.6 Staff Hiring

The staff should be skilled in their work and maintain a humble and empathetic attitude. Always hire and maintain the correct staff

- Make clear what is expected of them through a detailed manual
- Train them to be focused in their specific roles and reward them for their endeavours

- Hold meetings at frequent intervals to address problems and figure out solutions
- Always be an instructor and a student [21]
- Know when to fire an employee

43.4.3.7 Communication

Communication or Correspondence is most imperative for achieving the great name as an expert. Thinking from the patients' point of view and attempting to clarify in straightforward however non-phobic words about the method will help in building up the trust of patient for the specialist. This will likewise spare the legitimate ramifications if there should be an occurrence of adversity, which can emerge by not disclosing the intricacies appropriately to the patients. The way toward relieving a patient requires an all-encompassing methodology, which includes contemplations post treating a malady. It warrants a few aptitudes in a specialist along with the specialized ability. Studies have showed great correspondence ability in a specialist improves patient's consistence and general fulfilment. There are fundamental standards of rehearsing great correspondence. Persistent tuning in, compassion, and focusing on the para verbal and non-verbal parts of the correspondence are the essential steps that are often disregarded. Appropriate data about the nature, course and forecast of the infection are essential. Additionally, patients and orderlies ought to be clarified about the need and yield of costly examinations and dangers/benefits engaged with obtrusive strategies. One ought to be mindful while overseeing troublesome experiences and breaking awful news. Formal preparation of the specialists in improving relational abilities is vital and has demonstrated to improve outcomes. Furthermore, it is additionally helpful in overseeing difficult clinical experiences. This way diminishes the disappointment of both the specialist and the patient or chaperon in circumstances of enthusiastic upheavals. It has also appeared to diminish work pressure and increase work fulfillment [22].

43.4.3.8 Record Keeping

Record keeping is vital to a successful practice especially in view of the legal implications that come along with a failure to maintain the same. One should maintain both a hard copy and a virtual copy of their records as backups are most essential. Informed consent forms should clearly record possible complications in a language understood by the patient. Photographic records at the preop, intraop, and postop phases need to be maintained and become especially important when a patient has unrealistic expectations. It is also important to maintain well-documented out-patient records and operative notes. Never forget the seventh principle of the Caldicott report, an NHS report on patient information, which says '*the duty to share information can be as important as the duty to protect patient confidentiality*' [23].

43.4.3.9 Reformulating the Strategy

If at any point of time you come to realize that your practice is unable to achieve patient needs or financial goals, it is time to reconsider your strategy [16].

43.4.3.10 Professional and Financial Growth in Career

Nothing is permanent in life and in one's career. You can run your profession for a particular timeframe to be trailed by slow decrease in the training with age. Wellbeing and prosperity play a vital depiction to build the life span of the training (Fig. 43.4a). Till 45 years, there is a tendency to achieve followed by continuous decrease in the field. The thought is to augment the achievement with slow decrease. A specialist can viably work till the age 55–60, which can be expanded till 65–70 with great wellbeing and consistent learning. It is the duty of old specialists to offer approach to novel specialists for the improvement of field. Supportable model can be made to prepare novice specialists followed by naming them as partners.

43.4.3.11 Time Management (Fig. 43.4b)

Time is the most essential commodity that we have in our lives. Digitalization of many facets of hospital management has helped save time. This time can be re-invested in various other aspects of your clinical practice like discussion regarding treatment planning and discussion of various cases. Make sure you plan your day daily and weekly so that you are aware of the time that you have and be able to invest it wisely [24].

43.4.3.12 Management of Finances (Fig. 43.4c)

One must learn how to handle finances appropriately; unnecessary and exorbitant spending at the earlier stages is not a wise idea and can lead to a sudden financial crisis, which can even lead to the premature end of one's career. As mentioned before, expansion and modernization of the practice should follow a well-thought-out long-term incremental approach. Similarly, it is wise to slowly create an alternate source of income to help tide over any financial crises that one may face throughout the course of their career [25].

43.5 Conclusion

Oral and maxillofacial surgery is gaining popularity as a field and general awareness is increasing in India. It is the responsibility of new surgeons to contribute their best to the field in order to get the maximum out of their careers

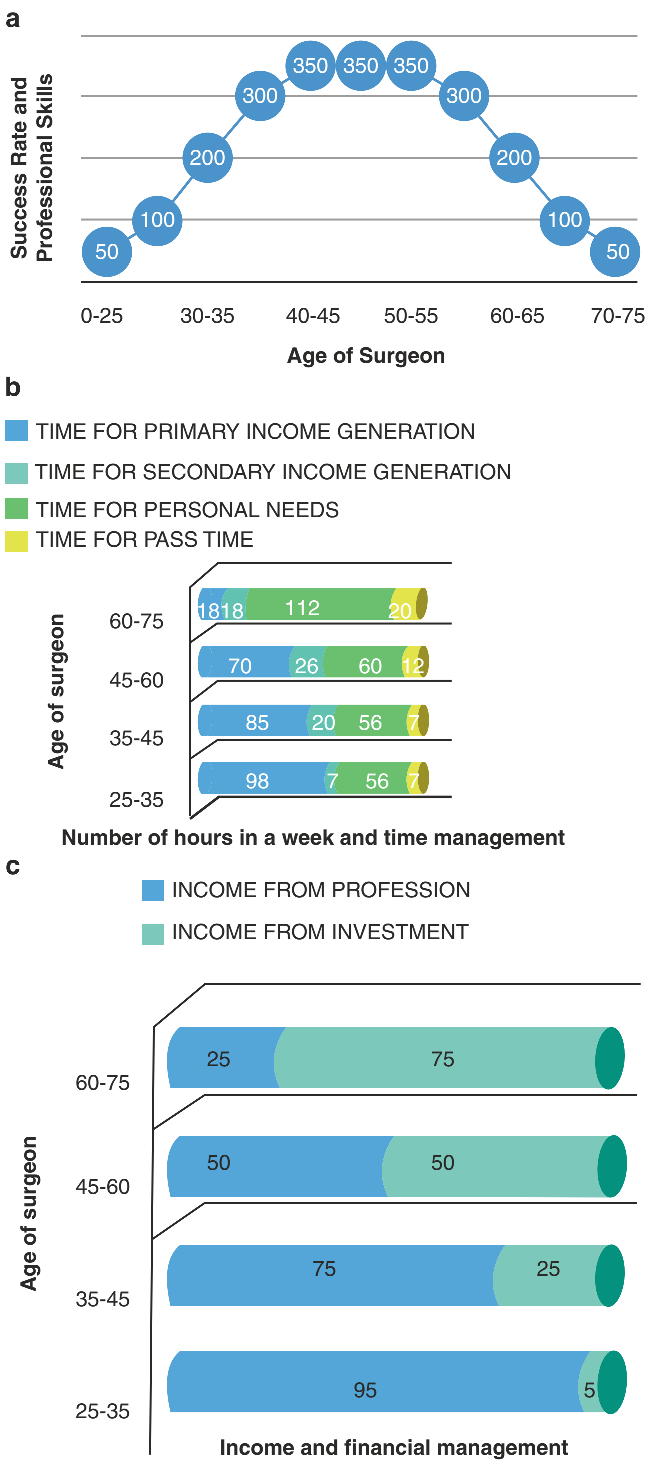

Fig. 43.4 (**a**) Professional life cycle of oral and maxillofacial surgeon. (**b**) Time management in the life of a maxillofacial surgeon. (**c**) Finances management in the life of a maxillofacial surgeon

and life. As is said 'Do good and it will come back in unexpected ways to you'. Never lose your principles and ethics in this competitive world as it will only tarnish your reputation. Everyone has a specific purpose in this world. The aim is to find that purpose and work upon it with the help of the skills and knowledge you have gathered. These were my rules for success that I stumbled up on while achieving my goals. The newer generation is getting smarter and sharper and will surely contribute to a new set of rules and redefine success.

'Those are my principles, and if you don't like them, well, I have others'—Groucho Marx

Disclosure Authors have no financial conflicts to disclose.

Medicolegal Issues in Maxillofacial Surgery

44

George Paul and Manjunath Rai

44.1 Introduction

In the modern world, human activity is governed by a set of rules and regulations collectively referred to as law. All professions must follow legal requirements and this is especially important while practising health care, including maxillofacial surgery. Doctors must be aware of their duties, rights and scope of practice within the framework of the laws governing their respective countries or states. This is especially important for maxillofacial surgeons, who straddle the line between medicine and dentistry. This chapter aims to outline the various legal issues that pertain to the maxillofacial surgeon. The laws referenced are mostly India centric, but the general principles are not very different from international laws.

44.2 What Are the Legal Issues That Must Concern the Maxillofacial Surgeon?

Since the role of a maxillofacial surgeon acts as a link between the medical and dental professions, the scope of practice has always been controversial. Maxillofacial surgeons have moved from beyond the oral cavity to the head and neck region, and even to distant body parts for procedures such as flap harvesting. All maxillofacial surgeons must be aware of what procedures they are allowed to practice under the law and what they must avoid.

During any procedure, legal documentation is of utmost importance. These include informed consent and filing medico-legal reports. Informed consent is a legal necessity to prove that a patient is willing to undergo a procedure. Medico-legal reports must be filed when one treats a case that could potentially become a legal issue. Maxillofacial surgeons may be called upon to testify as expert witnesses in legal cases such as assault and road traffic accidents. They should therefore be aware of procedures required to document evidence in these cases.

Finally, all medical professionals are vulnerable to malpractice suits. The surgeon must be aware of what actions could put them at risks for facing such suits and what procedure must be followed if one ever faces a malpractice litigation.

44.3 Scope of Practice of Maxillofacial Surgery as per the Indian Law

44.3.1 Historical Perspective

Oral and Maxillofacial Surgery has a unique place in the health care systems around the world. It is a stand-alone speciality in modern medicine that has its provenance in dentistry. However, when one realizes that modern medical systems are barely more than a century old, it is not long ago that the treatments of dental and oral diseases were a part of an integral system that encompassed holistic health care.

Dentistry as a separate autonomous specialty is an accident and an aberration in the history of modern medicine. In fact, the first dentists were medical doctors or surgeons like Pierre Fauchard in France who had a special interest in treating dental and oral conditions [1] and John Hunter [2] in England.

In the late nineteenth and early part of the twentieth centuries, dental schools and curriculums were established as courses separate from medical courses and the bifurcation became an established practice in different countries in almost all continents [3, 4].

It is through this prism that we need to view the speciality of OMFS and its future as a complex and distinct part of health care. In fact, training to become a maxillofacial

surgeon through the route of dental surgery is unique when compared to other distinct regional specialties, which emerge as a post-medical qualification, e.g. ophthalmology, otolaryngology, or gastroenterology.

Realizing the need for adequate training in surgery, substantial additions were made to the dental and oral and maxillofacial surgery curricula by including several basic medical sciences and clinical medical subjects in the undergraduate and post-graduate level, to help meet the medical training requirements of a surgeon.

The impetus for the evolution of OMFS was provided by the two World Wars of the twentieth century and other armed conflicts, where dental and oral surgeons were found to be invaluable in the treatment of facial bone fractures. Thus, Oral and Maxillofacial Surgery was born as a speciality of dentistry and went on to encompass a wide range of surgical work, including pathologies of the mouth and jaws, TMJ surgeries, surgical corrections of dento-facial deformities and cosmetic surgery of the face.

In many countries, including those in Europe, this resulted in the concept of dual degrees (medical as well as dental degrees) to better address surgery in a complicated region of the body where one needed a clear understanding of surgical principles as well as sound dental concepts. Duality is often mistaken for an additional medical degree. In fact, duality includes the need for a dental degree for those with a medical background. In countries like USA, India and several Asian countries, oral and maxillofacial surgery continues to be a surgical speciality of dentistry, although some surgeons chose to do medicine as additional qualification to further their interests and knowledge [5]. Similarly, dentistry was offered as an additional degree for those with medical qualifications only. Dentistry was however an essential pre-qualification to become a maxillofacial surgeon. It must be remembered that 90% of the world population is still serviced by OMFS with a single dental qualification re-enforced by rigorous surgical training as part of their post-graduate curriculum. This includes the USA, Canada, Latin America and the Caribbean, Africa, China, Russia, Central Asia, South Asia, Middle East Asia, South West Asia, Japan, and Far East Asia [6–12]. Starting in the 1970s, several countries also offered integrated 6–7 year residencies leading to OMFS that provide an additional Medical or Dental degree depending on their original background.

The curriculum for Oral and Maxillofacial Surgery in India and several other countries has been suitably modified for patient safety and competence. In India, the speciality of OMFS is regulated by the Dentist Act of 1948 as more than 90% of OMFS are dental-qualified surgical specialists [13]. OMFS has been included as a recognized speciality with distinct privileges in the medical health care system and has been included in significant legislations at the national and state levels, including the Clinical Establishment Act of 2012.

44.3.2 Current Legal Privileges

Oral and Maxillofacial Surgery is a recognized department in most multi-specialty hospitals and they are given privileges such as admissions and autonomous departments within the surgical or dental services.

The Dentist Act has defined Oral and Maxillofacial Surgery as a surgical branch of dentistry dealing with diseases affecting the mouth, jaws, and face. The updated curriculum of OMFS is a focused training in surgical management of diseases, injuries and deformities of the face and gnathic system. Training includes interdisciplinary rotation with allied surgical specialities and standard competence in dealing with complex surgical situations in the mouth, jaws and face.

In an increasingly competitive surgical arena, different surgical specialities compete for ownership of procedures based on their diverse backgrounds. It is therefore expected that OMFS, as an emerging surgical specialty, is sometimes in conflict with other specialities.

The legal competence to perform procedures is dictated by the qualification and training received as part of the curriculum set up by the respective statutory bodies through due process of law.

The legal remit and privileges of OMFS in India are based on the training received as part of the curriculum of the master's degree in Oral and Maxillofacial Surgery as outlined by the Dental Council of India in its regulation issued from time to time. The current syllabus, curriculum and training equip the specialist to deal with a wide range of surgical procedures in the face, jaws, oral cavity and teeth. This includes comprehensive management of defects or deformities of dento-facial region caused by congenital anomalies, injuries or surgical ablation. However increased competence, like in any other surgical speciality, is achieved through experience and continuous training in the form of fellowships and structured courses.

Oral and Maxillofacial Surgery falls into a grey area, overlapped by several other surgical specialities. However, competence is defined by the scope offered by legally approved training within the framework set out by the statutory bodies in the respective countries. In India, OMFS is an advanced surgical specialty of dentistry and its remit is regulated by the Dental Council of India.

44.4 Legal Requirements to Be Followed When Dealing With a Patient

44.4.1 Informed Consent

Consent to medical treatment as an ethical and moral principle is probably as old as medical science. It is inconceivable that a medical practitioner at any point in history would have treated or operated on a patient without his or her permission. However, consent to treat as a legally binding entity is of recent origin. Today, it is validated by multiple principles drawn from social and behavioural sciences, moral philosophy, human rights, ethics and laws of a particular country. One of the main guiding principles of Informed consent involves the rights of patients to make clear assertions of what can or cannot be done to their bodies based on unbiased and full disclosure of the benefits and risks that will ensue from treatment. While most diagnostic treatment procedures are today performed only with a clear informed consent, there are some which attract particular attention in the matter of informed consent, e.g., HIV testing and high-dose radiation in vulnerable patients.

44.4.1.1 Definition and Principles of Informed Consent

Farlex's free online dictionary [14] has a simple definition of Informed Consent. It is "Consent by a patient to a surgical or medical procedure or participation in a clinical study after achieving an understanding of the relevant medical facts and the risks involved." A more descriptive definition is sometimes employed to capture the nuances of informed consent. It may thus be defined as "Consent given by a patient after understanding his/her condition, procedure, risks and alternatives based on unbiased information by the medical professional in a language and manner which is unambiguous, lucid."

44.4.1.2 History and Theory of Informed Consent [15]

The key historical signposts in the evolution of the Informed Consent as a valid legal document can be traced to cases from the US judicial system, though the basic principles find their roots in English Common law.

- While consent has been a well-known moral requirement before treatment, it gained legal sanctity only in 1914 with the case of Schloendorf Vs Society of New York Hospitals. It set the tone for a legally acceptable premise of self-determination [15]. Justice Benjamin Cardoza summarized the basic philosophy in his judgment thus "Every human being of adult years and sound mind has a right to determine what shall be done with his own body and a surgeon who performs an operation without his patients consent commits an assault for which he is liable."
- However, it was with a series of case in the 1960s and 1970s that self-determination came to be legally binding as a legal principle and more importantly the importance of full divulgence by the doctor based on which a consent can be made became a dictum. Important cases include the Salgo Vs Le Land Stanford Jr Case (1972) and the Canterbury Vs Spence Case (1972) [16]. Thereafter, not obtaining informed consent became legal violation, equivalent to assault or "battery".
- With the advent of new technology and emergence of new diseases like HIV, Informed Consent documents are constantly being upgraded to include new medical procedures.
- Informed Consent Document (ICD) in research was largely evolved due to the World War II atrocities in Nazi Concentration camps. ICDs in research have been formulated and reviewed by the Nuremburg conference and the Helsinki declaration. They are closely monitored for content by organizations such as the WHO, FDA, and the ICMR in India.

44.4.1.3 Types of Informed Consent [17]

Informed consent may be of two types:

1. Implied and
2. Oral or written Consent
   - Implied Consent: It is given by the behaviour of the patient, such as entering the clinic and opening the mouth to be examined, etc.
   - Oral Consent: It is acceptable for inconsequential procedures such as examination, taking of impressions, or even routine low-exposure X Rays, etc.
   - Written Consent: While oral consent is an acceptable consent, it can often be challenged and the consent cannot often be proved or validated. It is therefore more binding to give a written informed consent.

44.4.1.4 Informed Consent in Oral and Maxillofacial Surgery

Informed Consent for orthognathic surgery is particularly important because of the nature of the procedure. It is an elective procedure and the patient often seeks treatment for enhancement of aesthetics and function. The expectations are high and therefore the scope for disillusionment as well.

Orthognathic surgery is a highly skilled procedure in a complex anatomical area. Treatment often involves multiple specialists, including orthodontists, anaesthetists, general dentists, and other surgical specialists like neurosurgeons, otolaryngologists, or plastic surgeons. In addition to results falling below expectations, which are largely subjective, patients may also have morbidity in the form of neurological deficit, infections, occlusal discrepancy, TMJ problems, and in rare situations excessive exsanguinations and even death.

Maxillofacial Surgery is a unique speciality of dentistry and medicine and involves complex procedures and outcomes. Some of the procedures are cosmetic whereas others are ablative. Being a surgical procedure involving the mouth, jaws and face, there are several issues of deformity and disability.

The informed consent should include the following (Box 44.1):

Box 44.1. Components of Informed consent for surgery
1. the purpose of the proposed procedure;
2. a summary of the surgical approach;
3. expected benefits and limitations;
4. a description of postoperative recovery; possible complications and known side effects, including those that are rare.
5. risks associated with the procedure and/or medications should include alternatives, including the option of no treatment or surgery at all.

Irrespective of whether the surgery is a minor dento-alveolar extraction or major reconstructive procedure, it may be cautious to take an informed Consent, which includes chance of injury or consequences that have disutility for the patient. While operating as a team there are decisions that can be taken jointly by the other members in the treatment process, e.g., Neurosurgeons or orthodontists. For instance, in orthognathic surgery, the Informed Consent Document may have several distinct parts. Gasparini G, Boniello R et al. suggest a three-part informed consent to include pre-op orthodontics, orthognathic surgery and post-op orthodontic treatment [17].

The informed Consent document may need to include the following principles and the surgeon and his team can make appropriate changes to accommodate them. These have been enunciated by Lord Scarman in the case of Sidaway v Board of Governors of Bethlehem Royal Hospital [18].

1. The individual should be of adult years (18 years in India) and sound mind and should have the legal mental capacity to choose what happens to his body.
2. It should offer a choice that entails an opportunity to evaluate knowledgeably the options available and the risks attendant on each (including no surgery option)
3. The doctor should therefore disclose all material risks. The material risks are determined by the "prudent patient test," which determines what a "reasonable" patient in a position of a plaintiff (complainant) would attach significance to, in coming to a decision on the treatment given.

In addition to this, in the Indian context:

4. All informed consent must be in a language understood by the patient (vernacular languages like Tamil, Malayalam, Bhojpuri, Kannada, etc.)
5. In case of illiterates, the informed consent must be read to them in the presence of an independent witness who must sign on the space provided.
6. In children below 18, a parent or guardian can sign on behalf of the child.

Recent concerns have suggested that informed consent should also cover diagnostic tests. It is a common practice in some countries, including India, to do a routine HIV testing. These can be undertaken only with an informed consent, including pretesting counselling. Many countries also insist on informed consent for multiple high-dose radiation, especially with the use of CT scan.

**A standard Informed Consent form is attached and can be used as a template. Any change depending on local conditions can be added (addendum).

44.4.1.5 Informed Consent and Negligence in Oral and Maxillofacial Surgery

Informed consent regulations today are largely governed by the principles of medical negligence rather than the tort of battery as in the early days. Any injury, even expected, may be considered a negligent act if there is no informed consent, e.g., paresthesia following Impactions or BSSO. The situation can be defended if the patient was informed and consent obtained. The civil liability for the same will be similar to the liability for medical negligence.

Similarly, Informed consent does not absolve the surgeon from liability for negligence, if it is proved that it could have been avoided if the surgeon had exercised reasonable care.

In short, liability for negligence can be mitigated by an informed consent, but informed consent cannot totally absolve a surgeon for an obvious negligent act.

Defence for non-information

Sometimes, the surgeon may encounter a non-reported or rarely reported complication despite reasonable care. In these situations, they can take defence in the principle of "Act of God!!" These are complications or sequels that may not have been anticipated by a reasonable surgeon.

Exceptions for the use of Informed consent

- Life-threatening situations, e.g., Carotid Ligation, Tracheostomy, etc.
- Incapacity of patient by virtue of age or mental status (It is taken from the guardian/parent).

44.4.1.6 Informed Consent for Clinical Trials and New Techniques

Informed consent has to be obtained if the patient undergoing the surgery is the subject of a new device, implant, or technique which is not a standard one. In India, devices are not covered by the DCGI (Drug Controller General of India). New techniques on an experimental basis, particularly in teaching institutions, must be communicated to the patient and should be cleared by an Institutional Review Board (IRB) or

Independent Ethics Committee (IEC). The ICD requirements for research are clearly enunciated in India by the ICMR.

In conclusion, Informed Consent Documentation is an important and critical part of all treatment plans and often includes invasive or potentially harmful investigations. A proper informed consent that is realistic and involves full disclosure, if the patient is exposed to a chance of injury for which he has no utility, is a necessary part of all treatment protocols. Informed consent documents respect the right of patients to take a decision on how their body is treated based on all available information. It is a moral, ethical and legal obligation to obtain a consent based on credible information. It also provides a safety net for the surgeon when unexpected adverse complications occur.

44.4.2 Dentist/Maxillofacial Surgeons as Expert Witnesses

Dentists and maxillofacial Surgeons are often called upon to give evidence in case of civil or criminal cases. When surgeons are called upon to give evidence as part of forensic evidence, they need to have a grasp of the subject. Forensic medicine and odontology have been used in many sensational cases in India, the Rajiv Gandhi assassination being one of the better-known ones.

Surgeons are often called upon in other more common situations as well.

1. Evaluation of disability after dental or maxillofacial injuries.
2. For opinions regarding the procedures adopted by other doctors/dentists in cases of alleged negligence.

Expert witnesses are issued summons as discussed earlier in the chapter. The surgeon is obliged to present himself before the court at the appointed time. He may be questioned by the lawyers of the prosecution, defence or the insurance company, as to the nature of injury and the quantum of disability. The surgeon is to clearly state his/her opinion without ambiguity and should remain non-committal about subjects that they are not sure about. If the surgeon has issued a wound certificate, the copy of the same will be given to him for reference at the time of testifying. The witness is to merely state the facts. They are not expected to involve themselves with the law on the subject, e.g., Loss of teeth, fracture of jaw, etc. They may answer truthfully to any other question pertaining to the same.

Today, there are only a few quantified disability criteria for dental and maxillofacial impairment in India. They include "The Manual for Permanent Disability" brought out by the CGHS, WHO, and AIIMS in 1981. A compendium of suggested dental and maxillofacial deformities/disabilities has been suggested by Paul G and Thomas S in the published book *Medical Law for the Dental Surgeon* [19]. It has been extensively used in courts of law. If unsure, the surgeon may state if the injury is grievous or not. He may also elaborate on the actual disability that the defect might cause.

Examples of grievous injuries are:

1. Fractures and loss of teeth.
2. Fractures of jaw.
3. Extensive soft-tissue injuries and scarring
4. Neurosensory or motor disturbances
5. Restricted function, e.g. limited mouth opening

Duties of Witness

Failure to appear in court without valid reasons after warrant has been issued can invite contempt of court.

Exaggeration or false statements given under oath are not only unethical, but can invite punishment under sec.181, sec.193.

44.5 Medical Negligence in Maxillofacial Surgery

44.5.1 What Is Negligence?

Negligence is usually a civil wrong or tort. It is the single most important issue in medical law pertaining to litigation for damages.

By definition, negligent torts (civil wrongs) are not deliberate but rather a failure to act as a reasonable person should in the conduct of duties to someone whom he or she owes a duty to.

The liability for negligence can however also be criminal or statutory.

Negligence as Tort (Civil liability)

It has several formal definitions, but a convenient one by Alderson explains it rather lucidly as "the omission to do something which a reasonable man, guided upon those considerations which ordinarily regulate the conduct of human affairs, would do, or doing something which a prudent and reasonable man would not do."

For an act to be considered negligent, the following aspects must be present, in regard to a surgeon (Box 44.2).

Box 44.2. Features of a Negligent act

1. That the surgeon owed a certain standard of care.
2. That the doctor/surgeon did not maintain that standard.
3. That there was an injury resulting from the lack of care.
4. There should be a proximate or causal relationship between the negligent act and the resultant injury.

Exceptions to negligence

Normally, carelessness is neither culpable nor a ground for legal liability, as there is no wrongful intention. However, in medical negligence, the outcomes have serious implications on the patient in particular and the public in general. The consequences of negligence by a surgeon who owes a duty of care are enormous and the law has imposed a duty of carefulness on the doctor or health worker in the interest of safe practices. However, there are several situations, which do not conform to the strict definition of negligence. In India, several judicial orders have placed many actions by doctors outside the ambit of negligence.

A review of Consumer cases (Under the Consumer Protection Act) shows that some of the situations mentioned here do not come under medical negligence.

- Not providing an ambulance, due to non-availability of the service does not constitute a negligent act.
- Any adverse outcome for a procedure done in good faith, in an emergency, beyond the call of duty, is not considered a negligent act. It is also called the Good Samaritan Act in some countries.
- Mere patient dissatisfaction with progress of treatment or desired relief cannot be construed as negligence.
- Non-availability of beds in an ICU is not negligence.
- Giving precedence of one patient over the other based on clinical risks or emergencies is not negligence.
- A fee, being perceived as exorbitant by the patient, is not negligence.
- Non-availability of a doctor outside his or her working hours may not constitute negligence.

44.5.2 Duty of Care

Minimum standard of care

The degree of carelessness for a particular profession depends on the risk that it poses to the person who is exposed to it.

Professional standard of care is therefore that standard of care or skill that is laid down by a body of professionals on behalf of the medical profession and which a surgeon or physician is expected to bring to his duty.

If skill and knowledge fall below this established standard, it will be considered to be negligent. A body of professionals can establish this standard by publication in books, reports of scientific studies, or by protocols established by them, e.g., text books, journals and protocols created by professional associations. Today, evidence-based science is the hallmark of best practices and is defined by the quality of evidence established through Randomized Clinical Trials (RCT) and meta-analysis of peer-reviewed publications.

When there is a difference of opinion on technical matters, an alternate method recognized by another body of professionals will be acceptable as a valid procedure and will not be considered as negligence. This is ascertained by the application of Bolam's law [20], which recognizes reasonable difference of opinion based on credible evidence or experience among peer professional groups.

The Bolitho test uses a different legal parameter and has undermined the usual dependence on the Bolam test. The Bolitho test goes beyond dependence on just two opinions and looks at credible scientific evidence as more important than mere difference of opinions.

In this context, it is important to discuss the semantics of customary and acceptable.

A professional cannot adopt a procedure merely because it is customary. Customary standards have been looked at critically because it does not provide incentive to adopt better practices. Because a particular procedure has been done for many years does not make it an acceptable practice. An acceptable practice, on the other hand, is not only time tested but also scientifically sound. An acceptable practice is usually the product of evidence-based science as opposed to customary practice, which is either anecdotal or proven to be inadequate or irrelevant by scientific scrutiny.

An often-quoted legal principle is that "The skill, diligence, knowledge, means and methods are not those that are ordinarily or generally or customarily exercised or employed, but those that are reasonably exercised or applied, negligence cannot be excused on the ground that others practice the same kind of negligence."

It may therefore be said that a "health worker is under a duty to use that degree of skill which is expected of a reasonable competent practitioner in the same class to which he belongs, acting in the same or similar circumstances." The Supreme Court has defined this duty in the case of Indian Medical Association Vs V.P. Shanta [21] as "In general a professional man owes to his client a duty in tort (civil wrong) as well as in contract to exercise reasonable care in giving advice or performing services."

Importantly, the court held that this standard should be outlined by the medical profession and it is not the duty of the "lay courts" to decide on what constitutes "standard" care. Negligence, in these situations, may be dependent on the locality, availability of facilities, specialization of the doctor, proximity to specialists and advanced technology. However, it is important to remember the dictum "no man is bound in law to be a good surgeon, but all men are bound *not to act* as a surgeon until he is good and capable as such."

The foregoing dictum indicates that a physician or surgeon should not venture to do a procedure unless he is trained and competent in performing it. Merely admitting that he had inadequate experience is no legal remedy. In other words, it is not legally wrong to be ignorant, but it is legally wrong to act in ignorance.

44.5.3 The Test of Negligence

The Bolam Test

This is a classical test widely used in the United Kingdom. The Bolam test is an acceptable test used by the National Health Service of the U.K. when a situation of negligence presents itself as observed in the landmark case of *Bolam Vs Friern Hospital managing committee. (1957) 2 AIIER 118.*

The Bolam test establishes that standard procedures be the basis of treatment. Importantly, it provides for alternate management protocols. If there is more than one school of thought, both alternates will be acceptable as a standard.

Bolitho Test

In a minority judgment comments in Bolitho, it was emphasized that the word "responsible" in the traditional formulation of the Bolam test meant that responsible practice is that which withstands the scrutiny of "logical analysis" from a judicial perspective. Today, courts are increasingly scrutinizing risk analysis from a patient view point, which undermines the traditional view point of only the care giver.

Negligence—Carelessness vs. Recklessness

While both words have almost the same meaning, there is a small difference. A careless person may not think of the eventuality while being careless. On the other hand, the reckless person is fully cognizant of the injury that his act may cause, but still takes the risk of possible injury. The former is passive, whereas the latter is an active act. Both acts are however are *not intentional* and is therefore often used to describe negligence.

Standards of Care in Hospitals

Legal standards applicable to hospitals are somewhat similar to those required of doctors or other health workers.

The hospitals are bound to maintain standards in two ways.

1. The facilities of a hospital should be that of a reasonable hospital engaging in similar type of health care.
2. The Hospitals should maintain standards laid down by statutory provisions (if available). In India, there are now basic standards for all medical establishments, which are defined by a legislated statute called the Clinical Establishment Act. It provides for the basic requirements of different categories of hospitals and the role of personnel in providing standard care.

In addition, the hospitals may be answerable for the negligence of their doctors, nurses and other health workers through what is called vicarious liability.

44.5.4 Contributory Negligence

In some situations, negligence arises fully or in part due to the patients or the complainant's fault. As the patient, wholly or partly, contributes to the negligent act, it is called contributory negligence.

The standard to be adopted to assess contributory negligence is somewhat similar to the standard adopted for the doctor. It may be said that 'contributory negligence is when a competent adult (patient) may be negligent by contribution when his conduct falls short of the degree of care that society expects a reasonable person to do or not to do for his own safety'. This would obviously preclude children and mentally incapacitated adult.

Examples

1. When a patient refuses to take a prescribed medication resulting in postoperative infection.
2. A patient who removes inter-maxillary wiring on his own resulting in non-union.

44.5.5 Remedy for Negligence Under the Indian Legal Systems

Negligence can be

1. Tortious (Civil wrong)
2. Contractual (Breach of contract)
3. Criminal
4. Vicarious (Liability passed on to hospital or employer)

Negligence can be remedied depending on what legal provision the complainant wishes to seek remedy.

The punishment under the law of Tort (Tortious liability) is unliquidated damages, i.e. whatever damages the judge wishes to award depending on injury, circumstances and other considerations like age, earning potential, profession, etc.

If an implied agreement was made between doctor and patient, then the remedy would be as specified in the contract. The judge may order a specific performance to do or not do something he has agreed to. However, guarantees for treatment are against ethical guidelines for treatment and it is not applicable in medical law.

If the complainant seeks punitive action against the doctor, he may file a criminal case under the relevant statutes. The Indian Penal Code for example, has provisions to punish doctors for death or disability. The remedy under criminal law is always in the form of a punishment (Penal). It may involve imprisonment or fine or both. Rarely, the court can order compensation or specific performance as well. Criminal law sees negligence as a crime against the state and not just against the plaintiff.

Doctors may also be liable under professional statutory laws governing the practice of the profession. In India, statutory bodies such as the Medical Council of India or the Dental Council of India can prescribe punitive action in accordance with laid down laws. The laws can be initiated only against persons registered under the particular statutory body. The Medical Council of India, for instance, cannot take action against a dental-qualified maxillofacial surgeon.

In some instances, a doctor may not have to answer for his negligence directly. The hospital or establishment employing him may have to answer to the allegation to negligence. This is called vicarious liability and is usually relevant to salaried employees who work for a contract of services and not a contract for services.

However, in practice, for the sake of regularity, it may be said that all permanently or part-time employed doctors are only vicariously liable. However, if the patient is admitted by a doctor in his personal capacity, then the doctor will be personally liable.

Contractual nature of liability

In a doctor patient relationship, an implied contract is established when a doctor accepts a patient for treatment. A breach of any aspect of this implied contract may amount to negligence when the doctor is under duty to

1. Treat with care
2. Continue to treat and not terminate until patient is cured or the patient discontinues treatment.

This may be considered the contractual nature of medical liability. However, Medical ethics does not provide for a written contract, which can be violated as in the case of a commercial transaction. So any liability based on breach of an implied contract will essentially lie within the realm of tortious liability.

Written contracts with promise to cure, failing which a refund is assured is against the ethics of medical or dental practice. It is this author's view that such contracts can be technically void, considering the ethical and legal issues involved.

Tortious Liability is usually dealt with in Civil Courts. In India, medical negligence comes within the ambit of the Consumer Protection Laws established to provide speedy relief to plaintiffs seeking redressals for goods and services that fall short of standards. The Consumer Protection Act defines medical care as contract for services, which makes doctors and hospitals liable under the Consumer Protection Act of 1986. The Consumer Courts are quasi-judicial legal redressal forums established for speedy justice. They are tiered under the District, State and National Forums depending on the place of the cause of action and the pecuniary jurisdiction (amount claimed as damages).

Criminal Liability

This liability normally lies with an identifiable individual or groups of individuals. However, recent trends indicate that Hospitals also may be held vicariously liable just as in civil liabilities.

Criminal liability is penal and involves punishment in the form of imprisonment or fine or both. Criminal negligence is considered to be a crime against society and not just the aggrieved party and is in violation of penal codes of countries. In India, it is a violation of various sections of the Indian Penal Code 1868 (amended several times).

The important offences inviting criminal liability with regard to negligence are:

1. Sec 304 A (IPC)—negligent homicide. A rash or negligent act resulting in Death, e.g. death on the dental chair or hospital or operating room.
2. Sec 336 (IPC) An act endangering the life of a person (even if there is no injury), e.g. conscious sedation without essential monitors or oxygen, even if no harm is caused.
3. Sec (337) (IPC) A rash or negligent act causing a simple injury, e.g. mild reversible thermal burns caused by bone-sectioning equipment.
4. Sec (338) (IPC) A rash or negligent act resulting in grievous injury, e.g. fracture of jaw during extraction due to excessive or improper force or avascular necrosis following osteotomy.

While these are the common sections under which a doctor may be liable, other sections also apply. Any offence against the human body (Sec 299 to Sec 377) or offences against property (Sec 378–462) can be used against doctors, e.g. abetting suicide, causing miscarriage sec 312–316 (subject to exemption from the Medical Termination of pregnancy Act 1971), etc.

Sections 78, 80, 81, 87, 88 are directly or indirectly relevant to the medical practitioner. Some can be used in defence of the doctor accused of negligence. Section 88 for instance is an act done in good faith not intended to cause death. It is a good defence in emergency care. Sections 86 and 87 IPC are in respect to harm or death caused by an act not intended to cause harm or death and is done with consent in the best interest of patients. Section 499 deals with defamation. It can be used by doctors to counter malicious charges by patients intending to spoil the good name of the doctor by frivolous or vexatious charges. It can also be used by patients as a criminal violation of confidentiality statutes. For example, revealing HIV status when the patient is not likely to be a public health hazard.

It is important to understand some terms in connection with criminal liability (Box 44.3).

Box 44.3. Terms related to criminal liability

- *Cognizable Offence*: A police officer can arrest without a judicial warrant based on his investigation.
- *Non-Cognizable*: An arrest can only be made by a judicial warrant.
- *Bailable: the arresting officer can provide bail*. Bail is a matter of right and has to be given unless the officer apprehends that the accused may abscond or tamper with evidence.
- *Non-Bailable:* Bail can be secured only from a magistrate. Heinous and violent crimes fall in this category, e.g., if there is a significant risk that the offender may commit further crimes, abscond or tamper with evidence.
- *Compoundable:* A crime in which a compromise between the suspected offender and the victim or his attendant can be worked out it is said to be compoundable
- *Non-Compoundable*: If the crime is against society and is of a serious nature, no compromise can be made between the accused and the victim. These cases are said to be non-compoundable.
- *Sec 304 A* is cognizable, bailable and non-compoundable. It can be punished with imprisonment of either description for a term of 2 years or fine or both.
- *Sec 337 and 338* are cognizable, bailable and compoundable. Sec 337 may attract an imprisonment up to 3 months and a fine up to Rs 250/ or both. Sec 338 can involve imprisonment up to 2 years and a fine up to Rs 1000/ or both.

It is important for the surgeon to be aware of these liabilities. It is also important for him to understand his rights. For example, bail is a matter of right in the foregoing situations and it is to be given by the police officer attempting to arrest a medical professional. Bail is granted on the surety given by the doctor or a colleague. A doctor can give surety on his own reputation. The burden of providing reasons for refusing bail rests on the police officer and he will have to give convincing reasons for *not granting bail*.

Representations to amend Criminal procedures for arresting Doctors

Doctors cannot be arrested arbitrarily.

In a landmark case referred to as the Jacob Mathew Case (2002), the Supreme Court of India has prevented arbitrary arrest and detention of doctors even in case of death or serious disability, as a part of treatment. Criminal liability and arrest can only be made on the basis of a credible Medical Board opinion duly constituted or recognized by the Government.

Statutory Liability

A doctor or nursing home is liable if there is any infringement of Statutes (rules). They then become accountable to a statutory body. The liability depends on the kind of infringement and the provisions in the statute to deal with it. There are many statutes dealing with practice of Doctors and Dentists, as well as Hospitals. Recently, the newly legislated Clinical Establishment Act provides guidelines for the whole of India.

Doctors and dentists may also be liable to other statutory laws such as The Pollution Control Board and the Drugs and Cosmetics Act, etc.

44.5.6 Legal Procedure and Evidentiary Requirements

(With special reference to medical/dental Negligence)

Legal Procedure (Procedural Law) Relevant to Medical/Dental Negligence.

It is important for the doctor/dentist to know the legal procedure involved in medical negligence. The legal procedure is slightly different for civil negligence, criminal negligence, and negligence under the Consumer Protection Act.

To understand legal procedures, one must be familiar with some of the procedural laws. They are,

1. Civil Procedure Code.
2. Criminal Procedure Code
3. The Indian Evidence Act
4. The Limitation Act
5. The Court fees Act
6. Procedure under CPA.

The Evidence Act

It is a very important procedural law. There are three concepts in Evidentiary Law.

1. Facts
2. Facts in Issue
3. Relevant Facts.

The facts are the material evidence.

The "facts in issue" are those that have to be explicitly proved. The facts in issue are proved by bringing into evidence the relevant facts. Sections 6–55 deal with these relevant facts.

There are also other rules in Evidence Law.

- *Who needs to bring in Evidence?*

The person who has to legally bring in evidence to prove or disprove a fact is said to have the 'burden of proof'". When one has the burden of proof he has:

1. The burden of establishing a case
2. The burden of introducing evidence.

The general rule (with some exception) is that the onus of proving any particular fact lies with the party who alleges it and not with the party who denies it. In other words, the onus of proof lies with the complainant and not with the defendant.

Negligence can be proved by

1. Direct Evidence
2. Circumstantial Evidence
3. Res ipsa loquitor (The matter speaks for itself)
   • Another aspect of evidentiary law is *standard of proof*.

The standard of proof in civil cases can be based on probability and circumstantial evidence. However in a criminal case, the standard of proof is more stringent and should be beyond reasonable doubt as sanction in criminal law is more severe and penal in nature.

• The limitation act (1963)

It is the statute dealing with the time limit for various suits, appeals, bail application and other legal actions.

• *Cause of Action*:

This refers to the incident, which has necessitated a legal process. Limitation period begins as soon as the cause of action takes place. The period of time varies according to the suit and it is given in the schedule of limitations.

Appeals/Application for leave of appeals
For appeals, the day of judgment marks the beginning of limitation period after giving time for obtaining the copy of decree (Judgment Order). This will not include 'writs' as the limitation Act does not apply to them.

If a suit or appeal is made after the statutory limitation period, the court may reject the petition on grounds of being barred by limitation. The court may however accept a petition even if it is barred by limitation, if it is satisfied that the delay was unavoidable. However, in criminal cases, the Act does not provide a period of limitation. Criminal proceedings can be instituted at any time after the offence has been committed. However, as per the guidelines given in Section 468 of CrPC, the limitation periods run thus:

(a) 6 months for offences punishable with fine only.
(b) 1 year for offences punishable with imprisonment up to 1 year.
(c) 3 years for offences punishable with imprisonment up to 3 years (not less than 1 year).

If the limitation period ends on a day when the court is closed, then the next working day is included as the limitation period. It may therefore be said that a suit should be filed as soon as the cause of action occurs.

Court Fees Act (Varies from State to State)
Any party who wishes to approach a court with litigation has to pay a court fees with some exceptions like the Consumer Court. Each state may have a different court fee structure. In a suit for money, the fee is usually computed based on the amount claimed by the plaintiff. Court fees are paid in the form of Stamps, which may be adhesive or impressed or both.

44.6 Conclusion

This chapter is unique as most textbooks do not address issues pertaining to law and ethics in practice.

The maxillofacial surgeon is often confronted with questions on their remit and scope of work as it overlaps with several other specialties and is constantly in conflict with issues of qualification and areas of competence. The sections on these issues will throw light on their practice privileges in addition to dealing with litigation for medical negligence, which has become all pervasive.

Disclosure Authors have no financial conflicts to disclose.

CONSENT FOR MINOR ORAL &MAXILLOFACIAL SURGERY

PATIENT 'S NAME : ……………………………………………….
DATE : ……………………………………………….
PLACE : ……………………………………………….
DIAGNOSIS : ……………………………………………….
TREATMENT PLAN : ……………………………………………….

- My doctor has explained to me that there are certain inherent and potential risks and side effects associated with my proposed treatment and in this specific instance they include, but are not limited to :

1. Post-operative swelling and discomfort that may require several days of recovery.
2. Prolonged or heavy bleeding that may require additional treatment.
3. Injury or loosening of adjacent teeth or fillings.
4. Post-operative infection that may require additional treatment.
5. Stretching of the corners of the mouth that may cause cracking or bruising and may heal slowly.
6. Restricted mouth opening during healing sometimes related to swelling and muscle soreness and sometimes related to stress on the jaw joints(TMJ),especially when TMJ problem already exists.
7. A decision to leave a small piece of root in the jaw when its removal would require extensive surgery or risk of other complications.
8. Fracture of the jaw (usually only in more complicated extraction or surgery)
9. Injury to the nerve adjacent to teeth, resulting in pain numbness tingling or sensory disturbances on the chin, lip, cheek, gums or tongue and which may persist for several weeks, months, or in rare instances permanently.
10. It has been explained that during the course of treatment unforeseen conditions may result that may require change in the procedure, I authorize my Doctor to use professional judgement to perform such additional procedures that are necessary to complete my surgery.

The Anaesthetic I have chosen for my surgery is

- ☐ Local anaesthesia
- ☐ Local with oral premedication
- ☐ Local with intravenous sedation
- ☐ General anaesthesia

It has been explained to me and I fully understand that a perfect result is not or cannot be guaranteed.

I have read and fully understood the above and discussed this operation and alternative treatment with ___________________. He has given me ample opportunity to ask questions about specific points and has answered those questions to my satisfaction.

PLEASE ASK YOUR DOCTOR IF U HAVE QUESTIONS CONCERNING THIS CONSENT FORM

____

Please initial on each page after reading. If you have any questions, please ask your doctor BEFORE initialing.

____

1. I hereby authorize Dr. ______________________________ and assistants to treat the condition described as ____
____.

2. The procedure offered to treat the condition has been explained to me and I understand the nature of the procedure to be: ________________________________
____.

3. I understand that incisions will be made in my mouth for the purpose of placing one or more endosteal root form structures (implants) in my jaw to serve as anchors for a missing tooth or teeth replacement or to stabilize a crown (cap), bridge, or denture. I acknowledge that the doctor has explained to me the procedure, including the number and location of the incisions and the type of implant to be used. I understand that the crown, bridge or denture that will be attached to this implant(s) will be made and attached by Dr.______________________ and that a separate charge will be made by the office.

4. I understand that the implant(s) may need to remain covered by gum tissue for at least three months before being used and that a second surgical procedure may be needed to uncover the top of the implant. No guarantee can be or has been given that the implant(s) will last for a specific time period. It has been explained to me that once the implant is inserted, the entire treatment plan must be followed and completed on schedule.If the planned schedule is not carried out , the implant(s) may fail.

5. I have been informed of possible alternative methods of treatment (if any), including
____
____
I understand that other forms of treatment or no treatment at all are choices that I have and the risks of those choices have been presented to me.

6. My doctor has explained to me that there are certain inherent and potential risks and side effects of any surgical procedure and in this specific instance such risks include but are not limited to:

A. Post-operative discomfort , Pain and swelling that may require several days of at- home recuperation.
B. Prolonged or heavy bleeding that may require additional treatment.
C. Injury or damage to adjacent teeth and soft tissue.

Signature -----------------

D. Post-Operative infection and inflammation of soft tissues around the implant that may require additional treatment.

E. Stretching of the corners of the mouth that may cause cracking and bruising and may heal slowly.
F. Restricted mouth opening for several days; sometimes related to swelling and muscle soreness and sometimes related to stress on the jaw joints (TMJ).
G. Injury to nerve branches in the lower jaw resulting in numbness, pain or tingling of the chin, lips, cheek, gums or tongue on the operated side(s). These symptoms may persist for several weeks, months or, in rare instances may be permanent.
H. Opening into the sinus (a normal bony chamber above the upper back teeth) requiring additional treatment. If the sinus is intentionally entered (sinus-lift procedure with grafting), there may be several weeks of sinusitis symptoms requiring certain medications and additional recovery time.
I. Fracture of the jaw or perforation of thin bony plates.
J. use of other materials which may have to be removed at a later date: _______________
K. Bone loss around implants and loosening of implants.
L. implant or prosthesis fracture, or loss of the implant due to rejection by the body.
M. Allergic or adverse reactions to any medications.
N. Accidental swallowing of foreign material.
O.other ____

7. It has been explained to me that during the course of surgery unforeseen conditions may be revealed which will necessitate extension of the original procedure or a different procedure from that set forth in paragraph 2 above. I authorize my doctor and his staff to perform such additional procedures as are necessary and desirable in the exercise of professional judgment.

8. I understand smoking is extremely detrimental to the success of my implant surgery. I agree to cease all forms of use of tobacco for 2-3 weeks after surgery, including the later uncovering procedure (when necessary), and to make a strong efforts to give up smoking entirely.

9. I consent to the administration of anesthesia I have chosen, which is:
☐ Local
☐ Local with Nitrous Oxide / Oxygen Analgesia
☐ Local with oral Premedication
☐ Local with Intravenous Sedation
☐ General Anesthesia

10.**ANESTHETIC RISKS** include: discomfort, swelling, bruising, infection, prolonged numbness and allergic reactions. There may be inflammation at the site of an intravenous injection (phlebitis which may cause prolonged discomfort and / or disability, and may require special care. Nausea and vomiting, although are rare, may be unfortunate side effects of IV anesthesia. Intravenous anesthesia is a serious medical procedure and, although considered safe, carries with it the risk of heart irregularities, heart attack, stroke, brain damage or death.

Signature -----------------

10. **YOUR OBLIGATIONS IF IV ANESTHESIA IS USED**

A. Because anesthetic medications cause prolonged drowsiness, you MUST be accompanied by a responsible adult to drive you home and stay with you until you are recovered sufficiently to care for yourself. This may be up to 24 hours.
B. During recovery time (24 hours) you should not drive, operate complicated machinery or devices or make important decisions such as signing documents, etc.
C. you must have a completely empty stomach. It is vital that you have nothing to eat or drink for eight (8) hours prior to your anesthetic. To do otherwise may be life-threatening.
D. However, it is important that you take any regular medications (high blood pressure, antibiotics, etc.) Or any other medications provided by this office, using only a small sip of water.

11. I understand that no guarantee can be promised and I give free and voluntary consent for treatment.

My signature below signifies that all questions have been answered to my satisfaction regarding this consent and I fully understand the risks involved of the proposed surgery and anesthesia. I certify that I speak, read, and write English.

BEFORE SIGNING, PLEASE ASK YOUR DOCTOR IF YOU HAVE ANY QUESTIONS CONCERNING THIS CONSENT FORM.

5. Consent for Orthognathic surgery

AOMSI CONSENT FORM
For A Safer Tomorrow

ORAL AND MAXILLOFACIAL SURGERY

CONSENT FOR ORTHOGNATHIC SURGERY

Patient's Name ______________________ Age /sex __________ Date __________

Please initial on each page after reading. If you have any questions, please ask your doctor BEFORE initialing.

Orthognathic surgery is being planned for you, and it is important that you understand the benefits and risks of such surgery. This is NOT minor surgery and you have the right to be fully informed about your condition and the recommended treatment plan. The disclosures in this consent are not meant to alarm you, but rather to provide information you need in order to give or withhold your consent to the planned surgery.

1. I hereby authorize Dr.__________________________and staff to treat the condition described as:____
____

2. The surgical procedure planned to treat the above condition has been explained to me and I understand the nature of the treatment to be:__________________________________
____

3. I have been informed of possible alternative forms of treatment (if any), including:________
____

4. My doctor has explained to me that there are certain potential risks and side effects of the surgery planned, some of which may be serious. They include, but are not limited to:

   A. Facial and jaw swelling after surgery, usually lasting several days.
   B. Bleeding, both during and after surgery, which may sometimes be severe enough to require blood transfusion. I have been informed about the opportunity for blood donation before surgery so that, my own blood may be transfused back to me (auto transfusion) if necessary.
   C. Allergic reaction to any of the medications given during or after surgery.
   D. Delayed healing of the bony segments; rarely requiring a second surgery and/or bone graft to repair.

E. Relapse: the tendency for the repositioned bone segments to return to their original position, which may require additional treatment, including surgery and/or bone grafting.

F. Bruising and discoloration of the skin around the jaws, eyes and nose. Possible Hematoma at injection site .

G. Diminished sense of smell (anosmia) in the upper jaw surgery.

H. A change in cosmetic appearance. Although this is primarily a procedure to restore jaw function, I am aware of some expected change in my appearance. I understand that certain cosmetic changes may not be totally predictable. There may also be changes in speech patterns which may require additional treatment.

I. Loss of feeling, pain or a tingling numbness in my chin, lips, tongue, gums, or teeth which occurs in a significant number of patients. Loss of taste sensation in tongue and palate . These symptoms may last for several days, weeks or months. I have been told that there is some chance that it may be permanent.

J. Possible decreased function of muscles of facial expression.

K. Scarring from external skin incisions if certain rigid fixation methods are used.

L. Malfunctioning or breakage of hard ware. Possible need for additional procedures to remove fixation devices, pins, screws, plates or splints.

M. In certain cases where bone cuts may be made in the marrow space between teeth, there is the possibility of devitalization of those teeth which may require later root canal procedures, and may result in the loss of these teeth.

N Fracture of the maxilla and mandible due to improper mobilization or incomplete osteotomies

O. In upper jaw surgery, the sinus will be affected for several weeks, and there may bleeding from nose in postoperative period. There may be a need for further sinus surgery to remedy any lingering problems.

P. Post-operative infection which may cause loss of adjacent bone and/or teeth and which may require additional treatment for a prolonged period of time.

Q Change in position of the jaw joints (TMJ) which may cause post-operative discomfort, bite change and chewing difficulties. If TMJ symptoms existed before surgery, there may be no improvement and even some worsening of these symptoms after surgery.

R. Stretching of the corners of the mouth with resulting discomfort and slow healing.

S. Inflammation of veins (phlebitis) that are used for IV fluids and medications, sometimes resulting in pain, swelling, discoloration and restriction of arm or hand movement for some time after surgery.

T. Hypernasality of voice due to swelling of nasal mucosa in immediate post operative period. Diffculty in swallowing and speech in cases of cleft patients due to velopharyngeal incompetence.

U I consent to being photographed (head and neck region only) before and After surgery and during the operation to be performed. .

These photographs may be used for medical, scientific or educational purposes, provided my name is not revealed by the pictures

V Airway compromise and fall back of tongue in cases of set back surgeries of mandible.

5. **General anesthesia** will be used for this surgery and I have been told of the risks, including bronchitis, pneumonia, hoarseness or voice changes, cardiac irregularities, heart attack or death. I am aware of the importance of not having anything by mouth (including clear liquids unless specifically authorized by my doctor or anesthesiologist) FOR EIGHT (8) HOURS PRIOR TO AND (8) HOURS AFTER SURGERY . **TO DO OTHERWISE MAY BE LIFE-THREATENING!**

6. I realize the importance of providing true and accurate information about my health, especially concerning possible pregnancy, allergies, medications and history of drug or alcohol use. If I misinform my doctor I understand the consequences may be life-threatening or otherwise adversely affect the results of my surgery.

ABOUT WIRING OF TEETH

If my teeth are wired together after this surgery, I understand there are certain associated risks and complications: oral hygiene will be diminished, there may be resulting gum disease, my teeth will feel slightly loose for some time after the wiring, compromised nutrition and there is always some concern about airway obstruction. I agree to carry wire cutters with me at all times when my jaws are wired and to avoid the use of alcohol and other activities that may cause nausea or airway problems.

Signature -----------------

INFORMATION FOR FEMALE PATIENTS

I have informed my doctor about my use of birth control pills. I have been advised that certain antibiotics and other medications may neutralize the preventive effect of birth control pills, allowing for conception and pregnancy. I agree to consult with my personal physician to initiate additional forms of birth control during the period of my treatment, and to continue those methods until advised by my personal physician that I can return to the use of oral birth control pills.

Signature -----------------

By signing this consent form, I acknowledge that I have read it completely and understand the procedure to be performed, the risks, and the alternatives to surgery. I have had all my questions answered to my satisfaction. I was under no pressure to sign this form and have made a voluntary choice to proceed with surgery. The fee for services has been explained to me and is satisfactory and I understand there is no warranty or guarantee as to the result and/or cure and that my condition may return or become worse. I certify that I speak, read and write English.

ORAL AND MAXILLOFACIAL SURGERY

CONSENT FOR TREATMENT FOR REPAIR OF TEMPORO-MANDIBULAR JOINT

Patient's Name Age/Sex Date

Please initial on each page after reading. If you have any questions, please ask your doctor BEFORE initialing.

Dr. ________________________________ has explained to me about the pathology (disease) that exists in my right and/or left temporomandibular joints (lower jaw joint).

I understand that my condition of limited or compromised function and/or pain may be secondary to a number of possible processes including, but not limited to

	Mark the symptoms
1.Traumatic injury	☐
2. Malocclusion	☐
3. Articular displacement (cartilage dislocation)	☐
4. Degenerative joint disease, inflammation	☐
5. Infection	☐
6. Arthritis	☐
7. Vascular injuries(hematoma formation)	☐

8. Instrument breakage during arthroscopy ☐

9. Ankylosis(fibrous union / bony union of joint) ☐

10. Chronic pain ☐

11. Material failure (foreign body reaction) ☐

12. Frey`s syndrome (sweating over temporal region on operated side) ☐

13. Neruosensory disturbances (numbness over skin and adjacent area of operated site) ☐

14. Otology complications (ear related) ☐

15. Intracranial injuries (Dural tear, cerebrospinal fluid leak) ☐

16. Post operative maxilla-mandibular fixation ☐

17. Objectionable scar formation. ☐

18 Facial swelling lasting for longer period of time ☐

I understand that the surgery to be performed is an exploratory procedure and the treatment rendered at that time will be based on the findings during surgery.

Surgical treatment may includes **mark the procedure**

1. Meniscus repair ☐

2. Meniscectomy (removal of cartilage) ☐

3. Placement of an implant ☐

4. Eminectomy ☐

5. Condylectomy. ☐

6. Arthroscopy ☐

7. Arthrocentisis ☐

8. Gap arthroplasty(release of ankylotic mass) ☐

9.Ligament Plication ☐

10.Interpositional Arthroplasty ☐

11.TMJ Reconstruction ☐

I (we) understand that my surgeon may discover other or different conditions which require additional or different procedures than those planned.

I (we) understand that no warranty or guarantee has been made to me as to a result or cure. I (we) also realize that the following risks and hazards may occur in connection with this particular procedure:

1. Facial nerve paralysis with inability to close eyelid on the affected side.

2. Inability to wrinkle the forehead.

3. Inability to blow air from mouth

4. burning sensation of eye due to inability to close eyelids

5. drooling of saliva from corner of mouth

6. Infection.

7. Resultant malocclusion (incorrect bite) and limited opening of jaw.
8. Lack of improvement or worsening of pain and jaw dysfunction.
9. Further degenerative changes with the temporomandibular joint (TMJ).

7. Consent for Trauma

AOMSI CONSENT FORM

For A Safer Tomorrow

ORAL &MAXILLOFACIAL SURGERY

CONSENT FOR TREATMENT FOR REPAIR OF FACIALBONE FRACTURES

Patient's Name Age/Sex Date

Please initial on each page after reading. If you have any questions, please ask your doctor BEFORE initialing.

My doctor has explained to me that there are inherent and potential risk and side effects associated with my proposed treatment and in this specific instance, but they are not limited to

1. Damage to or loss of teeth in the area of trauma or fracture, loss of vitality of those teeth with requirement for future root canal therapy, loss of dental restoration, accidental swallowing or aspiration of tooth or foreign object, devitalization of bone and soft tissue in the area of trauma which may result in some loss of tissue.
2. Unusual procedures required during surgery such as incomplete removal of tooth, which endanger adjacent vital structures.
3. Post operative swelling, discomfort, bruising, bleeding, hematoma (blood clot), wound infection or dehiscence, sinusitis and limitations of function, any of which require further care.
4. Adverse or allergic reactions to medications or anesthesia causing multiple side effects, some of which may be serious and require additional care or hospitalization.
5. Reaction to foreign material which may have been introduced into the wound by the trauma, or "tattooing" of the skin or mucosa from particles of foreign material
6. Change in occlusion (bite) and jaw function after treatment; secondary problems of the jaw joint (TMJ) which may be prolonged, or even permanent, and which may require future treatment.
7. Possibility of otologic (ear related) complications such as perforation, infections, decrease in function of parotid gland(one of the gland responsible for saliva secretion),formation of fistula over preauricular& retromandibular region(areas of lateral

surface of face), mandibular hypomobility in long term experience, ankylosis of TMJ during surgeries of TMJ joint.

8. Scarring either inside or outside of the mouth, depending on the nature and force of the trauma and the locations of certain incisions required in treatment.
9. Facial muscle weakness particularly of the lip, eyelid or other muscles of expression caused by injury to motor nerves in the area of the trauma. Such weakness may be partial or total and may be temporary or permanent.
10. Sensory nerve injury causing pain, numbness, or other sensory alterations anywhere in the mouth, tongue, cheek, lip, and areas of facial skin which may be temporary or permanent.
11. Wiring the teeth together during the time required for healing of bone fractures will significantly reduce oral hygiene effectiveness, which may then lead to or worsen periodontal (gum) disease, bleeding gums, discomfort and loosening of teeth. Following treatment for facial injury, any such conditions must be treated. Jaw wiring will decrease normal diet and cause temporary weight loss.
12. Certain wires, screws, plates, splints or other fixation devices may be introduced, and some may require later removal.
13. Unusual effects related to hardware used such as metal sensitivity, Infection ,screw fracture, plate fracture or plate exposure.
14. Non-union or malunion of bony fractures, possibly requiring re-treatment. Some cosmetic or functional deformity may occur in areas adjacent to the trauma or repair

I understand that additional injury may be discovered during treatment that might necessitate a change in approach or a different procedure from those explained above and I authorize my doctor to perform such procedures that are necessary and advisable in the exercise of professional judgment.

I understand that this is complex treatment and there can be no guarantee of complete resolution of my present symptoms or jaw/teeth/facial bone injury. Occasionally there may be increased symptoms post-operatively (for example, numbness). I also understand that additional treatment may be necessary post-operatively, including (but not restricted to) physical therapy, reconstructive dentistry, orthodontics, retreatment of bone fractures including bone grafting, removal of certain fixation devices, or TMJ treatment. I agree to cooperate with my doctor's recommendations during treatment, realizing that lack of cooperation will result in a less-than-optimal result.

I have discussed my past medical history with my doctor and have disclosed all diseases and medications, including alcohol and drug use (past and present).

Signature ------------------------

I have had an opportunity to have all my questions answered by my doctor that all blanks on this form were filled in prior to my signing, and I certify that I understand English. My signature below signifies that I understand the surgery and anesthetic that is proposed for me, together with the known risks and complications associated. I hereby give my consent for such surgery and anesthesia I have chosen.

8. Requisites for translation of "informed consent" to vernacular languages

AOMSI CONSENT FORM

For A Safer Tomorrow

Here is the Consent for informed consent and illiterates. This as per the standard requirement. You can dilute it or modify it.

1. All consent forms should be in the language of the majority of the population. Therefore it must be in the Vernacular of that region plus English or any other popular language. The English Consent form should be translated to the local language. There are two ways of doing it so that the essence and meaning are not lost.

A. Ethical committee approved consent forms in order to remain valid will need ' back translation'. The suggested or approved consent form must be translated into the vernacular. The thus translated matter must then be translated back to the original English by another person. Then the original and the 'back translated versions are compared. If the meaning remains unchanged then the translation is accepted. Please note that this is required only in approved consent forms in research etc. In the clinical setting the AOMSI consent for is only a template and such rigorous measures may not be necessary.

B. Alternately the approved consent in English can be translated by a Government approved translator (usually a University translation department). E.g. The Tamil University in Tanjore does approved translations.

2. For obtaining Informed Consent of illiterate persons the Consent form can be read out to the person giving consent in the language he/ she understands in the presence of an independent third party or relative of patient who should be literate. The consent form is then signed and attested by the independent witness in addition to signature or thumb impression of the consenting person.

3. In case of children below 18 years, the parent or legal guardian can sign on behalf of the children. However, child rights activists and the new law in several countries may require a consent (particularly in older children who can comprehend issues). Technically, in India, children below 18 are considered to be 'not legally competent'.

4. In mentally retarded or persons incapable of consenting due to mental incapacity, the parent or legal guardian (if unavailable -institutional heads of organizations taking care of them can sign on their behalf).
5. In hearing impaired illiterates the consent must be explained by sign language or any means that is used for communication to translate the document. It needs third party attestation. Similarly, in visually impaired persons the consent can be obtained through Braille or by oral communication with third party attestation.

Today, in many countries video recorded informed consent procedures are utilised. It may become mandatory in India too.

Caveat: informed consent, however carefully taken can be challenged on the grounds of being an unequal contract influenced by fiduciary relationship in doctor- patient relationship.

The above is my personal opinions based on experience and the use of consent approved by Ethiconsult Services of which Dr George Paul was a member secretary. It can be modified as per personal perception of what constitutes adequate consent.

9. Informed refusal of treatment

Informed refusal of treatment.

This form is primarily used when any recommended treatment is refused by a patient. (It may also be used for patients with TMJ implants who remain both asymptomatic and without imaging changes in joints and who, contrary to FDA and AAOMS guidelines, do NOT wish to have TMJ implants removed)

I have been informed by DRof my condition and the recommended treatment consisting of :

____

____

____

____

I have also been offered alternative treatment which include:

____

____

____

Afterconsideringthetreatment possibilities offered, and having the benefits and risks of each explained to my satisfaction, I have voluntary chosen to :-

____

____

____

____

I understand that my decision is contrary to my doctor's recommendation and that my condition may significantly worsen as a result, may require additional therapy additional therapy/ or hospitalization, and in rare circumstances may be life threatening. I AGREE TO RETURN TO THIS OFFICE FOR PERIODIC MONITORING OF MY CONDITION AS scheduled by my doctor.

I realize that I may consider my decision at any time by notifying my doctor.

A.2 Quantification of Disability

A.2.1 Quantification of Dento-facial Disability/Deformity: A Proposal [19]

Form and function are the quintessence of human life. Disability and deformity are interruptions to this harmony. Disability/deformity may be congenital or acquired. Governments have a social responsibility to mitigate such afflictions by creating an environment for re integrating them into normal social life. Most welfare states provide benefits for persons with disability.

Disability can also be caused by accidents, interpersonal violence and iatrogenic causes. These situations have legal overtones and often require compensation in some form. Benefits and compensation can only be calculated if the disability is quantified. Orthopedic disabilities in Civil and Military life have been calibrated and quantified. Similarly other disabilities involving loco motor, neurological, visual and hearing deficit have also been quantified. Unfortunately the maxillofacial region has not been adequately addressed in any of these quantification charts.

Quantification of the maxillofacial region is unique on account of the fact that there are two criteria to be evaluated—Disability and Deformity. While disability is more readily calculated, deformity is highly subjective and therefore any award for the latter is bound to be arbitrary. However it is not possible to ignore the importance of deformity to the face, and an attempt is made to establish a broad parameter in which it can be assessed.

Review of Quantification Criteria

Quantification of orthopedic disability is well established and has been in use for social benefits, rehabilitation, assistance and percentage reservations in labour market placement of disabled people. It has also been in use for legal and insurance compensations due to accidents, interpersonal violence and occupational diseases. The Phulhems profile by the Canadian Army was established as early as 1943. The McBrides criteria was the established reference in India till 1980. It did cover some aspects of the maxillofacial region and was generally accepted for dental injuries and dental loss. The McBrides criteria (1955) was replaced in India by the "Manual for Doctors to Evaluate Permanent Physical Impairment" (1981). Unfortunately the impairment and disability of the face is covered rather incomprehensively and inadequately, relegating the whole area of the face to one half of a chapter, with hardly 30 points being allocated to the face. Not one maxillofacial surgeon sat on the expert committee of 45 advisors. In the realm of physical rehabilitation and orthopedics, numerous references are available. Kessler (1970) covered various aspects of upper and lower extremity disabilities. The American Academy of Orthopedic Surgeons Manual (1966) discusses the concept of permanent impairment through a series of questions that reveal the permanency of the deficit. The Govt. of India notification (1986) covers visual disabilities, locomotor disabilities and hearing and speech disabilities. It recommends that Kessler's formula can be taken as a general guideline.

Significantly the only other Indian guideline for Maxillofacial region comes through a Government of Tamilnadu notification (1974) where complete facial disfigurement is dealt with. It simply awards a 50% for total facial disfigurement. No break up figures is given for type or severity of disfigurement.

The American Association of Oral and maxillofacial Surgeons and American Medical Association have given guidelines for assessment of maxillofacial injuries and disabilities. They however need modification to suit our population and needs.

The authors have depended on two major sources while making this evaluation.

1. Objective Evaluation of Impairment and Ability in Locomotor Handicapped by Sabapathyvinayagam Ramar. An excellent reference book on Physical Medicine and Rehabilitation.
2. Guidelines to the Evaluation of Impairment of The Oral and Maxillofacial Region—issued by the American Association of Oral and Maxillofacial Region.

The authors have modified the guidelines of the above sources to arrive at the recommendations.

The general aim of the exercise was to evolve quantification criteria for disabilities and deformities of the Maxillofacial region taking into account the special features of the problems encountered in India. It also endeavours to simplify the percentages awarded by eliminating complex variables. **The evaluation adopts a position of awarding a 100% to the face to be divided between deformity (50%) and disability (50%). It does not try to evaluate facial impairment as a part of the total body as it would significantly reduce the quantum of impairment and thus defeat the purpose of this exercise.** Consider a situation where 100% has to be divided between cardiovascular, alimentary, central nervous and locomotor systems in addition to sexual dysfunction, liver dysfunction, renal, endocrine and metabolic dysfunctions. Further distribution amongst visual, hearing, etc. will certainly minimize any help of giving value to the face.

The evaluation has also eliminated the need to go into variables like age, sex and occupation, which will modify the award percentages. These will rest within the realm of the government agencies, judiciary or insurance agents.

The criteria formulated shall simply make a statement of disability/deformity based on standards established within the purview of the 100% for the face—equally divided amongst the various structures and functions. **The total of these shall remain within hundred utilizing the formula**

$$A + \frac{B(100 - A)}{100}$$

where, A = higher value and
B = lower value.

Definitions

Based on Govt. of India Gazette Part I section 1 No. 4-2/83—HW III Ministry of Welfare, 1986.8

- *Impairment:* is defined as any loss (or) abnormality of psychological, physiological (or) anatomical structure (or) function.
- *Disability:* WHO defines disability in the context of health experience as any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner (or) within the range considered normal for a human being.
- *Deformity:* facial disfigurement involving soft and hard tissues arising from multiple genetic factors, environment influences, acquired defects, neoplastic processes and trauma.

Recommended Quantification for the Dento-facial Region

Areas of Deformity Evaluation—Hard Tissues:

A. **Loss of Teeth:**

Anteriors	*Deformity/Disability*
All anteriors (upper and lower)	: 25%
Between 8 and 11	: 20%
Between 4 and 7	: 15%
Between 2 and 3	: 10%
One tooth	: 05%

Though these are disabilities and deformities that can be replaced, it deserves the above percentile as the strength and function of false teeth are not considered equal to natural teeth. Orthopedic deformities are evaluated even if prosthesis is given.

Posteriors Disability

– Excluding third molars and including premolars.

All posteriors (16)	: 25%
Between 10 and 14	: 20%
Between 6 and 9	: 15%
Between 2 and 5	: 10%
Occlusal discrepancy	: 10–20%
One tooth	: 05%

Loss of teeth due to progressive dental pathology (e.g. Periodontitis, caries) are not considered. The dental surgeon will have to make an assessment based on the condition of remaining teeth or preexisting records.

B. **Loss of Bone** (Disability/Deformity)

Significant loss of bone causing
Deformity/Disability : 10–25%
Small bony fragment : 5%

C. **Mal-united Facial Bones: (Depending on extent of Disability/Deformity)**

Malunited facial bones 10–20%
– Occlusion to be combined whenever affected.

This is an incomplete quantification and will have to be assessed by the surgeon on the basis of the degree of disability/deformity caused by the malunion.

D. **Orbital Deformity (excluding visual field assessment)**

Subjective evaluation based on:
Bony orbit : 5–10%
Soft tissue e.g.) etropian, scar etc : 5–10%
Composite deformities including
Telecanthus etc : 15–25%

Areas of Deformity Evaluation—Soft Tissue

A. **Soft Tissue—Non-reversible**
Single linear scar : 5%
Multiple or deforming scars
Including Keloids : 10–30%
Significant loss of soft tissue
E.g. Loss of nose, ear, lips etc : 20–50%

B. **Facial Sensory Impairment (Ramar)**
Face has 34% sensory innervations of whole body.
Ophthalmic : 8%
Maxillary : 8%
Mandibular : 8%
Tongue : 10%

C. **Impairment Rate for Mouth Opening (Ramar)**
Impairment rate for interincisor distance of 4 cm : 0%
Impairment rate for interincisor distance of 3 cm : 10%
Impairment rate for interincisor distance of 2 cm : 20%
Impairment rate for interincisor distance of 1 cm : 30%
Impairment rate for interincisor distance of 0 cm : 50%

D. **Motor Disability (RAMAR)**
Jaw muscles (masticatory) : 5% right side, 5% left side
Tongue muscles : 15% either side.

E. **Facial Nerve Impairment**
Single branch : 05%
Five branches : 25%
Zygomaticotemporal : 10%

Bilateral problems are not addressed.

F. **Disfigurement criteria (AAOMS and AMA guidelines 1997 and 2002)**

- Class 1—(0–5%) Disorder of cutaneous structure e.g. visible scars
- Class 2—(5–10%) Loss of supporting structure with or without cutaneous disorder e.g. Depressed cheek and nose.
- Class 3—(10–15%) Absence of normal anatomical area of face. E.g. Loss of eye or part of nose. Visual or hearing loss will have to be separately evaluated.
- Class 4—(15–35%) Impairment of whole person. Facial disfigurement is so severe that it precludes social acceptance.

This criteria appears logical and it significantly simplifies an otherwise complex quantification of facial disfigurement. However we would encourage its use with the other mentioned parameters. The multiple percentages can be resolved with the Kessler's formula.

In multiple disabilities and deformities or when there is a combination of the two the Kessler's Formula $A+\frac{B(100-A)}{100}$ can be used, where A= the higher and B= lower value

Another formula has also been used by Ramar as per the Government of India notification: $A+\frac{B(90-A)}{90}$ again A being the higher value and B being the lower value.

The formula can be used in a few mock situations.

1. X has an injury resulting in the fracture of the mandible and loss of four incisors. He also develops a pareisis of the marginal mandibular nerve following surgery. His total percentile may be calculated thus: A = 15% and B = 5%.
   $15+\frac{5(100-15)}{100}=19.25$, whereas the sum of both would have been 20%.
2. Y has an injury resulting in the fracture of both condyles causing subsequent total bony ankylosis. He also has a large scar with keloid on his right cheek. His percentage is calculated thus:
   $50+\frac{20(100-50)}{100}=60$ whereas the sum of two injuries would have been 70. Please note that the value adjusts itself as the percentiles go up.

Discussion

Quantifying all kinds of disabilities/deformities is an enormous task. This paper attempts to deal with only those disabilities resulting from accidents. Congenital disabilities/deformities such as those found in cleft—craniofacial anomalies will require a more extensive analysis. Similarly disabilities and deformities caused by aggressive tumours and cancers of the head and neck comprise a wide range of problems, which are not necessarily regional. Cancer in particular may have numerous associated problems ranging from donor site morbidity to psychological impact affecting quality of life and mental depression.

Dental injuries and their resultant disability/deformity are closely linked to aesthetics and mastication. For the purpose of awarding percentiles, the anterior teeth were considered for aesthetics and the posterior teeth for masticatory function. The awards are arbitrary and based on the relative dysfunction caused by the absence of teeth in the masticatory apparatus. The American Association of Oral and Maxillofacial Surgery (AAOMS) guidelines award percentages for the complete masticatory apparatus. It awards 24% for a person who is restricted to liquid diet (40–60% if tube feeding is necessary) and 5–19% if person is restricted to semisolids (includes those with ability to wear dentures). We have taken the liberty of awarding points for individual teeth. However if the whole masticatory apparatus is to be evaluated, one may separately evaluate absence of teeth, occlusal disharmony, TMJ movement (craniomandibular articulation), muscle power etc and arrive at a figure by using the Kessler's formula of $A+\frac{B(100-A)}{100}$.

This appears as a reasonable formula, which accounts for individual disabilities within the framework of the masticatory apparatus.

Further the AAOMS guidelines classifies the percentiles into two categories (1) Percentage of normal. (2) Percentage impairment of whole person. The dichotomy does not seem reasonable and is likely to cause further confusion. Finer details such as lateral excursion etc which, have been dealt with in the AAOMS guidelines have been ignored.

Similarly the concept of deformity and disfigurement has been dealt with differently in the AAOMS and the AMA guidelines. The matter of disfigurement is complicated by issues such as personality crisis and the impact of social acceptance. As suggested earlier this criteria can be incorporated into Kessler's formula, thus resolving the issue of multiple disabilities and deformities.

Finally the question of who can give a disability certificate. The Indian sources are silent in the matter of maxillofacial injuries. However the law in many American states clearly provides for the role of a Board qualified Oral Surgeon or maxillofacial Surgeon to issue disability certification for the maxillofacial region.

Contrary to general perception, it is not necessary that these criteria need to be made by statutory bodies. General usage can give legal legitimacy. It would of course be in the best interest of the Surgeon, patient and the public if these suggestions can be scrutinized, amended and enlarged to accommodate a larger spectrum of disabilities and deformities.

A.2.1.2 Duties of Witness

Failure to appear in court without valid reasons after warrant has been issued can invite contempt of court.

Exaggeration or false statements given under oath is not only unethical, but can invite punishment under sec. 181, Sec. 193.

45 Research and Publishing in Oral and Maxillofacial Surgery

George Dimitroulis

45.1 Introduction

We have all been too quick to make up our minds and too slow to change them. In Oral and Maxillofacial Surgery, our opinions are slaves to our prior experience. Ignorant confidence is what defined early Surgery as there was a distinct lack of interest in proving and promoting what was effective. The "God complex" among early Surgeons meant that what they thought was true did not need scientific evidence. It is only in more recent times that Surgical practice has embraced evidence to guard against rumour, bias, misconceptions and misunderstandings. Indeed, just in the last few decades we have witnessed the gradual evolution of Surgery from eminence-based practice, the idea that senior experienced Surgeons held all the knowledge, to evidence-based practice, where fair tests are employed to compare one treatment against the other in order to find what works best. History has taught us that clinical research leads to reforms in the practice of Surgery while basic research leads to revolutions in Medicine.

Like in most other scientific disciplines, Surgical research is used to confirm facts, reaffirm the results of previous work, solve existing problems and ultimately develop new ideas of practical value. If you can understand more, you can make better decisions rather than blind guesses which is the hallmark of successful clinical practice. Judgements, predictions and plans are based on the latest available information and should be constantly updated in the light of new information derived from good research. The late British Economist John Maynard Keynes once said "when the facts change, I change my mind". So too, a good Surgeon must be open to new ideas and techniques which are essential to the progress and evolution of each surgical specialty, as change is only possible when key opinion leaders lead the charge.

G. Dimitroulis (✉)
Maxillofacial Unit, St. Vincent's Hospital – University of Melbourne, Melbourne, Australia

Essentially, the greatest discoveries in Surgery are those that force us to rethink our beliefs about human disorders and our role in managing it. Research builds our core knowledge, and the most useful knowledge is one that changes the behaviour and practice of Surgeons. The simple idea of washing your hands before handling patients met with immense resistance from the established medical community in the nineteenth century until the scientific evidence supporting microbial infection became too overwhelming to ignore. Knowledge increases your ability to predict the outcomes, and the knowledge of bacterial infections was one of the greatest breakthroughs in modern medicine that significantly reduced the mortality and morbidity of even the simplest of surgical procedures. Research has been pivotal to the success of surgery over the last two centuries and will continue to be an integral part of all future progress, especially in the rapidly expanding field of Oral and Maxillofacial Surgery.

Progress doesn't occur in a vacuum; it almost always builds on existing ideas with a series of incremental improvements. That is why most research is used to develop further knowledge on a topic by reaffirming the results, theories and problems of past work in the field. Occasionally, when trying to solve an existing problem, research may lead to the discovery of new problems, ideas and theories which makes the science of Surgery a dynamic process of knowledge acquisition that has no endpoint.

45.2 The Science of Research

The word Science comes from the Latin "scienta" which means knowledge or skill. Science is about new ideas and testing these in the most transparent way. What launched the Scientific revolution was the realization that we do not have the answers to their most important questions. To find the answers, experiments are what people devised when they weren't sure of the truth. Ignorance is the starting point of all

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_45

science, and curiosity about the world around us is what drives science. The more that is unknown, the greater the opportunity to discover, and that is how research has become an essential tool of discovery.

The word Research is derived from an old French term referring to seeking or searching. Research is all about the ability to test, reproduce, quantify and falsify an idea before it can be fully accepted as scientific fact. In research we learn more from the unexpected results than from those we anticipate. Understanding the research process helps generate new research questions. The trick is to ensure the right methods are used to answer the right questions. For example, when we are seeking verification, we must ask ourselves "Did I build the system right?", while if we want to validate something, we then ask "Did I build the right system?".

Scientific research is a systematic way of explaining things by collecting evidence which make practical applications possible. The goal of research is not only to yield new knowledge but also to make us better understand existing issues or topics. There are three main forms of Research; Exploratory research helps to identify a problem, while Constructive research proposes solutions to the problem. The third is Empirical research which tests the feasibility of the solution using either qualitative or quantitative methods. Qualitative research collects data in the form of words, images and video which is largely confined to the social sciences but may also have applications in Surgical techniques. The difference between quantitative (numbers) and qualitative (descriptions) research is well summarized by the famous scientist, Albert Einstein, who once said that "Not everything that matters can be measured, and not everything that can be measured matters". The world cannot be understood without numbers, and equally, it cannot be understood with numbers alone.

In Surgery, quantitative research is most often used to establish the existence of causal relationships between variables by collecting and analysing numerical data. By relying on random sampling, the quantitative research method allows for experimental, correlational and descriptive (i.e. survey) results that are easy to summarize, compare and generalize using statistics to determine the relationship between variables. For example, if the research question is about best mandibular reconstruction following tumour resection, the patients may be randomly assigned to different groups, each representing a different mode of reconstruction. If this is not feasible, the researcher may collect data related to the patient's demographics and situational characteristics to statistically control for their influence on the degree of morbidity following their particular mandibular reconstruction. Often the intent of the surgical research is to generalize from the study participants to a larger population which will require the researcher to employ probability sampling to select the study participants.

g. Data analysis—choose your statistical method
h Data interpretation—keep an open mind
i. Test/revision of hypothesis
j. Conclusion/recommendations for surgical practice
k. Reporting/communicating/publishing findings

45.3 The Scientific Research Method (Table 45.1)

Scientific research follows a structured process. Successful research is only possible when asking the right questions, engaging in the right observations, running the right experiments and networking with the right people to elicit ideas and feedback. The core principle of science and research are precision and transparency—being clear about your methods and honest with your results. Transparency is what gives science credibility. World-changing ideas and technology were built from a protracted process of trial and error. Experiments are designed to show what does work and what doesn't. It is by testing that we gain access to the feedback that drives progress. Formal research has a well-established pathway that follows the basic steps set out below.

45.3.1 Observation

Many people simply watch the world around them (on autopilot). Few people observe. An astute observer will see the problem only when they're not vested in the way things have been. Their ability to imagine how things should be is what drives change and progress. The hardest part of solving a problem is seeing it, and many surgeons blindly follow procedures that do more harm than good for the patient because they have failed to question the surgical technique they have been taught. In surgery, very few surgeons have ever asked the pivotal question—"Is there a better way?" Curiosity and an open mind is what drives progress, and unfortunately, most surgeons have achieved their chosen profession by not rocking the boat and adhering to conventional practices.

Many of the things we accept as objective truths are themselves assumptions based on uncertainty, even in the world of Surgery. No surgical concept or technique has an absolute and permanent value. Time, experience and better experimental tools give rise to new ideas that supplant the old ideas. In other words, all existing surgical ideas and techniques are sooner or later supplanted by new ideas and techniques which means surgery is a never ending marvel of evolution.

Before embarking on any kind of research, the first step is to look for any idea or technique that has not been adequately explained or supported by evidence. When looking to a topic or issue as a potential subject for research, the hierarchy of deliberation begins with (1) “Where is the evidence?”, (2) “How sound is the evidence?” and (3) “Has the evidence been properly interpreted?”. Once you have selected the appropriate subject or topic you would like to explore, the next step is to find out what the literature has to say and look for gaps in the existing knowledge.

45.3.2 Literature Review

All the world’s information is now at our fingertips, and to access scientific publications is a matter of a few keystrokes. Search engines like Google Scholar and PubMed have opened up a whole new digital world of scientific literature that even the largest University libraries could never hope to subscribe to. Access to the world’s scientific literature has never been simpler than it is today, and subscriptions to University libraries also allow students digital access to a wide range of local and international journals.

Once the research topic has been selected, a thorough review of the literature is required to establish what is already known. It is best to begin with the most recent peer-reviewed articles on the topic which will often summarize the existing body of knowledge. Meta-analysis papers, especially those that follow the PRISMA guidelines, are becoming more common, and these papers can form the foundation of your research topic. Good journal papers will commonly highlight the gaps in our knowledge, the weakness in the current evidence available, and what further research is required that will conveniently point you in the right direction.

45.3.3 Purpose of Research

Once you have gathered all the pertinent information from the literature review, the next step is to crystalize in your own mind why you are embarking on this research. The flaws or holes in previous research are identified so that the gaps in the literature will provide justification for the new research being proposed. Look for clues in the literature where there may be a deficiency in the evidence surrounding published statements, particularly those that make generalizations that are not adequately backed by evidence. Indeed, many Cochrane reviews have consistently concluded that the vast majority of clinical papers fail to provide the level of evidence required to make any firm conclusions. The aim or purpose of the research is pivotal to the whole project as it dictates the methodology required to adequately address the aims. It is also the main driver in funding applications and recruiting study participants.

45.3.4 Hypothesis

Science grows with every new piece of evidence with the hypothesis as the compass that directs the inquiries. Scientific theories have to make testable predictions that can be validated in experiments. Science is not just about confirmation; it is also about falsification. If a theory cannot be tested, then it’s logically impossible to ever falsify it. Karl Popper said “if it is not falsifiable, it’s not scientific”. If a theory cannot be tested with experiments, then it falls in the realm of religion or philosophy or pure speculation. Questions that generate the greatest emotional response are a great indicator of challenging the way things are.

The gap in the literature creates a research question which is otherwise referred to as the Hypothesis. The Hypothesis is a prediction which is set out as a statement that defines the relationship between two or more variables. In research, it is the hypothesis that is being tested as to whether it is true or false. If the hypothesis turns out to be consistent with the observations, then it is said to be supported rather than proven as it is still subject to further scrutiny. But if it is rejected, then support is claimed for an alternative hypothesis. The Null hypothesis is when there is no relationship between the variables being investigated.

45.3.5 Define the Variables

In the hypothesis statement, there will be two or more variables that will be the focus of the study. The study is designed to establish the relationship between the variables. However, before commencing the study, the variables must be clearly defined so that there is no doubt as to what each variable represents. Without clear definitions of the variables, studies cannot be repeated and hence impossible to validate.

45.3.6 Data Collection

What isn’t measured can’t be managed. Without data, we cannot make informed decisions. We gather data to collect information that becomes knowledge which is finally displayed as wisdom. Data has to be collected, processed and analysed for it to become information which can be used to make better decisions. Ultimately, the answer is only as good as the quality of the data fed into it.

Apart from field studies such as surveys and clinical audits, OMF Surgeons also conduct experiments that involve laboratory controlled conditions, often by recruiting the resources of other medical specialities such as pathology, microbiology, radiology, biochemistry, pharmacology and haematology. Data collection is easiest when data points can be quantified or represented with numerical figures. Even descriptive surveys can be quantified provided the responses can be listed on a sliding scale ranging from good to bad, high to low or positive to negative. A typical example is the visual analogue scale used by OMF Surgery researchers to quantify pain scales, chewing ability and quality of life outcomes before and after jaw surgery.

In Medicine, randomized trials where the patients and experimenters are blinded are least vulnerable to bias than observational studies, which are most prone to bias. Unfortunately, randomized trials are more expensive than observational studies and require a lot more manpower and resources to properly execute. In surgery, we most commonly rely on observational studies as the best evidence we have to go on for two reasons. Firstly, control groups with which to compare treatment outcomes, unlike a placebo sugar drug, are rare as it is ethically impossible to undertake sham operations. And secondly, it is practically impossible to blind surgeons and patients when it comes to evaluating surgical procedures. Evidence in the field of Oral and Maxillofacial Surgery therefore relies largely on observational studies derived from surveys and clinical audits of case series.

45.3.7 Data Analysis

Data science is about understanding the world by spotting patterns and predicting how one variable will affect another. While our instincts may give us a reasonable sense of how the world works, we need data to sharpen the picture as we can be easily blinded by our own experiences and prejudices.

Data shows us there is more to OMF Surgery than we think we see. Good data science can often demonstrate counterintuitive results—what you least expected to see. Selection biases are distortions of the results introduced either by the data collecting tools or by the method of data accumulation.

Statistics is a valuable tool that helps determine whether the results you have found are likely to be due to a chance rather than a true finding. Make sure the data is collected on an Excel spreadsheet, and work out what level of confidence you will accept as statistically significant which, in clinical research, is often the 95% confidence level (i.e. P value <0.05). In statistics, the smaller the sample, the lower the likelihood that it would mirror the broader population. Large samples yield more precise results, while small samples are more susceptible to extreme results. As sample sizes get larger, the statistical calculations from that sample get more precise. Small differences (1%) between two populations being measured require bigger sample numbers than large differences (25%) for the true value to emerge. This is called the power calculation which is an important measure to consider before embarking on any study. Statistics is a complex affair and beyond the scope of this chapter, so the services of an expert statistician may well be useful when it comes to crunching the data.

45.3.8 Data Interpretation

Information is interpreted by different people in different ways. People can look at the same set of facts and disagree. Data can be manipulated to support any argument. You don't always need a ton of data to find important insights. What you need is the right data. Numbers can be seductive. We can grow fixated with them, and in doing so, we can lose sight of more important considerations. When looking at data, it is not the raw crunching power you have that matters most, but what you do with it that is most important. Behind every statistic there is a certain set of assumptions and prejudices. Minds crave certainty, and when they don't find it, they impose it so we must keep an open mind when the data does not yield the results we expected to see.

45.3.9 Test or Revision of Hypothesis

Your judgement call about how the results support your hypothesis is essential to your conclusions. If the data does not support your hypothesis, then it is essential to state an alternate hypothesis that fits with what has been observed. The scientific method is tailor-made for cherry picking because of its hypotheses and caveats and refusal to embrace certainty. Even in Science, certainty still relies on the assumptions, interpretations and theories of researchers based on what they see. Nothing is definite, for doubt is an essential operating principle of science. This means that doubt still has a place in all scientific proofs, so that all evidence is provisional and not final. In other words, what you have ascertained in your research is not definite proof but rather tacit support for an idea.

45.3.10 Conclusions and Recommendations

The conclusion is a summary of the entire experiment or study that simply states the outcomes observed which must be clear, concise and to the point. Any ambiguity should be highlighted and recommendations made as to how future studies should be conducted to minimize the uncertainty. It may simply be a numbers game where more patients are required, or additional groups such as control patients which may provide a clearer outcome. For example, the effectiveness of Botox in Myofascial Pain (TMD) can never be properly evaluated if there are no control groups (i.e. that have normal saline injected) with which to compare.

The conclusion is the most sought after piece of information that others will first look at when reviewing your research. Although it sounds rather obvious, the conclusion(s) must be supported by the data; otherwise, the research makes no sense. The onus is on the researcher to make sure the conclusions also fulfil the goals and aims of the study. Recommendations based on the conclusions are essential in providing a practical guide to surgical practice. Research is what drives clinical advances in Surgery, and the change in behaviour of Surgeons can only be achieved with evidence.

45.3.11 Reporting/Communicating/Publishing Findings

Research is useless if it is not shared with the outside world. All humanity is now connected by digital technology which has rendered distance, time and costs irrelevant to the distribution and exchange of ideas. The digital world has made recording, storage and dissemination of information, research and ideas virtually free with costless reproduction and instantaneous global distribution. Reporting and publishing research findings is described in detail in Sect. 5.

45.4 Constraints in Surgical Research

Cultures that fail to encourage questioning also fail to come up with new ideas. Great institutions should teach us how to ask hard questions and where to look for answers. Knowing all the answers does not distinguish someone's intelligence—rather, the ability to ask the right questions and linking the unconnected is the mark of a true genius. Generally, it is considered a weakness and a sign of vulnerability for clinicians to appear unsure. Confidence in medicine is valued over uncertainty, but science is all about uncertainty which drives progress. If we knew it all, there would not be a need for research.

Nothing is as powerful as an idea whose time has come. New ideas are what drive behavioural change and innovation. A new behaviour needs social approval before others are likely to pick up the habit as their own. Only the curious, who are open to learning, have a much greater chance of creating a truly novel solution. Unfortunately, originality is not always embraced by the surgical profession who are generally conservative by nature.

It is much easier for Surgeons to accept familiar ideas than totally original ones because if the ideas are too original, then it may be too hard for the Surgeon to accept or understand. The goal is to push the envelope, not to tear the envelope. Radical ideas are best presented in a way that is less shocking and more appealing to mainstream surgical practice by planting the seeds of a simple idea before revealing the larger idea. If you want your ideas to be accepted by your peers, make your ideas more appealing by connecting it with other ideas that are already understood by your colleagues. Other constraints related to research involve ethics, funding and bias which are discussed below.

45.4.1 Ethics

There has been a push in recent years by institutions and clinical journals to have all animal and human research activities sanctioned by appropriate ethics review boards or panels attached to hospitals or Universities. Without ethics approval or clearance, it may be impossible to conduct even the simplest of clinical studies, including basic surveys. Some Journals now request a copy of the ethics clearance letter before the paper can even be put out to review.

Unlike pharmaceutical research, the level of evidence in clinical surgery is hampered by the fact that control subjects are often missing because you cannot ethically perform sham operations in humans. Therefore, when designing surgical experiments, consider whether animal, laboratory or cadaver studies may be useful instead. Otherwise, you are limited to clinical audits which provide useful information which may not be scientifically valid. For example, a hospital which boasts 100% survival of its patients achieves this by turning away the sickest patients. Or a hospital which has the worst outcomes may well be a tertiary referral centre that only treats the most complex of cases that other hospitals turn away. So, while clinical audits provide a snapshot of the Hospital Unit's activities, it tells us very little else as far as science, progress and innovation is concerned.

We must be suspicious of therapeutic claims that have not been properly tested. Equally, we must be even more suspicious of research results that cannot be replicated. Many people are driven by a deep human desire for recognition and affirmation of work well done. Sometimes it is possible to build an academic career by sounding clever, rather than being clever. Most academics chase large numbers of trivial publications instead of investing their energies in new frontiers. In other words, why search for something new when you can collect rents on everything that has already been done. Sadly, there are small numbers of academics and researchers who have built their careers on falsification and plagiarism. The desire for recognition and the need for promotion when combined with the pressure to publish can tip some academics, clinicians and scientists towards fraudulent activities where data is made up and text is plagiarized in order to churn out the maximum number of "scientific" papers. In science and surgery, reputation takes many years of hard dedication to build up and an instant to destroy when you're suspected of scientific fraud.

45.4.2 Funding

Scientists have an innate desire to innovate, share, collaborate and be recognized for it regardless of the financial incentives. Hence, good research requires funding from external sources. Unfortunately, the spirit of open scientific enquiry can sometimes be hijacked by the combination of self-interest and money, especially when industry offer to bankroll the study. Industry rely on profitable enterprises which grow shareholder value. Scientific support behind a product is perhaps the ultimate value-adding marketing tool, so industry are always looking out for research that shows positive outcomes related to their products. Furthermore, industry never leave anything to chance so they want control of scientific research through financial rewards to various research institutions. By directly funding research, industry have control over what is published (i.e. the positive results) and what stays buried in a locked cupboard (i.e. the negative results).

Therefore, the most respectable research is that which is funded by government or not-for-profit organizations such as Medical Societies and disease interest groups like the Heart Foundation or the Cancer Council and so on. Funding from non-industry groups are much more competitive as there is always a limited amount of money available for research so applications must be of high quality. Furthermore, the non-industry funding bodies give free reign to the scientists on how the data is used and published. Industry funding, on the other hand, have simpler applications but more control of the data which remains their property. Most importantly, industry insist on the final veto on whether or not the results are published.

45.4.3 Confirmation Bias

Confirmation bias is one of the shortcomings of science because the human mind is bad at seeing things it did not expect to see and a bit too eager to see what it expected to see. It is basically seeing what you want to see and ignoring everything else. In essence, confirmation bias is when you filter reality through biases by eagerly accepting evidence that confirms what you believe and ignoring evidence that refutes or challenges what you believe. Once we adopt a particular hypothesis or interpretation, we find it difficult to see things any other way. People will accept any explanation as long as it fits with their own understanding of the facts.

45.4.4 Cognitive Dissonance

Cognitive dissonance is another impediment to scientific progress that affects many people. It is simply a feeling of discomfort that people experience when presented with information that is inconsistent with their beliefs. When we are confronted with evidence that challenges our deeply held beliefs, we are more likely to reframe the evidence than we are to alter our beliefs. In most cases, instead of acknowledging an error in judgement, people tend to reformulate their views in a way that justifies their old opinions. We simply invent new reasons, new justifications, or new explanations or ignore it altogether. Some people go to absurd lengths to justify their beliefs or judgement even when confronted with clear contrary evidence. The more committed we are to a certain opinion, the less likely we are to relinquish it, even when confronted with massive or overwhelming contradictory evidence. As an example, the introduction of microvascular venous couplers in microsurgery was developed by those who could see the obvious benefits of speed and patency of the anastomosis, and yet was resisted by those who felt the skill of micro-suturing tiny veins would be lost, regardless of the benefits of reduced thrombosis and improved flap survival.

45.5 Publishing

Research cannot thrive without publishing. All research projects are conceived with publication as the end game. The excessively competitive field of research creates a tendency to rush to conclusions and publish results that have not been properly validated. Valid conclusions can only be drawn from reproducible data sets because results that initially look promising aren't always repeatable. It is little wonder that remarkably few published breakthroughs have ever led to any useful treatments.

There are numerous media that researchers can use to propagate their experimental findings which are discussed below.

45.5.1 Electronic Media

Digital technology has not only transformed but has revolutionized the way we live. The merger of the personal computer and the Internet allowed networking to blossom on a massive scale, and so surgeons and scientist are not wholly reliant on print media to propagate their ideas. Websites like ResearchGate encourage scientists and clinicians to upload their research, both published and unpublished, onto a digital platform for all to see and to foster collaboration between research groups across the world.

Digital media platforms like YouTube are fast becoming a quick, easy and virtually cost-free way of publishing your novel ideas and surgical techniques on the Internet for all to see. More and more Surgeons are bypassing the heavily fortified realm of print media for the highly accessible digital media which not only offers a global audience but also facilitates immediate upload of content with virtually no delay. The disadvantage is of course the lack of scrutiny which suggests the content has not been vetted by experts. Hence, the scientific value of the video post is virtually zero. While you may have a wide audience, it may not necessarily be the people you want to impress.

45.5.2 Magazines

Glossy magazines that specifically target general medical/dental practitioners are supported by lots of industry advertising which is interspersed with clinical articles that have not been peer-reviewed, but rather submitted on the invitation of the magazine editor. The articles, which often have more clinical pictures than text, are written by clinicians and academics as a general interest piece that provides the reader with an update of what is current clinical practice that is aimed at the non-specialist practicing clinician. Authors are generally paid for their contributions. These articles are of little value to the specialist trainee or clinician wanting to find out more about their own specialty.

45.5.3 Textbooks

Textbooks contain information that is current practice and accepted by the profession. Unfortunately, by the time a textbook is commissioned, written, published and finally released, the information is often about 2 years out of date. Therefore, the strength of textbooks is in the basic principle of surgical practice, and the weakness lies in the distinct lack of new information. Digital technology is gradually changing the need for printed textbooks as students are gravitating to knowledge that is presented in discrete digital packages with hyperlinks that cross-reference important concepts similar to "Wikipedia". While university and hospital libraries still purchase textbooks for student consumption, today's students are finding the expense of textbooks prohibitive and so seek other means of accessing surgical information and knowledge through the Internet, which is often up to date as long as they know what to look for and are able to critically evaluate the credibility of the information source.

45.5.4 Peer-Reviewed Journals

There are over 1 million academic papers published every year in over 24,000 academic journals where gaps in our knowledge are discussed and new experiments are conducted that might resolve these gaps. Unfortunately, published scientific papers tend to be biased towards reporting positive results. Negative results do not make headlines so they are rarely published. Publication in a journal is not a mark of truth but merely that the research has passed a certain standard that warrants entering the formal literature and further discussion.

Scientific journals sell scholarship back to the same universities whose scientists had produced, written, peer reviewed and edited largely for free. Hence the cost of producing scientific journals is kept as low as possible in order to facilitate as wide a distribution as possible. Unlike magazines, peer-reviewed journals with few exceptions keep industry advertising to a minimum as they are supposed to be impartial to avoid conflict of interest when reporting studies that may conflict with the interests of a big advertiser.

Peer-reviewed journals are the platform we use to announce new discoveries, to comment on or criticize the discovery of others and to synthesize and seek to build consensus about what is known. In Oral and Maxillofacial Surgery, case reports and technical notes account for about one-third of journal publications, while less than one in ten are randomized control (Level 2 evidence) or non-randomized control (Level 3 evidence) studies (Table 45.2). Because of the difficulty in performing high-level randomized control trials in surgery, Surgeons are more accepting of lower-level evidence which is based on observation. Indeed, it is unlikely to extract any high-level evidence research from surgical departments who rely on surgical trainees for their research output.

Table 45.2 Levels of evidence (Oxford Centre for Evidence-Based Medicine)

Level 1: Randomized control trials (RCT)
High-quality, properly powered and conducted studies with reduced bias when double blinded and multicentred
Level 2: Cohort clinical studies
Prospective, comparative clinical study without randomization
Level 3: Case-controlled studies
Retrospective clinical study
Level 4: Case series studies
Cross-sectional study (clinical audit) with or without intervention
Level 5: Case-based reasoning
Includes case reports, expert opinions and bench research

Note: The strength of systematic reviews and meta-analysis depends on the evidence levels of the papers being reviewed. If all the papers are Level 3 evidence, the systematic review will also be Level 3 evidence

Table 45.3 Factors to consider in the design of a clinical study

1. Where is the study being conducted? (field, hospital, clinic, laboratory, etc.)
2. Are there ethical issues? (animal or human studies)
3. Define your study groups or variables being investigated
4. Selection criteria (inclusion/exclusion)
5. Are there matched controls?
6. Describe the surgical or technical details
7. Method of data collection (randomized or blinded)
8. Method of data handling (statistical method)

Table 45.4 Criteria for a good surgical manuscript

1. Short, succinct title
2. Original ideas with practical or pragmatic applications
3. Clear purpose/aim(s)
4. Good grammar—clear and concise wording/short sentences
5. Methods described in adequate detail to allow independent verification
6. Results set out in clearly labelled tables, graphs, figures, photos, diagrams
7. Focused discussion with balanced literature that both support and refute results
8. The most recent references that adequately support discussion
9. Conclusion supported by the results of the study

Table 45.5 Anatomy of a poor surgical manuscript

1. Long, convoluted and ambiguous title
2. Wild, unusual, unethical or dangerous ideas of little practical value
3. No clear aims or purpose stated
4. Plagiarism and duplication (study previously published elsewhere under different title)
5. Poor grammar—incorrect wording/long convoluted sentences/ emotive language
6. Methods inadequately or poorly described that cannot be repeated
7. No data, tables, figures, graphs, photos or diagrams provided
8. Convoluted discussion without clear direction and biased to supportive literature
9. Old or antiquated references
10. Conclusion not supported by the results of the study

All journals subscribe to the IMRD layout which means all submissions must have an Introduction, Methods, Results and Discussion sections. The introduction builds the case for why you pursued the line of research and the final sentence is always the statement of the aim(s) of your study. The Methods section describes how the study was performed in terms of setting (e.g. Hospital or Laboratory), subjects (i.e. animals or humans), recruitment (e.g. inclusion/exclusion criteria), data collection (e.g. Surveys, measurements), variables being compared (experimental vs. control) and data analysis (statistics used) (Table 45.3). The Results section simply states the summary of the outcomes as depicted in the tables and graphs, while the Discussion critically analyses and compares the results in light of what has already been previously published on the topic. The discussion must include references that both agree and disagree with your findings so that a balanced argument can be presented which will add weight to the study.

Table 45.6 Guidelines for formatting papers for publication

1.	Randomized control studies:	www.consort-statement.org
2.	Observational studies:	www.strobe-statement.org
3.	Systematic reviews:	www.prisma-statement.org
4.	Case series:	www.processguideline.com
5.	Case reports:	www.scareguideline.com

The final paragraph in the discussion is a summary of the research results with mention of any practical clinical applications that may arise from the study.

Authors must keep in mind that originality and a clear message are essential in getting their papers published in the highly competitive world of scientific journal publishing (Table 45.4). The high impact factor journals generally attract articles with high evidence levels so it is imperative to select a journal that caters to the subject and evidence levels of your particular study to avoid rejection and delays in publication of your paper. Original contributions that add new information to the existing body of knowledge are more likely to be considered for publication. However, wild or fanciful ideas are unlikely to garner support from journal editors who are looking for papers that lend respectability to their journal.

Unlike works of fiction, good scientific communication is based on clear and concise wording with short titles and tightly controlled sentences that describe complex ideas in the simplest language possible. Poor grammar, emotive language and long-winded descriptive wording must be avoided so that the ideas being conveyed are not buried in a convoluted tangle of discourse (Table 45.5). When evaluating the importance and relevance of published articles, surgeons and scientists look for the facts, not fancy prose.

To improve the acceptability of your paper for publication in a peer-reviewed journal, there are general guidelines available online that help you set out your paper in a format that is recognized and accepted throughout the world (Table 45.6). By following the guidelines, you improve the chances of your paper being accepted for publication. For instance, if you want to submit an observational case cohort study, then the "STROBE" statement will guide you in how to properly format your paper. If it is a case report then it is worth checking out the "SCARE" guidelines. Alternatively, if you want to undertake a systematic review of a topic, the "PRISMA" statement is essential.

45.6 Conclusion

In Surgery there is no greater accomplishment than being the first to successfully implement a successful treatment that changes the history of medicine. However, the person with the first idea is usually not the one recognized by history. Credit often goes to the person who convinces the world, not to the one with the original idea, because the credibility of all new ideas requires convincing evidence. If you make a claim about something, you provide the evidence, or at least a reference to the evidence that backs your claim. Research is the essential tool that builds the evidence which provides a better understanding of how and why things worked or failed. Good surgical practice must be based on evidence.

Surgical innovation is a constant work in progress because any new ideas or techniques are quickly supplanted by an even better ideas and techniques. Gaps in the literature are what fuel research, and the journey of discovery is paved with potholes that need to be filled. To paraphrase the great scientist Sir Isaac Newton, if you want to see further than anyone else has seen before, you need to stand on the shoulders of giants. Your voyage of discovery begins once you have secured your footing on the shoulders of the surgeons and scientists who have gone before you, so you can see the path they have built for you to follow.

Salivary Gland Pathologies

46 Salivary Gland Pathologies

Nisheet Anant Agni

46.1 Introduction

The salivary glands secrete saliva which has lubricating, immunologic, digestive, and cleansing functions. They are affected by systemic and local inflammatory conditions, obstructive pathologies, as well as neoplasms. Most of the tumors are parenchymal in origin, whereas few could be interstitial. Majority of tumors affecting major glands are benign, but those affecting minor salivary glands are more often than not, malignant. The disorders that involve these glands can either be acute or chronic inflammatory lesions, congenital abnormalities, systemic disorders, or benign and malignant tumors. However the most, common disorders affecting salivary glands are tumors and infections.

46.2 Surgical Anatomy

46.2.1 Parotid Gland

The gland lies in the retromandibular fossa bound medially by the styloid process and superiorly by external acoustic meatus and mastoid process, and it touches the medial pterygoid muscle and mandibular ramus (Fig. 46.1). A part of the gland may also cover the TMJ in front of the ear but never extends beyond the zygomatic arch. The parotid capsule is a dense, adherent fibrous condensation of deep cervical fascia which is tough and unyielding. Hence parotid space infections show minimal swelling but are severely painful. Incision and drainage is needed early on, without a frank fluctuant abscess to relieve the pressure within the capsule to prevent pressure necrosis of the parenchyma. Due to weakness in the capsule covering the deep surface of the gland, parotid abscess may spread into the lateral pharyngeal space, if not drained promptly [1]. Benign tumors grow slowly and hence take a longer time to manifest as external bulges. Parotid gland has a superficial lobe (80%) and a deep lobe (20%) connected by an isthmus with the facial nerve passing between the two lobes.

The facial nerve is related to the parotid gland in a number of ways [2].

1. (a) Superficial and deep lobes are united above, so that the gland is essentially folded over the nerve.
   (b) An isthmus uniting the two lobes.
   (c) Combination of (a) and (b)
2. The gland and nerve can also lie intertwined within superficial and deep lobes; relation will vary according to plane of section.

The intratemporal and intraparotid facial nerve has varied pattern of branching which is of immense surgical importance and might show bifurcation and trifurcation of the main trunk within the mastoid segment (Fig. 46.2). This intratemporal division of the facial nerve is associated with congenital abnormalities of the pinna or inner ear (Table 46.1).

Parotid duct or the Stensen's duct crosses the masseter about a finger breadth below the zygomatic arch. It then takes a sharp turn medially at the anterior border of the masseter further traversing through the buccal fat pad and buccinator muscle. It then runs obliquely between the buccinator and oral mucosa to open on the parotid papilla, opposite the second maxillary molar. The obliquity of the duct in between the buccinator and mucosa acts like a valve to prevent inflation of the duct while blowing air. The duct lies between the upper and lower buccal branches of the facial nerve. Its caliber is about 3 mm, but at the point where it penetrates the buccinator muscle, an isthmus narrows down the duct to 1.2 mm, and at the orifice (ostium), it is 0.5 mm.

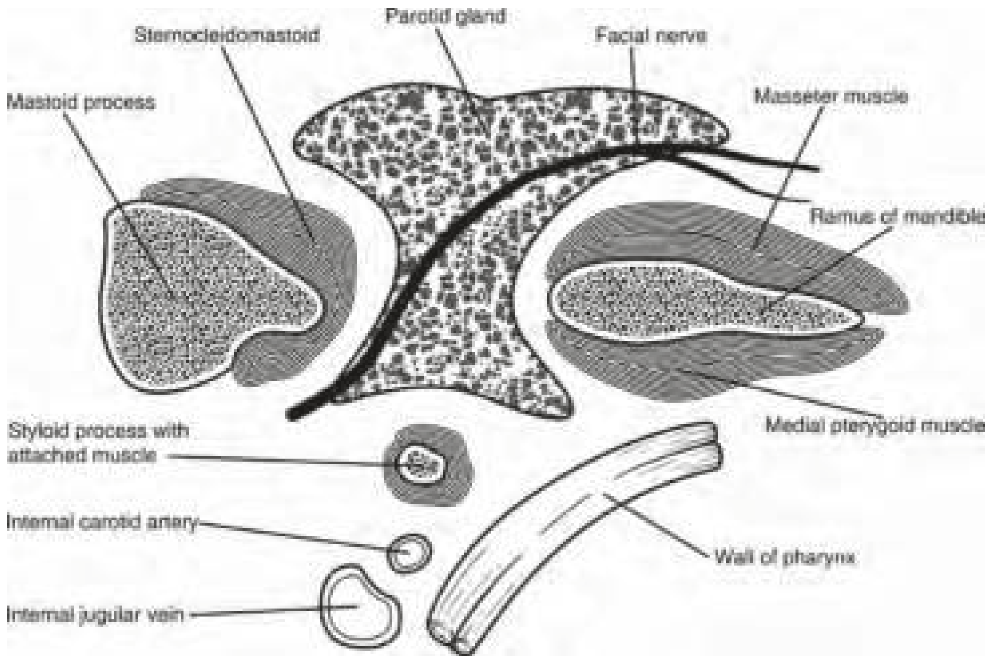

Fig. 46.1 Transverse section of parotid gland

Structures traversing the parotid gland from lateral to medial (superficial to deep) include the facial nerve, retromandibular vein, and external carotid artery. Few parotid lymph nodes are also present within the gland.

Parasympathetic secretomotor fibers from the inferior salivary nucleus of the ninth cranial nerve supply the gland. Nerve fibers pass to the otic ganglion via the tympanic branch of the glossopharyngeal nerve and the lesser petrosal nerve. Postganglionic parasympathetic fibers reach the parotid gland via the auriculotemporal nerve, which lies in contact with the deep surface of the gland. Postganglionic sympathetic fibers reach the gland as a plexus of nerves around the external carotid artery [4].

46.2.1.1 Identification of the Facial Nerve [5, 6]

The facial nerve identification can be done either proximally or distally. Proximally the main trunk of the nerve is identified before it enters the gland. Distally it is identified as branches after the nerve leaves the gland (Table 46.2).

There are four facial nerve pointers at the stylomastoid foramen. However more techniques have been added later on by various authors. They are as follows:

1. The cartilaginous pointer of Conley (1978) is created at its anterior inferior border and is the least reliable one. The backward pull on the cartilage causes the meatus to assume the shape of a horn, the curved extremity of which allegedly points to the position of the facial nerve. The nerve is located medial and inferior to the pointer (Fig. 46.3).
2. A short segment of the facial nerve lies in between the stylomastoid foramen and parotid gland and is an ideal location to identify it. It can be located in the tympanomastoid sulcus which is formed by the edge of the bony external meatus and anterior face of the mastoid process. The nerve emerges from the stylomastoid foramen some 3–4 mm deep to the outer edge of the bony external canal. The tympanomastoid sulcus is filled with fibrofatty lobules that mimic the facial nerve trunk which may lie as deep as 1 cm to this landmark.
3. The anterior superior aspect of the posterior belly of the digastric muscle is inserted just behind the stylomastoid foramen. The posterior belly of the digastric muscle lies just inferior to the nerve and is the most reliable landmark to identify the nerve (Fig. 46.4).
4. The styloid process is a confirmatory landmark. The facial nerve lies lateral to the styloid process near the styloid base. The posterior auricular artery bleeds frequently while looking for the facial nerve since it lies below and just lateral to the nerve, and hence it cannot be relied upon for identification of the nerve.
5. Borle's triangle has been recently introduced to locate the facial nerve trunk. Lines are drawn from the tip of the mastoid process, running along the superior border of the posterior belly of digastric muscle and posterior border of the ramus of the mandible. These two lines intersect with each other anteriorly, forming the apex of the triangle (angle a). The base of the triangle is marked by drawing the third line starting from the tip of the mastoid process (angle b), running anteriorly till it joins

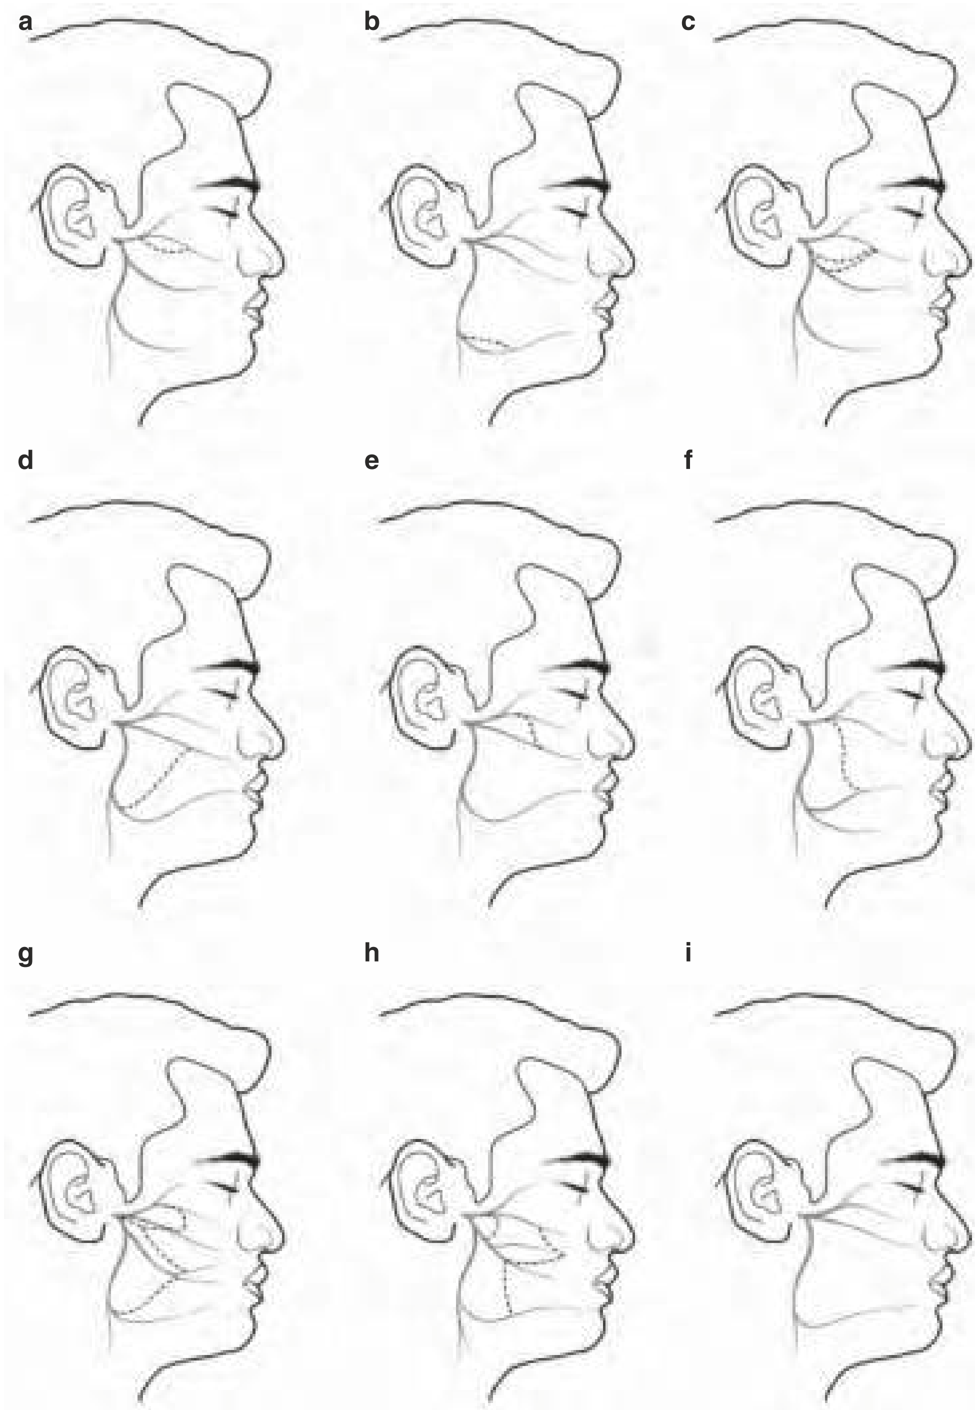

Fig. 46.2 (**a**)–(**i**) Katz-Catalano classification based on operative findings

Table 46.1 Katz-Catalano classification

Type 1	25%	Branches are separate
Type 2	14%	Buccal branch fuses with zygomatic branch
Type 3	44%	Major communicating, buccal, and other branches
Type 4	14%	Complex branching between all branches
Type 5	3%	More than one major trunk

Katz and Catalano [3], 1987

Table 46.2 Facial nerve identification

1	Anterograde approach—Direct identification of main trunk at stylomastoid foramen
2	Retrograde approach—Early identification of mandibular branch over posterior facial vein or other branches along the parotid duct
3	Supravital staining of parotid—gland is stained blue, tumor is unstained, and facial nerve is gleaming white

Fig. 46.3 Showing relation of cartilaginous pointer and facial nerve main trunk

Fig. 46.4 Showing relation of the posterior belly of the digastric muscle and main trunk of the facial nerve (muscle pointed by mosquito forceps)

the second drawn line along the posterior border of the ramus (angle c). The facial nerve trunk is often found within this triangle just above the angle b formed by the first and the third line if gentle and blunt dissection is carried out at this point. The mean distance of nerve trunk from the angle b is 12.18 ± 2 mm within a range of 9–15 mm [7] [Fig. 46.5—https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6126203/. doi: https://doi.org/10.1016/j.jobcr.2018.08.004. *(open access)*].

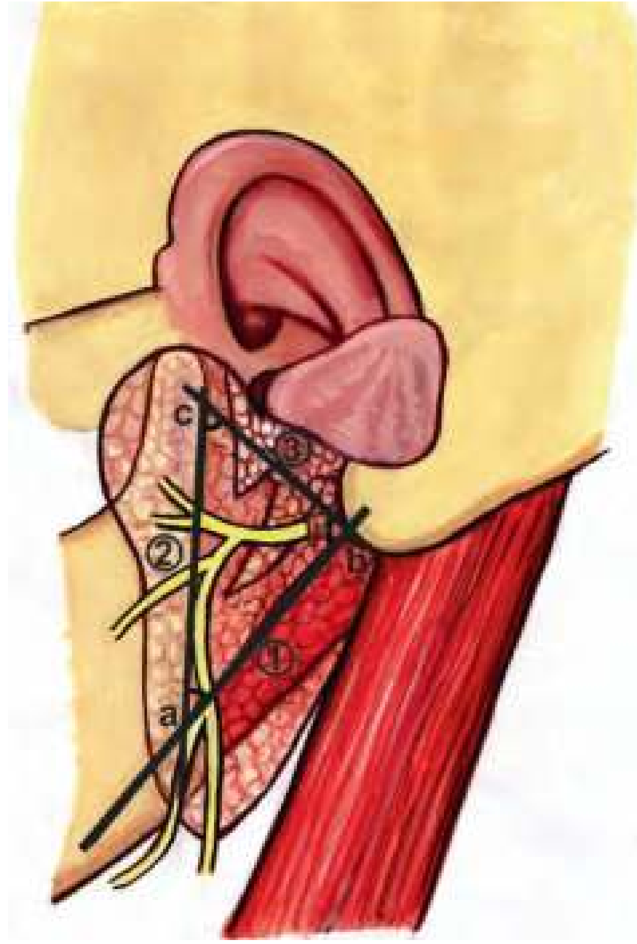

Fig. 46.5 Borle's triangle. *Line 1: Started from mastoid process tip and running along the superior border of posterior belly of the digastric muscle. Line 2: At the posterior border of ramus of the mandible. Line 3: Starts from the tip of the mastoid process running anteriorly till it joins the second line. Angle a: Lines 1 and 2 intersect with each other forming the apex of triangle. Angle b: Is the base of the triangle. Angle c: Is the angle where third line meets second line*

When identification of facial nerve trunk is difficult using the above said pointers due to distorted anatomy due to the tumor, a retrograde approach can be used by identifying a peripheral branch of the nerve and tracing it proximally. The easiest branch to locate is the marginal mandibular nerve. Baker et al. have reported that the marginal mandibular nerve is located 1–2 cm below the inferior border of the mandible. The marginal mandibular branch can be used to trace the facial nerve in a retrograde direction by identifying it at the point of emergence of the retromandibular vein and then carrying out a proximal dissection. By working backward along the nerve, the two divisions, the other branches, and the main trunk can be found [8].

Figure 46.6 represents the average distance of facial nerve pointers from the surrounding landmarks (Table 46.3).

Intraoperative facial nerve monitoring using electromyographic techniques can also be used for identification of the main branch or the peripheral branches in centripetal or retrograde approach. In pediatric population the facial nerve trunk

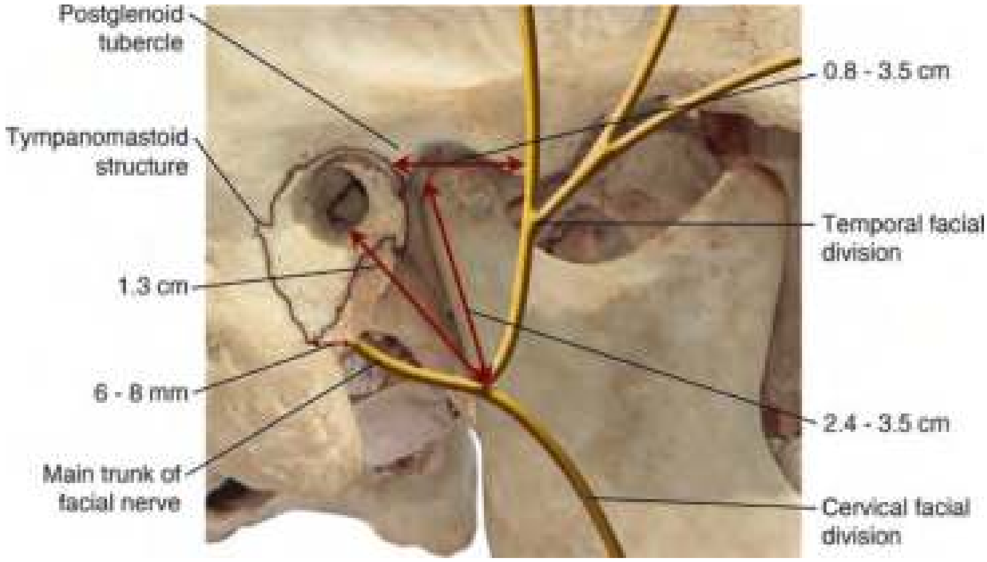

Fig. 46.6 Distance from facial nerve pointers

Table 46.3 Distance of the facial nerve pointers from the surrounding landmarks [10]

Sr. no.	Pointer	Distance in mm	Mean in mm
1	Tragal pointer	24.3–49.2	34
2	Posterior belly of the digastric muscle	9.7–24.3	14.6
3	External auditory canal	7.3–21.9	13.4
4	Tympanomastoid suture	4.9–18.6	10.0
5	Styloid process	4.3–18.6	9.7
6	Transverse process of axis	9.7–36.8	16.9
7	Angle of the mandible	25.3–48.69	38.1

exits the stylomastoid foramen and is found approximately 1 cm anterior to mastoid process and 1.5 cm posterior to the ramus of the mandible. The parotid does not extend posterior to the ramus of the mandible in the newborn infant and consequently covers only the lower distal branches of the nerve [9].

46.2.1.2 Facial Nerve Monitoring

There are two types of facial nerve monitoring:

- Electromyography
- Pressure or strain gauge sensor

Facial nerve monitoring is performed with a nerve stimulator which can either be monopolar or bipolar. The monopolar stimulator is more useful for identifying the nerve, while the bipolar is more useful if the nerve course is evident. However, a bipolar stimulator is more precise.

46.2.2 Submandibular Glands

It is a U-shaped gland with a smaller deep lobe and larger superficial lobe enveloping the mylohyoid muscle. Hence during surgical removal, the mylohyoid has to be retracted anteriorly to expose the deep lobe and the Wharton's duct. The capsule is loosely attached to the gland substance, and hence the gland can be shelled out easily.

Since the submandibular group of lymph nodes are in contact with the gland or embedded in it, it is essential to clear the nodes along with the gland during a neck dissection.

The facial artery loops around the submandibular gland. The facial artery is visualized by retracting the posterior belly of the digastric muscle inferiorly. Hence, during excision of the submandibular gland, the facial artery and vein were customarily ligated. However, during neck dissection, the current standard is to try and save it so that it can be used for anastomosis during a free flap reconstruction.

The facial artery is ligated away from the external carotid artery, so that in case the vessel retracts into the tissue, it can be located and religated and bleeding can be controlled. In case the ligature slips and the facial artery retracts, the posterior belly of the digastric muscle is divided for easy location of the bleeding vessel.

The lingual nerve passes below the duct and forms a loop around its outer aspect before inserting into the tongue mucosa. It is at risk when the deep part of the gland is being mobilized. The submandibular duct or Warton's duct is longer and has a tortous, uphill course. Thus the secretions have to be emptied against gravity, and there are increased chances of retention. Also, the mineral content of the secretion is high, especially calcium content which along with increased retention of secretions results into higher incidence of calculus formation and inflammatory pathologies in the submandibular gland and duct.

Figure 46.7a, b shows the relations of the submandibular gland.

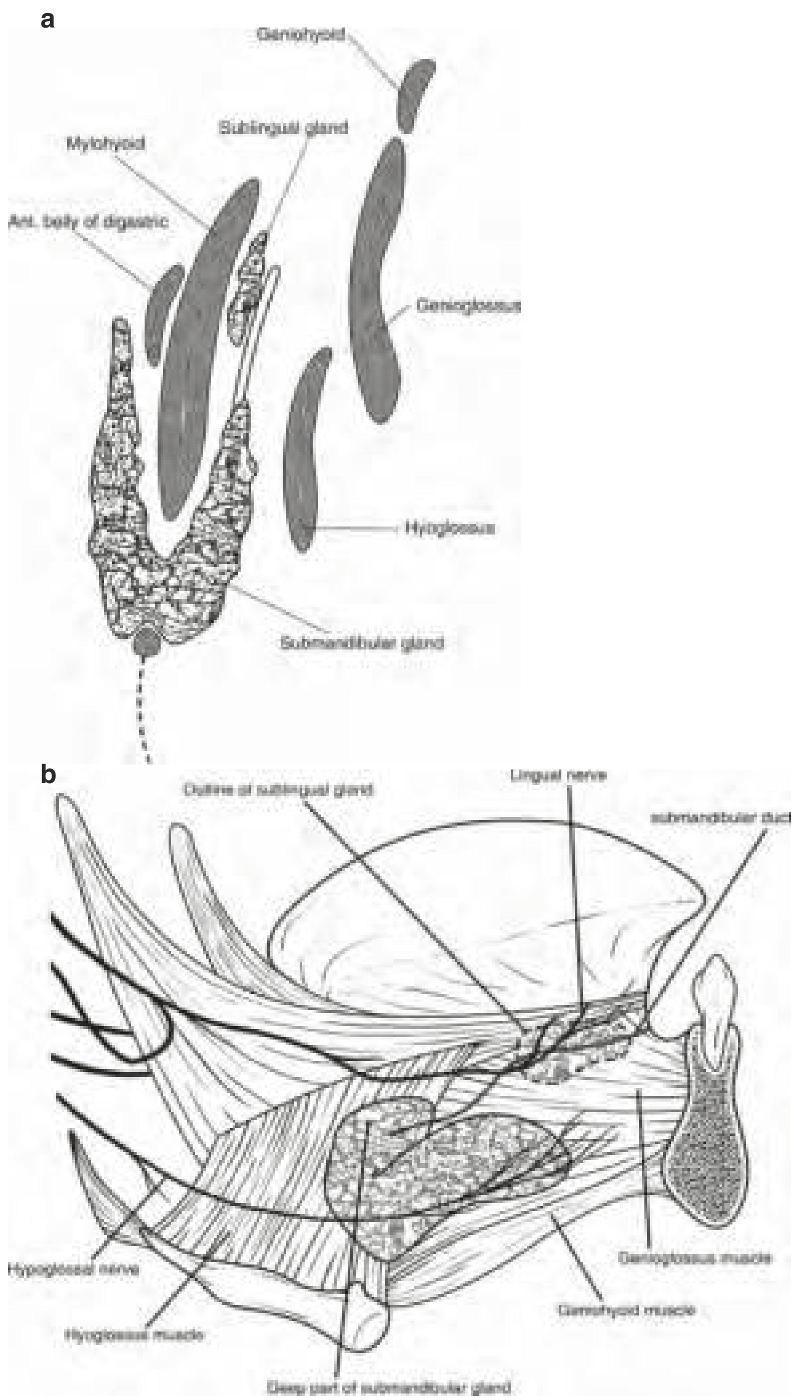

Fig. 46.7 (**a**, **b**) Relations of submandibular gland

46.2.3 Sublingual Glands

They are located beneath the mucosa of the floor of the mouth and appear as an elevation in the floor of the mouth. The excretory ducts of the sublingual glands are very superficially located and open in the floor of mouth at a superior level than the gland. Hence, they easily get damaged, and any trauma or infection of the ducts leads to salivary retention and formation of a mucous retention cyst which is called "ranula" due to its bluish color resembling the belly of a frog. The international statistical classification of diseases and related health problems shown in Table 46.4.

Table 46.4 International statistical classification of diseases and related health problems

K 11	Diseases of salivary glands
K 11.0	Atrophy of the salivary gland
K 11.1	Hypertrophy of the salivary gland
K 11.2	Sialadenitis
	Excludes epidemic parotitis and uveoparotid fever
K 11.3	Abscess of the salivary gland
K 11.4	Fistula of the salivary gland
	Excludes congenital fistula of the salivary gland
K 11.5	Sialolithiasis
	Calculus/stone of salivary gland or duct
K 11.6	Mucocele
	Mucous extravasation cyst/retention cyst
	Ranula
K 11.7	Disturbances of salivary secretion
	Hypoptyalism Ptyalism Xerostomia
	Excludes dry mouth NOS
K 11.8	Other diseases of the salivary glands
	Benign lymphoepithelial lesion of the salivary gland Mikulicz' disease Necrotizing sialometaplasia Sialectasia
	Stenosis/strictures of salivary ducts
	Excludes Sicca syndrome (Sjögren's syndrome)
K 11.9	Diseases of the salivary glands unspecified
	Sialoadenopathy NOS

10th Revision (Version for 2003) [11]

46.3 Diagnosis and Diagnostic Aids

A thorough history followed by meticulous examination holds the key to proper diagnosis of salivary gland pathologies. Salivary gland neoplasms are usually slow growing and non-tender. A slow-growing swelling of the salivary gland is suggestive of a neoplasm, whereas a sudden, painful swelling is suggestive of an infective pathology although it can sometimes indicate a malignant tumor with secondary infection. Nerve weakness and skin infiltration are always associated with malignant tumors which have already infiltrated the nerve or skin although the vice versa is not always true.

Major salivary glands are palpated, and secretions milked out to check flow, quantity, and quality of secretion. A turbid salivary discharge may indicate an infection, whereas reduced salivary flow could indicate either less secretion or obstruction to flow. Function of facial nerve should be checked and documented during parotid examination. On inspection submandibular gland swelling can be easily identified and compared with the contralateral side; however the submandibular glands are bimanually palpated (Figs. 46.8 and 46.9).

Fig. 46.8 Clinical photo showing submandibular gland enlargement, right side

Fig. 46.9 Bimanual palpation

Various diagnostic aids for investigating salivary gland diseases are as follows:

1. Diagnostic imaging
   (a) Routine radiographs: It is useful only for diagnosing sialoliths and parenchymal calcifications. Radiopaque salivary calculi in the gland or duct can be picked up on plain films such as occlusal X-ray for submandibular gland and duct and a posteroanterior (PA) skull with blown-out cheeks for parotid calculi.

(b) Ultrasonography: Ultrasonography (USG) is a noninvasive modality that utilizes non-ionizing radiation, gives good soft tissue discrimination, has excellent sensitivity for mass lesions, and can be repeated as frequently as required. Normal gland is relatively homogenously hyperechoic than adjacent muscle, and so is cyst and tumor from parenchyma [12, 13]. It helps to distinguish a cystic lesion from a solid mass in space-occupying lesion (Fig. 46.10). USG with color Doppler is useful to rule out vascular lesions and also aids in assessing vascularity of lesions.

(c) Sialography: It assesses obstructive pathology by instillation of radiopaque contrast medium to locate obstruction in the ductal system. The technique is more or less obsolete now with the advent of MRI imaging. It is a technique which involves injection of a radiopaque dye into the ductal system of the major salivary glands and taking plain X-rays to see the pattern of the dye into the ductal systems. Most commonly the contrast dyes used are iodine based. They can either be lyophilic (oil based) or aqueous (water based or water soluble). Lyophilic (oil-based) contrast dyes include Lipiodol (iodized poppy seed oil) and Pantopaque (organic iodine compound). Aqueous contrast dyes include iothalamate (Conray) and metrizoate (Triosil). Aqueous-based dyes are most commonly preferred. Sialography is indicated to diagnose obstructive pathologies and duct anomalies, degenerative changes in the gland, chronic inflammatory conditions, and intra- and extraglandular tumors. It is contraindicated in acute infections of the gland and in case of allergies to the dye.

Fig. 46.10 USG of submandibular gland

Procedure: The duct orifice is enlarged using a lacrimal probe and cannulated with a 22 gauge cannula after infiltrating local anesthetic (Fig. 46.11a, b). The selected dye is injected into the ductal system using a Luer lock syringe with gentle continuous pressure with simultaneous massage of the gland. Once the patient feels some discomfort, dye injection is stopped. X-rays are taken during the filling phase and emptying phase as well.

The X-rays show different patterns:

(i) The normal parotid gland shows “tree in winter” or “leafless tree” pattern, and submandibular gland shows “bush in winter” appearance. This is because the normal acini do not allow dye to enter and it is seen only in the ducts and ductules (Fig. 46.12—normal sialography: leafless tree).
(ii) In chronic inflammation the dye enters the ductules, and the empty acini give a “blossom tree” or “leafy tree” appearance.
(iii) Sjögren’s syndrome and Mikulicz’ disease show a “snow storm” or “branchless fruit-laden” appearance.
(iv) Stricture in a duct is seen as a filling defect, whereas multiple strictures show a sausage string appearance.
(v) “Cannon ball” appearance is seen in intraglandular tumors, whereas extraglandular tumors show a “ball in hand” appearance.
(vi) Duct perforation and sialocele show dye spillage in the soft tissues.

(d) Radionucleotide scanning: It is used to distinguish between obstructive and nonobstructive sialadenitis. It involves both dynamic and static scanning. Radionuclide scanning is useful when a sialogram is contraindicated to distinguish between acute obstructive and nonobstructive sialadenitis [14].

(e) CT scan: It is used to evaluate masses in parotid glands and surrounding structures as it gives excellent soft tissue details (Fig. 46.13) especially when used with a contrast dye. Bony changes in the course of facial nerve like erosions, sclerotic margins, and widening of stylomastoid foramen or fallopian canal suggest involvement of nerve. Plain computed tomography (CT) scans have a major role to play for diagnosis of obstructive pathologies like a calculus.

(f) MRI scan: It allows assessment of salivary masses and early diagnosis of perineural spread due to excellent soft tissue contrast. In the case of neoplasms, it helps in demonstrating involvement of the facial nerve (Fig. 46.14).

(g) Arteriography: It assesses the vascularity and source of vascular supply of the tumors.

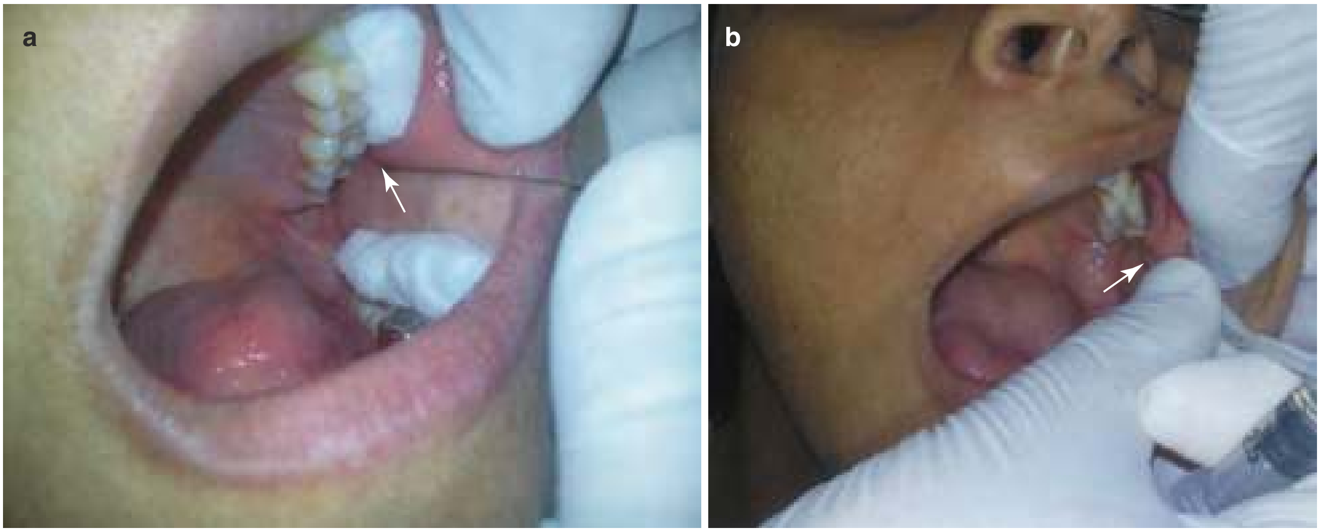

Fig. 46.11 (**a**, **b**) Sialography technique

Fig. 46.12 Normal parotid gland in sialography

Fig. 46.13 CT scan showing parotid tumor

(h) Positron emission tomography (PET): Uptake of radiotracer fluorodeoxyglucose used with PET scans by salivary glands makes this diagnostic technique useful for salivary gland tumors. Although this is an expensive technique, measurement of metabolic activity makes it more reliable than CT and MRI scans. It can be used to diagnose recurrences, tumor hypoxia, and proliferation rates [15].

2. Histopathology: The gold standard of diagnosis for neoplasms will always be histopathology (HPE). However, as the major salivary glands are deeper structures, an FNAC (fine-needle aspiration cytology) is considered as a standard of care for diagnosis to avoid tumor seeding, which might follow an open biopsy. An open biopsy can be considered for minor salivary gland tumors or malignant tumors affecting major salivary glands with skin infiltration, needing skin excision to achieve surgical clearance. HPE for salivary gland

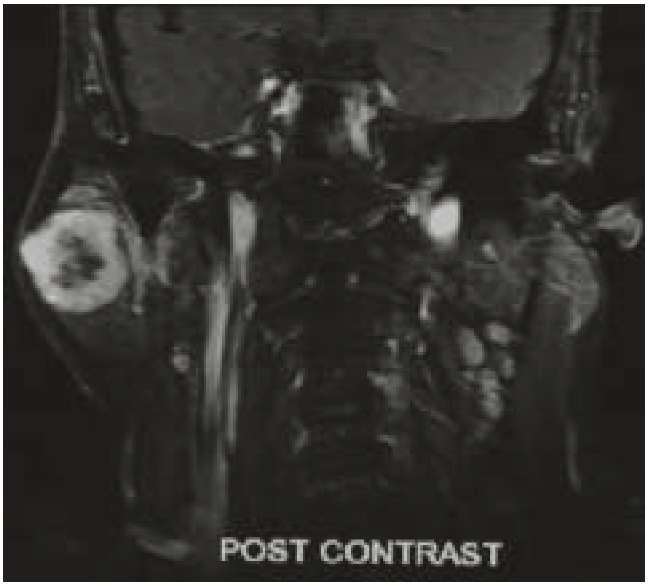

Fig. 46.14 MRI showing parotid tumor, right side

pathologies is very challenging, and hence diagnosing lesions on FNAC is more difficult. It is important to distinguish benign and malignant pathologies on FNAC even if the exact malignant variant is missed, because except adenoid cystic carcinoma which has perineurial spread, the surgery doesn't change for any other malignant tumor variant.

(a) Fine-needle aspiration cytopathology (FNAC): It shows high diagnostic accuracy both for benign and malignant tumors. Complete histological features and status of invasion can't be revealed by this technique.

(b) Incisional biopsy: It is not a reliable technique as there is high possibility of seeding of tumor cells as well as fungation through skin.

3. Frozen sections: These help in diagnosing the nature of tumor, but accurate histopathologic features can't be diagnosed.

46.4 Non-neoplastic Diseases (Table 46.5)

46.4.1 Acute Bacterial Sialadenitis

Parotitis (Fig. 46.15) occurs secondary to decreased salivary secretions, and various reasons are attributed.

Table 46.5 Important terminologies in relation to salivary gland diseases

Sialadenitis: Sialadenitis is inflammation of the gland parenchyma. It could either be suppurative (with pus) or nonsuppurative (without pus). It can also be classified as acute, subacute, or chronic.
Sialodochitis: This refers to inflammation of the salivary gland duct. It may be associated with duct strictures and/or sialoliths.
Sialectasis: This refers to cystic dilatation of the ducts due to either a sialolith or ductal strictures. It is most commonly seen in parotid gland infections. It can occur due to any condition causing chronic inflammation of the gland.
Sialorrhea: This refers to excessive secretion of saliva or drooling of saliva. It is most commonly seen in patients with cerebral palsy and neuro-degenerative disorders.
Sialosis: It is defined as an asymptomatic, non-neoplastic, non-inflammatory parenchymal salivary gland disease which manifests as persistent painless bilateral salivary gland swelling, most commonly involving the parotid gland [16].
Sialodochoplasty: It is repair of the salivary gland duct usually by translocating the ductal opening.

Fig. 46.15 Parotitis left side

The common etiologic factors for parotitis are reduced salivary flow due to severe dehydration, in patients with debilitating diseases, old age, post-operative patients, post radiotherapy for head and neck cancers, poor oral hygiene leading to recurrent infection, mechanical obstruction to flow, compromised host resistance due to systemic illnesses like Diabetes Mellitus, renal failure, HIV, post transplant immunosuppresants. The drugs which induce systemic dehydration such as antihypertensives, diuretics, tricyclic antidepressants , phenothiazines, barbiturates, anticholinergics and betablockers also lead to reduced salivary flow rate [17].

Fig. 46.16 Submandibular sialadenitis left side

It may be retrograde contamination of salivary ducts and parenchymal tissues by oral microflora providing a bacterial source of infection. Stasis of salivary flow through the ducts and parenchyma may also promote acute suppurative infection. There is a higher risk of sialolith in the submandibular duct causing secondary suppurative sialadenitis (Fig. 46.16 showing submandibular sialadenitis).

46.4.1.1 Clinical Features

- Sudden onset of pain and swelling, exacerbates with food sighting or smelling
- Generalized malaise, fever, body ache, and sometimes signs of dehydration.
- Diffuse inflammatory swelling, induration, erythema, edema, and extreme tenderness over the affected gland.
- Tense, glossy, and erythematous skin.
- Raised ear lobule is pathognomonic sign of parotid swelling.
- The duct orifices are inflamed, and milking of gland may exhibit lesser salivation or purulence.
- Systemic sepsis occurs more commonly in parotid sialadenitis as compared to submandibular sialadenitis.
- Parotid swellings are not fluctuant due to fixity of overlying investing parotideomasseteric fascia and are extremely painful due to the mounting pressure as the fascia is nonyielding. This mounting pressure leads to ischemic necrosis of the gland, and the abscess may spontaneously burst in the external auditory canal.

Routine blood count to rule out impending sepsis in addition to a plain radiograph or USG to rule out a sialolith in the duct is indicated. Sialography is contraindicated in cases of acute infections and also sialoliths. Aspiration might not yield frank pus.

46.4.1.2 Management

Treatment is managing underlying cause and adequate hydration and systemic antibiotics. If swelling doesn't subside with medical management in 2 days or shows an increasing trend, an incision and drainage is indicated. The cellulitic phase may not yield any frank pus, but toxic fluid is drained and it releases the pressure over the gland and prevents pressure necrosis of the gland parenchyma. Parotid space abscess has the tendency to spread into the pharyngeal spaces and cause respiratory distress and descending mediastinitis or burst into the auditory canal or TMJ and cause septic arthritis of the TMJ.

46.4.2 Chronic Bacterial Sialadenitis [18]

It is a recurrent sialadenitis with episodic relapsing swellings of the salivary glands, most commonly seen in the parotid gland. Salivary retention and stasis are the main predisposing factor. It might be preceded by an acute sialadenitis. Strictures may also form in the ducts leading to salivary stasis and eventually chronic sialadenitis. Generalized constitutional symptoms may be low grade, and salivary gland milking may yield scanty saliva. MRI is more specific than CT scan.

46.4.2.1 Management

Management consists of short-term corticosteroids to eliminate glandular inflammation followed by use of sialogogues to increase salivation and flush the debris. Sialoendoscopy can play a role in increasing the salivary flow.

The sialoendoscope is advanced slowly into the duct with continuous saline irrigation to help visualize the system and also dilating the strictures with help of the sialoballoon. This is followed up by placing a stent into the duct for 4 weeks.

Superficial parotidectomy with facial nerve preservation can also be considered in case of chronic pain, provided imaging studies determine the involvement of superficial lobe.

Chronic recurrent parotitis if left untreated may lead to benign lymphoepithelial lesion which can progress to lymphoproliferative disorders like non-Hodgkin's lymphoma, carcinoma, or pseudolymphoma.

46.4.3 Obstructive Disorders (Video 46.1)

Sialolithiasis or salivary calculi are most commonly seen in the submandibular gland and duct (Fig. 46.17a, b). Symptomatic calculi are much lesser in occurrence. Only those cases with superadded infection and inflammation of the gland and duct result into pain.

46.4.3.1 Etiology

Salivary stasis is a major etiologic factor for formation of sialolith. The right-angle bend of the Stenson's duct where it pierces the buccinator and the 90° bend of the Wharton's duct at the border of the mylohyoid is the common location for sialoliths. They can also result from chronic sialadenitis. Systemic abnormalities of calcium metabolism are not associated with any increased risk of salivary stone formations. Gout is the only systemic illness known to predispose to salivary stone formation [19].

Salivary stasis changes the mucoid element of saliva to a gel framework for deposition of salts and organic substances creating a stone. Unknown metabolic phenomenon increases salivary bicarbonate content altering the calcium phosphate solubility and leading to precipitation of calcium and phosphate ions [20]. Wharton's duct is longer than the Stenson's duct, and the submandibular gland is situated at a lower level than the opening of the duct. Hence the duct has to follow an uphill, tortuous course and drain against gravity. So stagnation of secretions is more common than parotid gland.

In the submandibular gland, the calculus results in sialadenitis, whereas in the parotid gland, sialadenitis causes calculus formation. In the parotid gland, stones are most commonly located at the hilum or parenchyma, whereas submandibular sialoliths develop in the duct [21]. Sometimes typically the sialolith is expelled out of the gland through the duct and is seen at the duct orifice.

46.4.3.2 Diagnosis and Management

Sialography can be used for diagnosis of sialoliths but is contraindicated if the calculus is already diagnosed on plain radiographs. Smaller stones can be expelled out through the

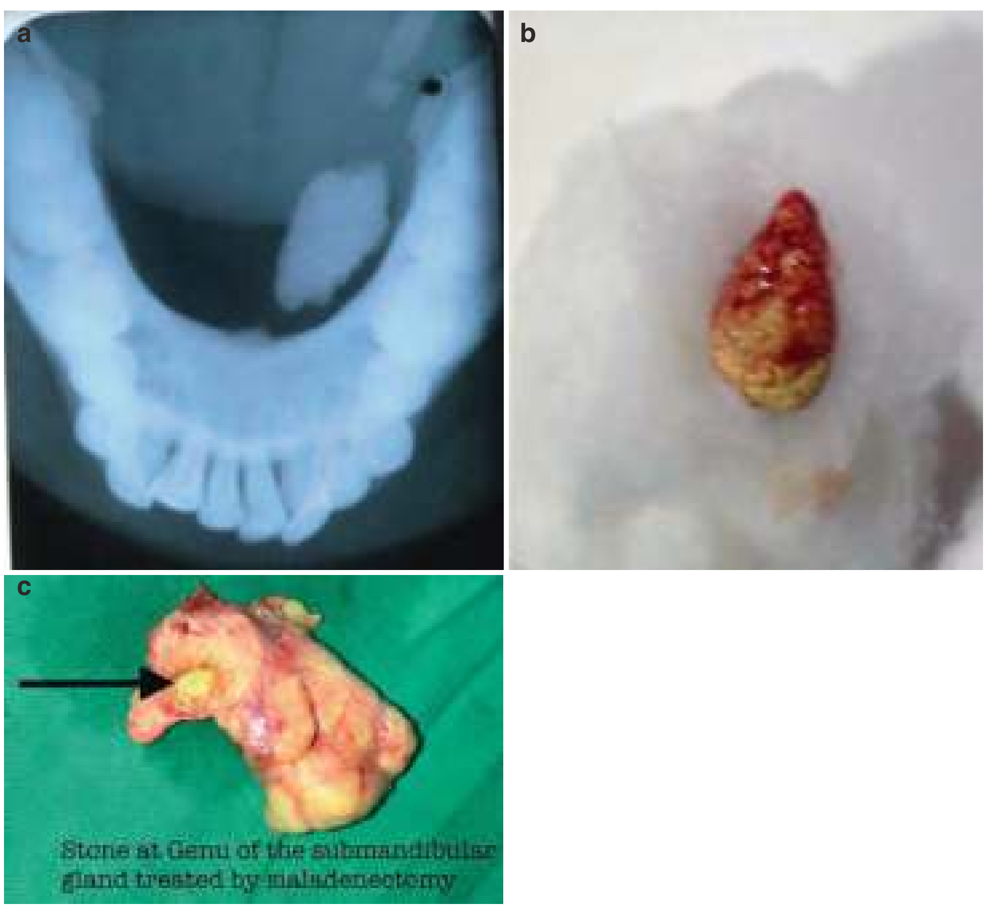

Fig. 46.17 (**a**, **b**) Left—Submandibular duct calculus (**a**). Right—Calculus after surgical removal (**b**). (**c**) Submandibular gland specimen showing calculus at the gene

duct opening using local massage, sialogogues, and adequate hydration. Larger stones are managed surgically according to its location in the duct and gland.

If the stone is palpable in the oral course of the duct, the duct is dilated with a lacrimal probe and cut open to retrieve the stone. The duct margins are sutured to the adjacent mucosa to avoid stricture formation. A stay suture can be placed around the duct proximal to the stone to avoid accidental pushing of the stone into deeper inaccessible part of the duct. In submandibular stones which are at the genu of the duct or deeper into the gland, a sialadenectomy is needed (Fig. 46.17c).

If the sialolith is posterior in the duct, a suture is placed behind the stone to prevent slippage of stone into the duct. The incision is placed over the duct to extract the stone, and the duct is left without suturing (Fig. 46.18a, b).

Sialodochoplasty is a procedure wherein the incised duct margins are sutured with adjacent mucosa leading to a translocation of duct orifice [22, 23].

In the case of parotid sialoliths, only those in the duct distal to the masseter muscle can be accessed transorally and removed. All deeper stones warrant a parotidectomy.

Extracorporeal shock wave lithotripsy and use of sialoendoscopy are newer modalities to manage sialoliths. Lithotripsy reduces calculi to small fragments that are then flushed out of the duct with spontaneous salivation or use of sialogogue [24]. The primary requirement for salivary stone lithotripsy is a functional gland which produces saliva which will clear the fragmented stone. A "gum test" which involves chewing of a sour gum can be done to test the functionality of the salivary gland. If the salivary secretions are normal, a visible swelling in the region of the gland will be noticed. If the test is negative, the patient cannot be taken up for lithotripsy.

46.5 Viral Infections of Salivary Glands

46.5.1 Mumps

Mumps is an acute nonsuppurative viral parotitis caused by paramyxovirus also known as epidemic parotitis. The term "mumps" is derived from the Danish word "Mompen" which means mumbling (like an old man) and describes the difficulty with speech because of inflammation and trismus [17].

46.5.1.1 Pathogenesis

It is an endemic disease and spreads by airborne droplet dissemination. It has an incubation of 2–3 weeks followed by 3–5-day viremia. The virus localizes to the salivary glands,

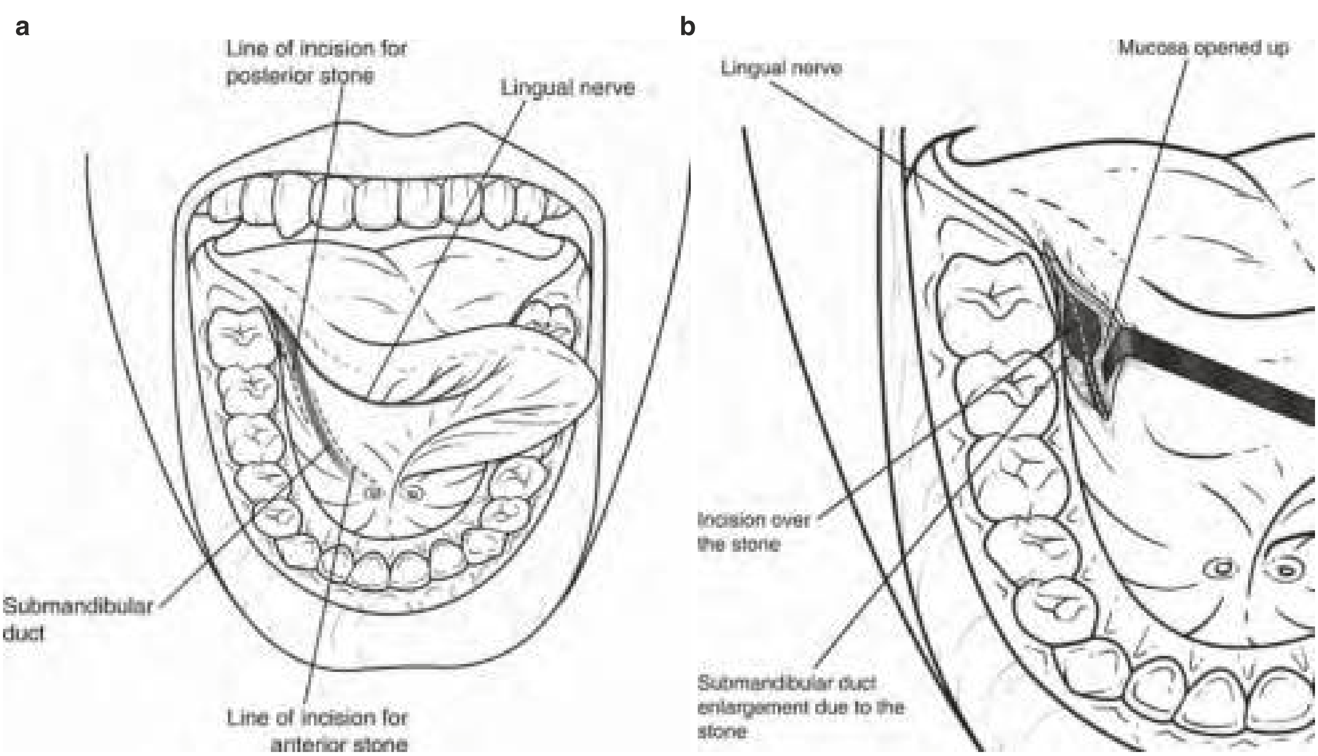

Fig. 46.18 (**a**, **b**) Technique of sialolith removal from submandibular duct

germinal tissues, and CNS [25]. The infection has a strong predilection for the parotid gland. It is highly contagious and occurs in children below 15 years of age with peak incidence being in the 4- to 6-year-old group of children [26]. Adults are rarely infected due to the immunity because of childhood exposure or due to the MMR vaccine [17].

46.5.1.2 Clinical Features

Prodromal symptoms include headache, myalgias, arthralgias, anorexia, and malaise prior to development of parotitis. It starts with an earache, pain around the gland, trismus, and dysphagia. Pain is exacerbated by salivary stimulation during meals. The parotid papilla may be inflamed and puffy. Palpation of the gland reveals a swelling of the gland which may be tense, rubbery, and firm with non-pitting-type edema. The overlying skin is tensed and shiny without erythema or increased local temperature. Swelling lasts for 1–5 days and can displace the pinna. Seventy-five percent cases result in bilateral involvement of parotid gland. However, it begins as a unilateral swelling and involves the contralateral gland after a period of 1–5 days [25].

Diagnosis is primarily clinical, but a blood count shows leukocytopenia with relative lymphocytosis. Serum amylase levels are also raised. It peaks during the first week and starts declining in the second or third week and comes back to normal later [25].

"S" or soluble antibodies directed against the nucleoprotein core of the virus appear within the first week of infection and peak within 2 weeks and disappear within 8–9 months. "V" or viral antibodies directed against the outer surface hemagglutinin appear several weeks after the "S" antibodies and persist at low levels for approximately 5 years following exposure. A fourfold rise in antibody titer is diagnostic of active infection. Mumps skin test is not useful in the diagnosis of acute infection because dermal hypersensitivity does not develop until 3 or 4 weeks following viral exposure.

46.5.1.3 Treatment

The disease is self-limiting, and treatment is primarily supportive such as rest, adequate hydration, antipyretics, and anti-inflammatory medicines.

Live attenuated Jerry Lynn vaccine is given combined with measles and rubella as MMR vaccine after 12 months of age. Immunized population is less likely to get the disease but may be infected with a nonparamyxovirus.

46.5.1.4 Complications

Orchitis and oophoritis can occur as systemic manifestations and rarely lead to complete sterility. Mastitis has been associated with decreased lactation. Aseptic meningitis occurs in 10% of cases, and asymptomatic meningeal inflammation is more common. Five percent patients are affected by acute pancreatitis, wherein serum lipase levels are also increased. Sensorineural hearing loss complicates 0.05–4% of patients and may be permanent and profound [26]. Tinnitus, aural fullness, and vertigo are associated symptoms, but they resolve over a period of few weeks. Additional complications include myocarditis, polyarthritis, hemolytic anemia, plasmacytosis, lymphocytic leukemoid reactions, and thrombocytopenia [12]. These conditions are self-limiting or resolve with or without steroid therapy.

46.5.2 HIV Parotitis

HIV-associated salivary gland disease is the term used to describe the diffuse enlargement of the salivary glands that affects HIV patients throughout all stages of the disease. In fact, HIV-SGD may be the first presenting sign of HIV. Like most of the salivary diseases, the parotid gland is the most frequently affected. Clinically, HIV-infected individuals show reduced salivary flow rates. Parotid gland enlargement is reported to occur in 1–10% of the HIV-infected population. It is usually secondary to development of benign lymphoepithelial cysts within the parotid gland [25].

46.5.2.1 Management

Antiretroviral therapy with zidovudine, maintenance of oral hygiene, and use of sialogogues form the mainstay of management.

46.6 Noninfectious Inflammatory Diseases

Mikulicz' disease and Sjögren's syndrome are closely related to each other and are autoimmune in origin, wherein the salivary tissue itself becomes antigenic [27].

46.6.1 Mikulicz' Disease

46.6.1.1 Clinical Features [28]

Middle-aged females are affected commonly. It behaves like an inflammatory as well as a neoplastic disease. Presenting symptoms may be diffuse, poorly outlined, unilateral or bilateral enlargement of the parotid or submandibular glands with an occasional increase or decrease in size of the swelling. There is mild local discomfort, occasional pain, and xerostomia. Fever, upper respiratory tract infection, tooth extraction, or some other local inflammatory disorder may precede the disease. Sometimes the lacrimal glands may be enlarged. FNAC can help diagnose the condition.

46.6.1.2 Management

Mild cases once diagnosed do not warrant any treatment. In some cases, the swelling might regress spontaneously. Persistent cases can be managed by sialadenectomy [28].

46.6.2 Sjögren's Syndrome

Sjögren's syndrome or Sicca syndrome is a chronic autoimmune disorder of the exocrine glands involving multiple extraglandular sites and can even evolve into a lymphoid malignancy. Sjögren's syndrome shows a triad of symptoms—keratoconjunctivitis sicca, xerostomia, and a systemic disease, usually but not always rheumatoid arthritis. Primary Sjögren's syndrome also known as Sicca complex presents with only dry eyes and dry mouth. Secondary Sjögren's syndrome has in addition to the above features systemic manifestations such as systemic lupus erythematosus, polyarteritis nodosa, polymyositis or scleroderma, and rheumatoid arthritis [28].

Arthritis is the most frequent first complaint, followed by ocular complaints and then xerostomia which leads to difficulty in chewing and swallowing, sore mouth, recurrent dental caries, and fungal infections in the oral cavity. The tongue appears bald with loss of filiform papillae and fissuring of tongue. The saliva is usually cloudy due to pus and abnormally viscous due to gel-like consistency. Parotid gland enlargement is seen in 25–66% cases of primary Sjögren's syndrome but is uncommon in secondary cases. Xeropthalmia leads to chronic irritation and destruction of the corneal and bulbar conjunctival epithelium, referred to as keratoconjunctivitis sicca. The patient complains of redness, itchiness, or burning sensation in the eye, rope-like secretions, dryness, and a foreign body sensation in the eye and may not be able to tolerate smoke, air draft, or light [27].

Schirmer's test is used to confirm lacrimal secretions. Patients complain of easy fatigue, general malaise, low-grade fever, myalgias, and arthralgias. Respiratory tract symptoms range from dry cough due to xerotrachea to dyspnea due to interstitial disease or even airway obstruction. High-resolution CT scan shows bronchial and peribronchial thickening, whereas transbronchial biopsies show bronchiolar lymphoid infiltrates and follicular bronchiolitis [29]. Sensorineural hearing loss is associated with Sjögren's syndrome in 21–46% of cases [30]. Dysphagia results from drying of the pharynx and esophagus. Other complications include renal disease, Raynaud's disease, inflammatory vascular disease, peripheral sensory or sensorimotor polyneuropathy or mononeuritis multiplex, skin dryness, vasculitis, and frequent allergic reactions. Labial salivary gland biopsy is used as a means of assessment of salivary pathology in Sjögren's syndrome.

46.6.2.1 Management

Xerostomia and keratoconjunctivitis sicca are managed by use of 0.5% methylcellulose artificial saliva and tears. Preventive dental care and fluoride application and maintenance of general hygiene are necessary. Eye patching and boric acid ointment can be used for corneal ulcers. Pilocarpine hydrochloride can be used as a secretagouge for management of xeropthalmia and xerostomia. Systemic corticosteroids can be used for systemic complications such as vasculitis, glomerulonephritis, and interstitial lung disease.

46.6.3 Mucoceles (Video 46.2)

Mucous retention cyst arises from ductal obstruction in a minor or accessory salivary gland due to traumatic severance of the duct due to biting of the lips, cheeks, and tongue or due to injury due to lip pinching during extraction. Majority of cases are an extravasation type of cysts which result from collection of salivary secretions in the soft tissues due to traumatic injury to the gland or duct. Lower lip was affected in 44–79% of cases. It occurs in any age with no gender predilection [31].

46.6.3.1 Clinical Features

Superficial lesions appear like a circumscribed, raised vesicle with a bluish translucent hue due to the thin overlying mucosa. However, deeper lesions being covered by normal mucosa have a normal color and texture. Mucoceles may get traumatized and rupture spontaneously and may recur later.

46.6.3.2 Management

Surgical excision of the mucocele along with a few normal minor salivary glands is the procedure of choice. Care should be taken to avoid creation of any other partially transected minor salivary glands which might give rise to the recurrent mucocele.

Mucocele can be excised by giving an elliptical incision around the lesion and closure (Fig. 46.19a–d), [32] or as the case requires, an incision may be given over the mucocele; lesion can be excised carefully without rupture and closure attained (Fig. 46.19e–h).

Huang I et al. [33] recommended use of carbon dioxide laser vaporization to treat the lower lip mucocele with good results and less complications.

46.6.4 Ranula

Ranula is a mucocele arising from the sublingual salivary gland in the floor of the mouth (Fig. 46.20). It presents as a large blue, tense vesicle in the floor of the mouth. The appearance is of that of a frog's belly, hence the term ranula (frog belongs to genus Rana). It is firm on palpation. The cyst is usually present above the mylohyoid curtain, but when it presents in the upper part of the neck, it is called as a "plunging ranula." Plunging ranulas may grow to a sufficient size so as to compromise respiration and swallowing and may also extend into mediastinum [32].

46.6.4.1 Management

Excision of the ranula and entire sublingual gland through a transoral approach is management of choice taking care to avoid damage to the lingual nerve. The incision is made through the mucosa in the lingual fold from the second molar to canine tooth. Blunt dissection is done up to the mylohyoid muscle. The gland is dissected free from the surrounding soft tissues and the Wharton's duct. The gland can be retracted using holding sutures, and blunt dissection is carried out till the lingual nerve is identified as it crosses the Wharton's duct. The gland is delivered once it is dissected free from the entire surrounding soft tissues taking care to prevent damaging the submandibular duct and lingual nerve [34].

Marsupialization can be used as an alternative modality wherein the ranula is deroofed and the mucosa sutured to the cystic lining followed by open packing of the cyst and sequentially reducing the size of the pack till it heals completely.

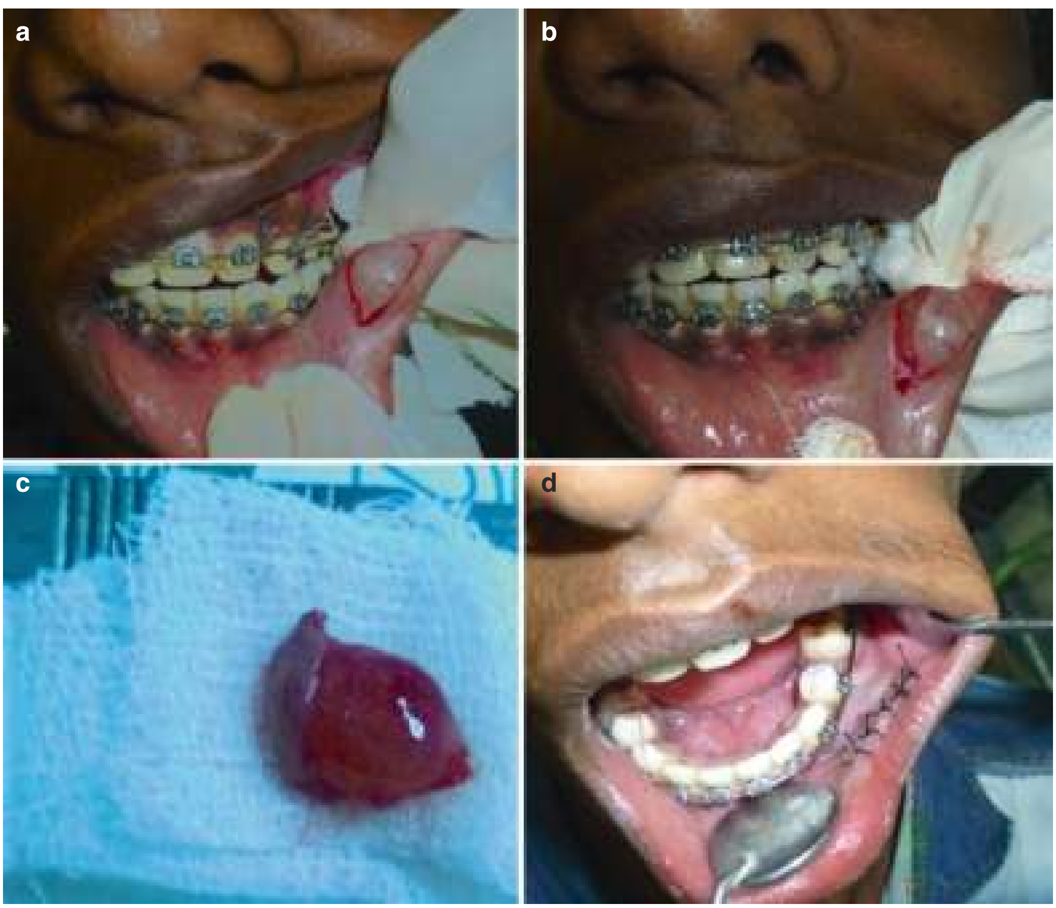

Fig. 46.19 (**a**)–(**d**) Figure showing surgical removal of mucocele by elliptical incision. (**e**)–(**h**) Figure showing excising mucocele by incision directly over the lesion

Fig. 46.19 (continued)

Higher recurrence rate (61–85%) has been reported with simple marsupialization and ranula excision. To lower the rate of recurrence, total sublingual excision is the treatment of choice [35].

Kono et al. [36] recommended an injection of sclerosing agent, OK-432 (Picibanil), as a safe and effective method of treating intraoral ranulas. The number of injections used was 1–4 (mean 1.70) in their study.

46.7 Salivary Gland Tumors

46.7.1 Etiology

Although no specific etiology has been attributed to occurrence of salivary gland tumors, its association with radiations, viruses, hormones, lifestyle, or occupation and like factors can't be denied.

- Radiation: Evidence exists regarding susceptibility of lymphoid component rather than parenchymal component of gland to low radiation and UV ray damage (140 rad) [37–39].
- Viruses: It is believed that genetic component, environment, and immunity of host play a key role in malignant transformation of salivary gland tumors. Viruses like human papillomavirus, Epstein-Barr virus, cytomegalovirus, and polyomavirus have been speculated to be responsible for occurrence of salivary gland tumors.
- Hormones: Endogenous hormones play an important role in carcinogenesis of these tumors. Patients of breast cancer are more prone to salivary gland neoplasms.

Fig. 46.20 Ranula in the floor of the mouth

- Lifestyle: Tumors like Warthin's tumor or epidermoid carcinoma have been associated with cigarette smoking. Salivary gland enlargements are observed in nutritional deficiencies, but there are no reports of malignancies [40].
- Occupation: Those who engage in occupations which involve manufacturing and use of rubber products, asbestos mining, and plumbing are at increased risk of developing salivary gland tumors [37].

46.7.2 Incidence

Salivary gland tumors occur rarely both among Indian population and around the world. Incidence of benign and malignant salivary gland tumors in major portion of the world ranges from 1 to 2 cases per 100,000 people per year [41]. There is no specific predilection of occurrence of these tumors in any particular gender, although Warthin's tumor is more common in males and acinic cell tumor in females. Site wise incidence varies for both benign and malignant tumors. Seventy-five to eighty percent of benign tumors occur in the parotid glands, 5–10% in submandibular glands, and only 1–2% in sublingual glands. Malignant tumors are more common in sublingual glands (80%) and least in parotid glands (17–20%). Benign tumors affect a mean age group of 40 years, and malignant tumors affect an age group of 55 years. Both benign and malignant tumors by large resemble each other clinically. Hence, histopathologic examination is pivotal to establish a correct diagnosis.

46.7.3 TNM Staging of Salivary Gland Tumors According to American Joint Commission on Cancer (AJCC) 2002 [42]

Tumor (T): T with a letter/number describes the location or size of the tumor

TX: Indicates the primary tumor cannot be evaluated.

T0 (T plus zero): No evidence of a tumor was found.

T1: Describes a small, noninvasive (has not spread) tumor that is 2 centimeters (cm) at its greatest dimension.

T2: Describes a larger, noninvasive tumor between 2 cm and 4 cm.

T3: Describes a tumor that is larger than 4 cm but not larger than 6 cm and has spread beyond the salivary glands but does not affect the seventh nerve, the facial nerve that controls expression, such as smiles or frowns.

T4a: The tumor has invaded the skin, jawbone, ear canal, and/or facial nerve.

T4b: The tumor has invaded the skull base and/or the nearby bones and/or encases the arteries.

Nodes (N): N is for lymph nodes. Lymph nodes of the head and neck region are regional lymph nodes, and those away from this region are distant nodes.

NX: The regional lymph nodes cannot be evaluated.

N0: There is no evidence of cancer in the regional nodes.

N1: Cancer has spread to a single node on the same side as the primary tumor, and the cancer found in the node is 3 cm or smaller.

N2: Describes any of these conditions:

- N2a: The cancer has spread to a single lymph node on the same side as the primary tumor and is larger than 3 cm but smaller than 6 cm.
- N2b: The cancer has spread to more than one lymph node on the same side as the primary tumor, and none measures larger than 6 cm.
- N2c: The cancer has spread to more than one lymph node on either side of the body, and none measures larger than 6 cm.

N3: The cancer found in the lymph nodes is larger than 6 cm.

Metastasis (M): Describes the cancer that spreads to different body parts.

MX: Indicates distant metastasis cannot be evaluated.

M0: Indicates the cancer has not spread to other parts of the body.

M1: Describes cancer that has spread to other parts of the body.

46.7.4 Classification of Salivary Gland Tumors

Salivary gland tumors were first classified by WHO in 1972. It was later modified in 1991 wherein the term "tumor" was replaced by "carcinoma" to denote acinic cell carcinoma and mucoepidermoid carcinoma [43]. It was further revised in 1997, and a greater number of entities of adenomas (myoepithelial adenoma, basal cell adenoma, canalicular adenoma) and carcinomas (acinic cell carcinoma, mucoepidermoid carcinoma, polymorphous low-grade adenocarcinoma, salivary duct carcinoma, myoepithelial carcinoma) were redefined with emphasis on the prognosis and therapy [44]. A revised classification was put forth by WHO in 2005 also. The latest classification of WHO which was given in 2017 consisted of the following changes:

- Secretory carcinoma, borderline tumor—sialoblastoma—and sclerosing polycystic adenosis were added as new entities under malignant tumors.
- Simplification of terminologies of polymorphous adenocarcinoma, clear cell carcinoma, and intraductal carcinoma was done.
- Rare entities like adenocarcinoma, NOS, canalicular adenoma, and poorly differentiated carcinoma were regrouped (Table 46.6).

Table 46.6 Revised classification of salivary gland tumors (2017) [45]

Malignant Tumors	*Benign Tumors*
Mucoepidermoid carcinoma	Pleomorphic adenoma
Adenoid cystic carcinoma	Myoepithelioma
Polymorphous adenocarcinoma	Basal Cell Adenoma
Epithelial-myoepithelial carcinoma	Warthin's tumor
Clear cell carcinoma	Oncocytoma
Basal cell adenocarcinoma	Lymphadenoma
Sebaceous adenocarcinoma	Cystadenoma
Intraductal carcinoma	Sialadenoma papilliferum
Cystadenocarcinoma	Ductal papillomas
Adenocarcinoma, NOS	Sebaceous adenoma
Myoepithelial carcinoma	Canalicular adenoma and other ductal adenomas
Carcinoma ex pleomorphic adenoma	*Other Epithelial Lesions*
Carcinosarcoma	Sclerosing polycystic adenosis
Poorly differentiated carcinoma 1) Neuroendocrine and non-neuroendocrine 2) Undifferentiated carcinoma 3) Large cell neuroendocrine carcinoma 4) Small cell neuroendocrine carcinoma	Nodular oncocytic hyperplasia Lymphoepithelial lesions Intercalated duct hyperplasia *Soft Tissue Lesions* Hemangioma
Lymphoepithelial carcinoma	Lipoma/sialolipoma
Squamous cell carcinoma	Nodular fasciitis
Oncocytic carcinoma	*Hematolymphoid Tumor*
Borderline Tumors	Extranodal marginal zone lymphoma of MALT
Sialoblastoma	

46.7.5 Pleomorphic Adenoma

"Pleomorphic adenoma" suggested by Willis closely resembles the unusual histologic pattern of the lesion [28]. The tumor derives its name from the Greek words Pleos = many and morphus = form because of the heterogeneous nature of its histologic appearance [46].

46.7.5.1 Clinical Features

Most frequently found in the superficial lobe of the parotid gland, it presents as a firm, slow-growing asymptomatic mass which is smooth, rounded, lobular, and mobile with a rubbery consistency causing ear lobule to be raised (Fig. 46.21a). If the tumor involves both the superficial and deep lobes of parotid, it is classically referred to as dumbbell tumor. Incidence of the tumor except those found in the pharynx is more in females than males, and they are often seen in the fourth and fifth decade. A bilateral tumor occurrence rate is estimated at 1 in 40,000 [47].

They are encapsulated and do not show fixity to the deeper tissues or the overlying skin in major salivary gland tumors, which can be confirmed on an MRI (Fig. 46.21b), but in the case of the minor salivary glands of the palate, it may appear to be fixed to the underlying palatal bone but does not invade or erode the bone. Pain is uncommon but 50% patients experience a pressure sensation. Accumulation of mucus can occur so that elastic swellings or frankly fluctuant cysts may form in the tumors.

In the case of the submandibular gland, palpation of the mass both extraorally and bimanually helps in localizing it and differentiating it from a lymph node, but FNAC is always needed to differentiate it from sialadenitis.

46.7.5.2 Histopathology [48]

On light microscopy morphologically complex and diverse cellular elements are seen. Both epithelial and myoepithelial elements are present. Based on cellular types, Foote and Frazel [49] have classified pleomorphic adenomas as follows:

- Principally myxoid (36%)
- Equally myxoid and cellular (30%)
- Predominantly cellular (22%)
- Extremely cellular (12%)

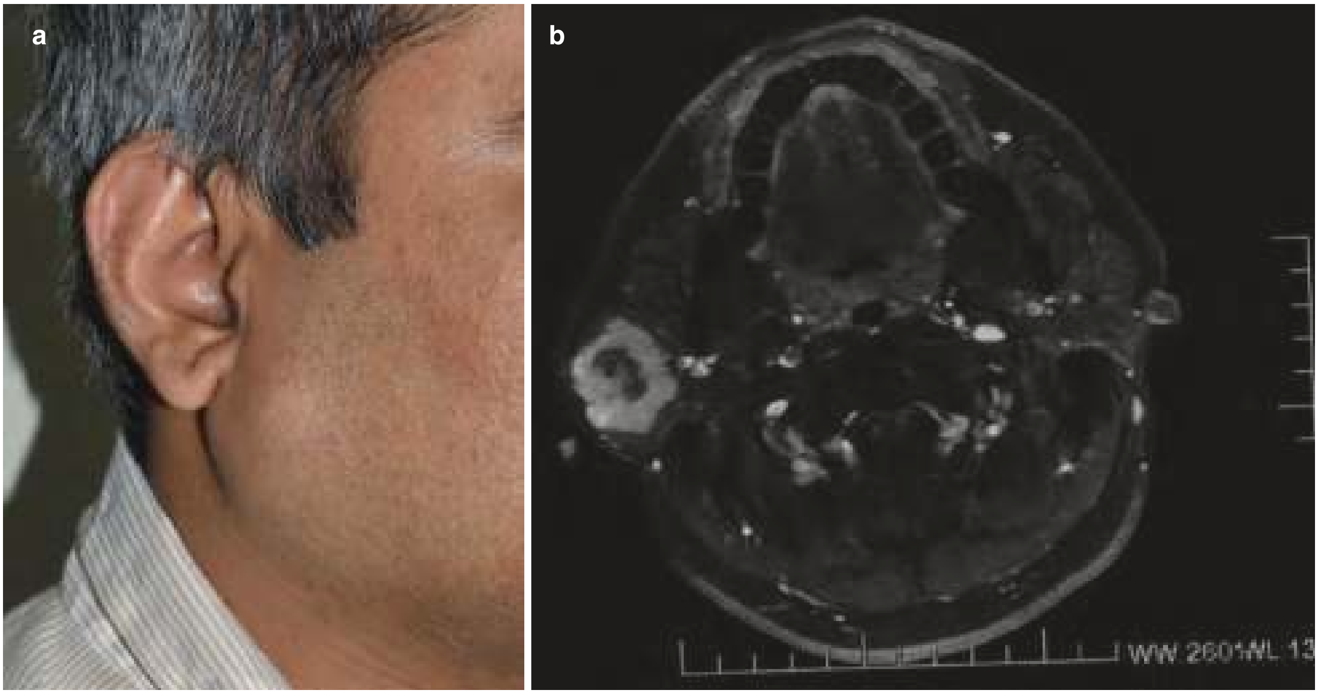

Fig. 46.21 (**a**) Parotid tumor showing elevation of ear lobule (pathognomonic sign). (**b**) MRI axial view showing the tumor

46.7.5.3 Management

Surgical excision is the treatment of choice. Historically, enucleation was practiced which resulted in inadequate surgery and recurrences [50]. Superficial parotidectomy is the most widely accepted technique in the treatment of pleomorphic adenomas in the superficial lobe of the parotid gland, and total gland excision with facial nerve preservation is carried out. Tumors of the submandibular gland are usually contained within the gland, and their resection is usually confined to the gland and surrounding fat or lymph nodes until the neoplasm is a malignant and invasive tumor. As with the parotid gland, most neoplasms are asymptomatic. Small palatal pleomorphic adenomas usually cause pressure resorption of the palate but do not invade the bone. A disk of palatal mucosa is outlined well clear of the visible swelling because the tumor is flattened owing to the toughness of the palatal tissues. The tumor along with the periosteum of the palate is excised in continuity with each other. In case the pleomorphic adenoma invades the palate or proliferates into the floor of the maxillary sinus, a partial maxillectomy or total maxillectomy depending on the extension of the tumor has to be performed.

Although pleomorphic adenoma is a benign tumor, it may cause problems in clinical management due to its tendency to recur and risk of malignant transformation.

46.7.6 Monomorphic Adenoma

The WHO classification subdivides the monomorphic adenomas into three groups [45]:

- Adenolymphoma (Warthin's tumor)
- Oxyphilic adenoma (oncocytoma)
- Others

A number of other classifications of monomorphic adenomas have been put forth, but there is no unanimity. Two main histologic patterns have evolved:

- Basal cell adenoma
- Canalicular adenoma

46.7.7 Warthin's Tumor

Warthin's tumor, also known as papillary cystadenoma lymphomatosum and adenolymphoma, is the second most common benign tumor of the salivary glands, around 5% of neoplasms [51].

It was first described by Hildebrand in 1895 as a form of congenital cyst of the neck. It is known as Warthin's tumor in recognition of the pathologist who first described it in the USA in 1929. He described two cases and also coined the term papillary cystadenoma lymphomatosum [52].

46.7.7.1 Clinical Features

The majority of the tumors arise in the parotid gland, more often bilaterally, in the elderly and occurs in the fifth and sixth decades of life. A predilection for male sex is seen, more in Caucasians. Both tumors do not occur simultaneously but are metachronous in their manifestation. A concept of multicentric and multifocal disease has been put forth to explain this. It is a solitary, nodular, slowly enlarging swelling, most commonly located in the inferior pole of the parotid next to the angle of the mandible. It varies from moderately firm to fluctuant on palpation and is asymptomatic. It is not as discrete as the mixed tumor. Very few patients present with complain of pain, pressure, or rapid increase in the tumor size. Scintigraphy may be helpful due to its increased uptake of technetium-99m pertechnetate. It appears as a smooth-margined, radiopositive "hot" nodule in contrast to the mixed tumors, nonfunctioning malignant tumors, and metastatic tumors which appear as a "cold" nodule in scintigraphy. Positive scintigraphy with ^{123}I is indicative of Warthin's tumor but may also signify presence of ectopic thyroid or metastatic thyroid tumor.

46.7.7.2 Management

Surgical removal is the established treatment for Warthin's tumor. As the tumor is superficial in the parotid gland, it is easily removed with minimal loss of glandular function and with preservation of the facial nerve.

Treatment philosophies given are:

- Tumor enucleation with resection of minimal amount of surrounding normal tissue
- Superficial parotidectomy, which is more aggressive than enucleation
- Local excision of parotid gland

Local excision of the tumor is preferred to enucleation of the tumor because lymph nodes at the posteroinferior part of the gland cannot be cleared by enucleation. Preoperative diagnosis of Warthin's tumor must be confirmed by coordinating the clinical findings with imaging and fine-needle aspiration biopsy reports before local excision is carried out. If there is associated chronic obstructive parotitis, superficial parotidectomy is essential. Similarly, if the tumor is located in front of the ear, a superficial parotidectomy is the treatment of choice.

46.7.8 Oncocytoma

An oncocytoma is a tumor characterized by large epithelial cells, i.e., oncocytes that contain a brightly eosinophilic, granular cytoplasm. The oncocyte is derived from the Greek word "onkousthai" meaning swollen or enlarged and was described in 1897 by Schaffer who observed this tumor in ductal and acinar elements of salivary glands in the tongue, pharynx, and esophagus. Jaffe was the first to introduce the term oncocytoma [53]. However, he had termed Warthin's tumor as oncocytoma. The other terminologies used to describe this tumor are oxyphilic adenoma and acidophilic adenoma.

46.7.8.1 Clinical Features

There is no race predilection for occurrence of this tumor. Oncocytoma is predominantly a tumor of the major salivary glands, parotid being the most common. Bilateral occurrence is also known. Among minor salivary glands, which are rarely affected, palatal mucosa followed by buccal mucosa and tongue is affected.

The oncocytoma is a small benign lesion which generally does not attain a great size. It most frequently presents as an indolent, single, often multi-lobulated, firm, solid, and mobile mass in the superficial lobe of the parotid gland. It can also be located in the deep lobe of the parotid gland and may be insinuated between the branches of the facial nerve. However, it does not cause any symptoms of pain or paresthesia unless the branches of the facial nerve are compromised. Tumor size varies with the duration of the lesion but generally does not increase beyond 4.0 cm. Intraoral tumors do not exhibit any special characteristic diagnostic features. However, their overlying mucosa may become ulcerated due to trauma [53].

46.7.8.2 Management

Partial parotidectomy with facial nerve preservation whenever possible is the treatment of choice. It ensures complete removal of the tumor and reduces the rate of recurrence. Curettage or simple enucleation of the tumor is to be avoided to avoid recurrence. Complete sialadenectomy is the treatment of choice in cases of submandibular gland oncocytomas. In the case of minor gland tumors, local excision of the tumor with a margin of normal tumor-free tissue is carried out. Radiation therapy after surgery has been tried but it has shown to be ineffective.

46.7.9 Basal Cell Adenoma

It was first reported as a separate entity by Kleinsasser and Klein in 1967 [28].

46.7.9.1 Clinical Features

Basal cell adenomas occur between the third and ninth decade, but the peak incidence is in the sixth decade with a slight male predilection of 5:1 [28]. They are clinically indistinguishable from mixed tumors and occur in the superficial portion of the parotid gland. They are slow-growing, painless, round or ovoid, well-circumscribed, and freely mobile masses with a smooth-surfaced capsule and a soft to moderately firm consistency. They may be mistaken for a hyperplastic lymph node because of their encapsulation, size, and color.

Clinically basal cell carcinoma of skin, ameloblastoma, pleomorphic adenoma, and adenoid cystic carcinoma can be considered in the differential diagnosis.

On the basis of histopathologic appearance, they may be divided into four subtypes:

- Solid
- Trabecular
- Tubular
- Membranous

46.7.9.2 Management

Surgical excision with a sufficient clear margin of normal tissue is the treatment of choice.

46.7.10 Canalicular Adenoma

46.7.10.1 Clinical Features

It is seen between the fourth and ninth decade, highest incidence being in the seventh decade with a female/male ratio of 1.7 to 1.0 and a higher incidence in Caucasians. It is seen more commonly in the minor salivary glands of the lip and cheek and rarely affects the major salivary gland [54].

It presents as a non-ulcerated, painless, mobile nodule that exhibits slow growth unless it is traumatized, wherein there is presence of ulceration. Clinical appearance is similar to that of a mucocele [54]. The overlying mucosa may be normal colored or bluish.

In the case of upper lip lesion, a sialolith, mucocele, mucous retention cyst, and pleomorphic adenoma can be considered in the differential diagnosis.

46.7.10.2 Management

Surgical excision, enucleation, or limited extracapsular excisions have been used as treatment modalities in these tumors with success.

46.7.11 Sialadenoma Papilleferum

First described by Abrams and Finck in 1969, it was termed sialadenoma papilleferum because of its histologic similarity to syringocystadenoma papilleferum of skin adnexal origin [55].

46.7.11.1 Clinical Features

Sialadenoma papilleferum presents as a subcentimetric, asymptomatic, exophytic, papillary surface lesion which can be confused with squamous papilloma. The most common site of occurrence is the minor salivary glands at the junction of soft and hard palate with the tumor located on one side of the midline. This tumor occurs at an average age of 56 years, cases being reported from 2 years to 87 years. Male predilection is seen in the ratio of 1.5 to 1. However, there is no racial predominance [55].

Clinically it resembles a squamous papilloma, and a differential diagnosis of verrucous carcinoma or a warty dyskeratoma needs to be considered.

46.7.11.2 Management

Being small, these tumors are easily excised usually with a clinical diagnosis of a squamous papilloma. However, recurrence is rare.

46.7.12 Inverted Ductal Papilloma

Inverted ductal papilloma is a rare tumor and was first described by White et al. in 1982 when they reported four cases [56].

46.7.12.1 Clinical Features [56]

It occurs as a firm, asymptomatic, discrete nodule of 1–1.5 cm beneath the normal mucosa which in some cases may be contiguous with a small surface pore. The mean age of occurrence is 50 years without any sex predilection. The sites usually involved are the lower lip and buccal vestibular mucosa in descending order with occasional cases reported in the upper lip, floor of mouth, and soft palate.

46.7.12.2 Treatment and Prognosis

It is treated by simple surgical excision as it is not known to recur.

46.7.13 Intraductal Papilloma

It is a rare tumor. These tumors present as asymptomatic, submucosal swellings that vary in size from less than 1 to 1.5 cm in the minor salivary glands. The ages of patients range from 29 to 77 years, with a mean age of 54 years. Men and women are equally affected.

46.7.13.1 Treatment and Prognosis

Excision is curative, and these tumors are not known to recur. In case the tumors are small, all types of papillomas of the minor salivary glands, including intraductal, inverted, and sialadenoma papilliferum, can be excised in the dental office or the clinic under local anesthesia [55].

46.7.14 Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common malignant salivary gland neoplasm. They are classified as grade I (low grade) which are well differentiated, grade II (intermediate grade) which are moderately differentiated, and grade III (high grade) which are poorly differentiated tumors.

46.7.14.1 Clinical Features

Mucoepidermoid carcinomas occur more commonly in the minor salivary glands with a female predilection [57]. It occurs as a painless, circumscribed, mobile solitary enlargement of the body or tail of the parotid or the submandibular region with over a year duration generally. Pain, facial paralysis, and fixation to the overlying skin are usually suggestive of high-grade lesions [57]. Minor salivary gland lesions present as a bluish or red-purple, fluctuant, smooth-surfaced mass that is often clinically mistaken for a mucocele or hemangioma [57]. Large lesions at the base of the tongue or in the oropharynx may cause dysphagia. Aggressive tumors show ulceration. Numbness of the teeth may occur when the bone is involved. Histopathologically, mucoepidermoid carcinomas are graded as low-grade, intermediate-grade, and high-grade carcinomas. They are generally partially encapsulated and don't show adequate circumscription.

46.7.14.2 Management

Complete, adequate, and radical surgical excision is the treatment of choice for all grades of mucoepidermoid carcinomas [58]. In the case of stage I and stage II mucoepidermoid carcinomas of the parotid gland, conservative excision with preservation of the facial nerve, if possible, is recommended. The affected submandibular gland should be removed entirely. Radical neck dissection is performed in patients with clinical evidence of cervical node metastasis and is considered in any patient with a T3 lesion. In the case of facial nerve involvement, total parotidectomy with facial nerve sacrifice up to histologically tumor-negative nerve trunk is done. The 5-year disease-free rate in patients receiving this aggressive treatment was about 60% [58].

Treatment of minor salivary gland mucoepidermoid carcinomas entails a wide surgical excision with the bone if involved, to achieve a negative margin, and the wound is left to heal secondarily [59]. For small low-grade tumors in the absence of bone involvement, wide excision down to periosteum with 1 or 2 cm tumor-free lateral margins is adequate therapy [59]. High-grade and advanced stage tumors must be treated aggressively at any site. The overall recurrence rate of mucoepidermoid carcinomas is approximately 25%. Better survival is seen among younger patients and among females. Tumors in the submandibular gland and in the base of the tongue generally have a poorer outlook than those at other major and minor salivary gland sites. Also invasion into bone signifies a poorer prognosis. Survival is closely related to the clinical stage and the histologic grade.

46.7.15 Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is a highly aggressive, destructive, and clinically unpredictable tumor of the head and neck region [60]. The other terms used for ACC used in the past are cylindroma and adenomyoepithelioma. Foote and Frazell [49] proposed the currently accepted term adenoid cystic carcinoma in their classic paper in 1953 and in their fascicle on major salivary gland tumors in 1954.

46.7.15.1 Clinical Features

Adenoid cystic carcinoma occurs in adults between 50 and 70 years of age with equal prevalence in males and females [61]. The most frequent locations of this tumor are the parotid, submandibular, and palatal salivary glands [62]. They are only rarely observed in the sublingual gland [61].

Clinically adenoid cystic carcinoma manifests in the major and intraoral accessory salivary glands as a slow-growing swelling or mass. Pain and fixation to skin as well as surrounding deeper structures generally occur during the course of tumor growth. An ominous feature of adenoid cystic carcinoma of the parotid gland is paralysis of the facial nerve. Radiographic examination is valuable in assessing the extent of osseous destruction. Symptoms may have been present for months or years and are generally of longer duration than those associated with squamous carcinoma, which is the most frequent malignancy of this location. Adenoid cystic carcinomas of the maxillary antrum, nasal cavity, and ear canal produce symptoms of pain, obstruction, and deafness, respectively.

Histopathologically, ACC are classified into cribriform pattern, tubular pattern, and solid pattern. A major microscopic feature in most adenoid cystic carcinomas is the propensity for the tumor to involve peripheral nerves, reported to occur in 20–80% of the patients. Although perineural invasion is characteristic of adenoid cystic carcinoma, it is not unique to the tumor.

46.7.15.2 Management of Adenoid Cystic Carcinoma

Complete excision like all other tumors is the treatment of choice. Elective regional lymph node dissection is not indicated, because distant metastasis is more common than cervical (regional) node involvement. According to Maciejewski et al., radical surgical excision with histologically proven negative margins with postoperative radiotherapy for all cases should be the treatment of choice. Lymph node dissection is recommended only in cases of histologically proven positive lymph nodes [60]. A frozen section diagnosis to achieve tumor-free safe margins is necessary to specifically look for safe perineural margins because ACC is known to spread quickly along the nerve.

The slow biologic growth of adenoid cystic carcinoma along with a late metastasis of the disease results in relatively favorable 5-year survival rates. Factors that indicate a poor prognosis include failure to achieve clear margins at first surgery, a solid pattern histologically, recurrent disease, and distant metastasis [63].

In a study by Witten et al., local recurrences have been seen in almost 32% of the cases [63]. The risk of distant metastasis is also high, approximately 40%, and can occur in less than 8 years after treatment.

46.7.16 Clear Cell Carcinoma

Clear cell neoplasms of salivary glands have been classified as both adenomas and carcinomas [64].

46.7.16.1 Clinical Features

It occurs predominantly in the palatal minor salivary glands followed by parotid and submandibular glands without any sexual or racial predilection. It occurs between the ages of 18 and 86 years, mean 56 years. Clinical manifestation is of a swelling similar to other tumors. It may be confused with mucoepidermoid and acinic cell carcinoma as well as metastatic renal cell carcinoma. A positive reaction to mucicarmine would preclude the possibility of renal cell carcinoma.

46.7.16.2 Management

Due to their infiltrative growth and the incidence of recurrence and regional lymph node metastases, it is appropriate to consider them low-grade adenocarcinomas. Hence surgical treatment is the mainstay of management.

46.7.17 Epithelial-Myoepithelial Carcinoma

The epithelial-myoepithelial carcinoma of intercalated duct origin is a rare biphasic type of low-grade salivary gland carcinoma that constitutes less than 1% of salivary gland neoplasms.

46.7.17.1 Clinical Features

It occurs more commonly in females around 60–70 years of age. Parotid gland is the most frequently affected [65]. Patients present with an asymptomatic or painful salivary gland swelling with a history of steady increase in size over an extended period of time and may also present with facial paralysis [66]. In patients with maxillary involvement, nasal obstruction and facial deformity may be the presenting complaints. Differential diagnosis includes pleomorphic adenoma, acinic cell adenocarcinoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, sebaceous carcinoma, and oncocytoma.

46.7.17.2 Management

Surgery is considered the primary mode of treatment. Total parotidectomy with facial nerve preservation is advocated for tumors in the parotid gland unless the nerve is involved by the tumor. Recurrences and distant metastasis are a known complication.

46.7.18 Carcinosarcoma

Carcinosarcoma, also known as true malignant mixed tumor, shows malignant cells in both the stromal and epithelial components [67]. When these tumors metastasize, both components metastasize together.

46.7.18.1 Clinical Features

Carcinosarcomas are rare tumors with an average incidence of 0.4% in major salivary glands and 1% in minor salivary glands. It occurs between 25 and 85 years of age (average 58.5 years) with the frequency of occurrence being more in parotid than submandibular gland and then minor glands in palate and tongue [67].

It presents as an enlarging mass with a rapid increase in size and may be associated with pain and facial nerve paralysis. Rarely, patients present with metastases or experience difficulty in swallowing or breathing. A patient with a central nervous system metastasis has been reported to present with headaches [67].

46.7.18.2 Management

The data available is insufficient to recommend one type of therapy as definitive. However radical surgical excision, together with radiation therapy and lymph node dissection for palpable disease, seems to be the most prudent form of therapy. Radiotherapy as the only means of therapy has not proved effective. Tumor metastasis is most frequent to the lungs followed by hilar and cervical lymph nodes. Distant metastasis is also rarely found [67].

46.7.19 Undifferentiated Carcinomas

This group includes three distinct entities:

1. *Lymphoepithelial carcinomas (malignant lymphoepithelial lesion):* It is more prevalent in females and occurs between fourth and fifth decade of life. The parotid gland is most commonly involved followed by submandibular gland. Painful indurated mass and occasional facial paralysis are the presenting symptoms. It might be preceded by benign lymphoepithelial lesion for many years. It is managed by wide surgical excision with or without neck dissection and may be supplemented with radiotherapy.
2. *Undifferentiated large cell carcinomas:* It occurs predominantly in older population with a male predilection. It most commonly affects the parotid followed by submandibular and minor salivary glands. Histologically it shows predominantly poorly differentiated large cell components. It carries a poor prognosis and has a higher risk of locoregional as well as distant metastasis and recurrences. The worst prognostic factor is the size of the lesion. Less than 4 cm, mean survival time was 46 months, and more than 4 cm it was reduced to 7.7 months [51].
3. *Undifferentiated small cell carcinomas*: It rarely affects the salivary glands and is primarily a pulmonary tumor. When it occurs, it shows a male preponderance and occurs between fifth and seventh decade, in the parotid mainly followed by submandibular gland. It presents as a rapidly growing mass which may or may not be painful. Management is primarily wide surgical excision with neck dissection for clinically positive neck node involvement. Chemoradiotherapy may be used as an adjunctive modality for treatment. It tends to metastasize via the hematogenous route, and hence a distant metastasis needs to be ruled out.

46.7.20 Squamous Cell Carcinoma

The diagnosis of primary squamous cell carcinoma is limited to the major glands because distinction between possible minor salivary gland primary tumors and those originating from mucosal surface epithelium is generally not possible.

46.7.20.1 Clinical Features

It occurs between 7 and 95 years of age, the mean age being 60.5 years with a male predilection of 2:1. Parotid gland is the most commonly involved followed by submandibular and sublingual glands [68]. It presents as an asymptomatic mass with occasional pain and facial nerve palsy. This tumor often replaces the entire gland with fixation to underlying structures and skin.

Ductal squamous metaplasia, high-grade mucoepidermoid carcinoma, and lymphoepithelial carcinoma should be considered in the differential diagnosis of squamous cell carcinoma of the salivary gland.

46.7.20.2 Management

Surgical management is the mainstay of treatment. Parotidectomy with or without facial nerve preservation depending on the case is needed for parotid tumors. Submandibular sialadenectomy is needed for submandibular gland tumors. A neck dissection is done in clinically positive necks at the slightest suspicion. Locoregional failure is the most significant problem, and hence a composite resection in larger submandibular malignancies might be needed. Postoperative radiotherapy when combined with surgery may improve the locoregional control [68].

46.8 Surgical Management of Parotid Tumors (Video 46.3)

The following procedures are performed:

- Local excision of the parotid gland
- Superficial parotidectomy
- Functional superficial parotidectomy
- Complete parotidectomy with facial nerve preservation
- Radical parotidectomy with or without neck dissection
- Parotidomandibulectomy
- Temporoparotidectomy

46.8.1 Skin Incisions for Parotidectomy [69]

The ideal incision should combine good exposure with the best ultimate cosmetic result. This part of the procedure is common to all the resection procedures unless skin is being excised because it is involved by the tumor.

Gutierrez (1903)—The incision had a temporal extension, a preauricular component, and a limb extending onto the neck in one of the skin creases (Fig. 46.22). The chief drawback of this incisions was esthetics in case of development of a keloid.

Redon and Vaillant and Laudenbach—The incision line is similar to that proposed by Adson (Fig. 46.23).

Adson and Ott have described a "Y"-shaped incision with a preauricular part, a postauricular part, and a cervical incision line that splits off from the site of union of the first two branches (Fig. 46.24). The advantage of this incision is improved esthetics because it lacks a temporal incision line, but the drawback is that it impairs dissection. Also, one section of the incision is located in the carotid region.

Samengo (1961)—The incision has a preauricular, a postauricular, and a neck extension in the incision line (Fig. 46.25).

Fig. 46.22 Gutierrez incision

Fig. 46.23 Redon and Valliant and Laudenbach incision

Fig. 46.24 Adson and Ott incision

Fig. 46.25 Samengo incision

Appiani (1967)—The incision within the lower portion of the scalp is hidden by the hair instead of the vertical incision line. The benefit of this incision is better esthetics. However, the temporal extension of this incision is short, and this impairs access to the anterior portion of the gland (Fig. 46.26).

Ferreria JL et al. [69] modified Appiani's incision by extending the temporal incision line but not beyond the hairline. It provides a better access to the anterior portion of the parotid gland without compromising esthetics. Also, the angles are rounded off where the incision line changes direction reducing dehiscence and salivary fistula formation.

Fig. 46.26 Appiani's incision

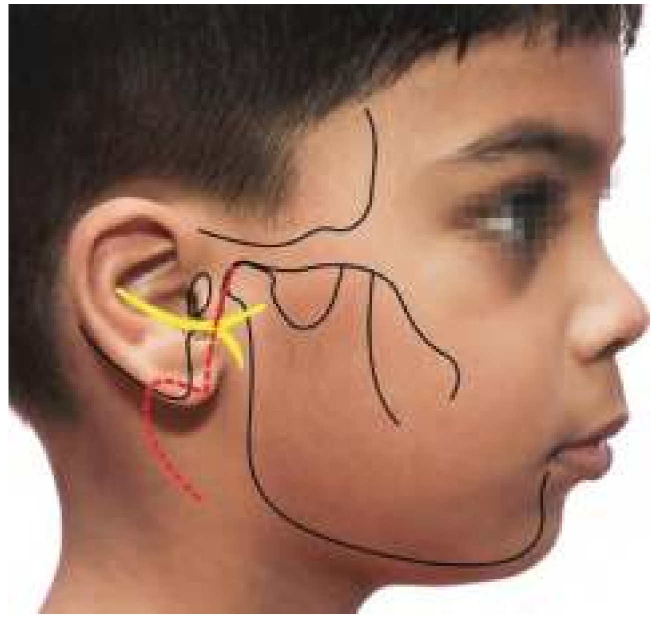

Fig. 46.27 Modified Blair incision in pediatric patient

Farrior et al. recommended a single curved incision 1.5–2.0 cm below the mandible and extending over the mastoid region 1.5 cm behind the postauricular crease in children. The preauricular crease used in adults is avoided because of the superficial location of the facial nerve and possibility of facial nerve damage during flap elevation [68] (Fig. 46.27).

The Blair incision is an S-shaped incision that starts from the preauricular region and extends in the neck. The major disadvantage of the Blair incision is a visible scar in the neck that may cause facial or cervical disfigurement causing patients dissatisfaction [70].

The standard incision is a modified Blair incision (Fig. 46.28) wherein the skin incision is placed in a preauricular crease and doesn't extend beyond the level of the root of the helix. It extends inferiorly around the ear lobule over the mastoid tip. It gently curves down along the sternocleidomastoid muscle and then slightly forward in a natural crease in the upper neck [71].

A facelift incision can be used to avoid the hollowing after parotidectomy, and the defect can be filled with SMAS advancement flap (Bananno and Casson [72], 1992). However, the SMAS-lifting technique is not a routine procedure for many surgeons [73].

Rai A et al. [74] advocated use of posterior belly of the diagastric muscle flap (PBDMF) for reconstruction of the surgical defect after superficial parotidectomy. PBDM inserts very close to stylomastoid foramen, and it is considered as an important landmark in the identification of facial nerve main trunk. The harvesting and dissection of PBDMF becomes easier as it lies in the surgical site, and no extra incision is required to harvest it. It can be used in thin and young patients with good esthetic results.

Fig. 46.28 Modified Blair incision in adults

46.8.2 Identification of the Facial Nerve

This has been previously described in the section on applied anatomy of the parotid gland.

46.8.3 Surgical Management

The selection of type of procedure for surgical management of parotid tumors depends on the site, size and clinicohistopathologic features. The various procedures are described briefly as under:

46.8.3.1 Local Excision of Parotid Gland

This technique is used for management of a small tumor in the tail of the parotid gland less than 3.5 cm. Due to small tumor size, most of the functional gland along with the duct can be preserved.

46.8.3.2 Parotidectomy with Preservation of the Facial Nerve [75]

After marking the incision, infiltration is usually done with Saline Plus 1 in 200,000 parts adrenaline instead of lignocaine with adrenaline to avoid blocking the facial nerve fibers. In case lignocaine is used, care should be taken to avoid deep injections. Care should be taken to avoid extending the incision too far posterior beneath the ear lobe to avoid persistent edema [75].

The incision in the neck crease is deepened to raise a flap in the subplatysmal plane (Fig. 46.29). The greater auricular nerve is identified and preserved. It branches over the surface of the gland where two or more branches should be followed and then divided.

Once the deep fascia has been identified, rest of the wound is deepened to this level and skin reflected forward from it. At the zygomatic bone, some subcutaneous fat should be left on the fascia to avoid damaging the branches of facial nerve which lie more superficially as they emerge from the upper part of the parotid. The main trunk of the nerve is found by first separating the lower pole of the gland from the anterior border of the sternomastoid and then from the mastoid process and the cartilaginous part of the external auditory meatus (Fig. 46.30). The wound is deepened anterior to the margin of the sternomastoid, and the lower pole is dissected free as far forward as the external jugular, uncovering the posterior belly of the digastric muscle. The vein should not be divided and tied at this stage because this will increase the venous engorgement of the parotid and the ooze from its divided tissues.

Neither should the lower pole be raised further forward because the branches of the facial nerve often pass superficial to the vein and emerge from the gland anterior to it. The parotid is retracted forward as the dissection proceeds and the pointed, lower extremity of the tragal cartilage (pointer) will be uncovered. Where possible, the edge of the fascia should be raised and the underlying tissue separated by blunt dissection until the nerve is seen as white cords some 2–3 mm thick.

Fig. 46.29 Flap raised in the sub platysmal plane exposing the superficial surface of tumor

Fig. 46.30 Representing facial nerve main trunk

The stylomastoid branch of the posterior auricular artery passes superficial to the nerve to enter the stylomastoid foramen. Damage to this vessel should be avoided as bleeding may hamper vision, and also it supplies a nutrient branch to the nerve. The curved mosquito forceps are used for dissection by opening the blades a little at a time to stretch the tissues and raise it, so as to lift the gland substance off the surface of the nerve, and then expose it by cutting through the gland with scissors. At all times when a cut is made, the adjacent nerve must be seen clearly.

Almost immediately the nerve trunk starts to travel laterally within the parotid, and just below the neck of the condyle, it splits into an upper temporofacial and a lower cervicofacial division. Follow the lower division first, and trace the cervical or the marginal mandibular branch anteriorly to a point in front of the parotid to mobilize the lower pole completely. Then by progressing upward, branch by branch further mobilization can be achieved (Fig. 46.31). Some tissue should always be left on the tumor to ensure complete removal.

In general, the nerves pass superficial to the retromandibular vein, but some may pass deep to it. Careful mobilization of both nerve and vein with division and ligation of the latter is necessary. Tiny vessels should be sealed with bipolar diathermy avoiding damage to adjacent nerves.

Fig. 46.31 Parotidectomy with preservation of the facial nerve

46.8.3.3 Functional Superficial Parotidectomy [76]

This is superficial parotidectomy where gland function is preserved by preservation of the Stenson's duct. If the duct is superficial to the buccal branch, its preservation is contraindicated as it will obstruct the surgical procedure. After raising the skin flap and exposing the parotid gland, the duct is identified passing on the masseter muscle. Stenson's duct is located; dissection and ligation of the duct are avoided unless it is located superficial to the buccal branches of the facial nerve. Rest of the procedure is similar to superficial parotidectomy.

Advantages

- It is a simpler surgery than conservative superficial parotidectomy.
- It preserves partial function of the parotid gland.
- It avoids the influence of subsequent gland atrophy on facial contour.

It decreases postoperative complications.

46.8.3.4 Partial Superficial Parotidectomy

This is similar to local excision of parotid gland. Maximum healthy tissue is left behind without compromising on the clearance. The advantage of this procedure over superficial parotidectomy is relatively low incidence of Frey's syndrome. The reported incidence of this complication is 4.8% [77]. In addition, better gland function is preserved due to more parenchyma that is left back [78].

46.8.3.5 Intraoral Deep Lobe Tumor Excision [79]

It is a transoral approach used in removal of few benign tumors of the deep lobe, which are easily visible displacing the superior portion of the tonsil and soft palate medially. An incision is made with cautery or knife over the most prominent aspect of the swelling in the tonsil and palate area, extending above and below the apparent location of the tumor. The constrictor muscle is identified, and dissection is continued through thinned constrictor muscle by dividing it above and below the tumor. Pressure on the neck often assists in removal of the tumor. Fascial connections from the tumor into the adjacent bed are removed with blunt dissection, and the tumor is delivered into the mouth. Any vascular connections to the tumor should be cauterized, and meticulous hemostasis should be achieved. The superior and inferior portions of the wound are closed with interrupted sutures. The middle portion of the wound is left open to heal secondarily.

Complications

- Tumor rupture
- Incomplete removal
- Uncontrolled hemorrhage

46.8.3.6 Total Parotidectomy with or Without Facial Nerve Preservation

It is usually indicated in tumors affecting the deep lobe. A neoplasm of the deep part of the parotid enters the soft palate through the interval between the styloid process and the back of the mandible and is often of dumbbell shape with the isthmus lying in this gap. After raising a skin flap, the facial nerve is identified and dissected out leaving a layer of glandular tissue on it. An access osteotomy either in the form of vertical subsigmoid or mandibular body distal to the mental foramen is used to open up the interval between the mandible and the styloid process through which the tumor has passed. The stylohyoid muscle may be divided close to the styloid process and turned forward. The external carotid artery will be encountered emerging above the muscles and should be divided. The origin of the facial artery should be identified to check the identity of the vessel.

As the parotid gland and the tumor are freed, it may be raised up between the two nerve bundles or below both bundles. Next entry is made intraorally over the tumor, and under direct vision tissues are divided to deliver the mass. Care is taken to avoid damaging the internal jugular vein and internal carotid artery which lie deep to styloid process. Following removal of the mass, the wound is irrigated, and the oral tissues closed with care using resorbable suture. The drapes are replaced over the mouth, gloves changed, and the mandibular fragments fixed together and the wound closed in the normal way.

46.8.3.7 Parotidectomy Using SMAS Plane for Dissection [73]

The advantages of this flap are that exposure of the gland is sufficient and the dissection is easy to perform. There is no donor-site morbidity, minimum additional operating time, and no extra cost. It seems to decrease the incidence of Frey's syndrome. The speed of the recovery of the facial nerve has been highlighted in the literature. It is more satisfactory from the patient's point of view.

46.8.3.8 Parotidomandibulectomy and Temporoparotidectomy [80]

Parotidomandibulectomy is indicated where there is invasion of the mandible by a malignant neoplasm.

In temporoparatidectomy, small-scale resection of the external auditory canal may be included with the excision of the pinna and overlying skin of the parotid where these structures are involved. The deficiency may be made good with a deltopectoral or other suitable flap.

46.8.4 Parotidectomy in Continuity with Neck Dissection

In the case of lymph node metastasis as stated in surgical pathology, neck dissection can be done in continuity with parotidectomy by increasing the neck skin crease incision and clearing the lymphatic structures.

46.8.5 Complications of Parotid Surgery

- Facial paresis or paralysis often results from poor technique and failure to preserve small nerve branches.
- Bleeding and hematoma formation, which can significantly compromise the airway.
- Rarely, persistent salivary leakage or sialocele formation occurs.
- Frey's syndrome.
- Skin flap necrosis.

46.9 Surgical Management of Submandibular and Sublingual Gland Tumors

Small tumors confined to the gland are treated by sialadenectomy, and tumors spreading beyond the confines of the gland are treated with a wider en bloc excision, which may include resection of the floor of mouth and mandible depending on extent of tumor. The neurotropic tumors might involve the lingual, hypoglossal, mylohyoid, and marginal mandibular nerve leading to a perineurial spread which can be confirmed on frozen section. Thickening and nodularity of the nerves may indicate perineural involvement [81].

46.9.1 Incision

For submandibular sialadenectomy, a skin crease incision below 3 cm from the lower border of mandible is taken to avoid damaging the marginal mandibular nerve which loops below the lower border of the mandible (Fig. 46.32).

For simple excision of the sublingual gland, an incision is made in the floor of the mouth lateral to the submandibular

Fig. 46.34 Facial artery preservation in submandibular sialadenectomy

duct taking care to limit it up to premolar region, as at the molar region, there is a chance to damage the lingual nerve. When sublingual gland excision is necessary for a tumor, it should be removed with a wide margin including a rim resection of the mandible.

46.9.2 Extracapsular Excision of the Submandibular Salivary Gland [82]

After making an incision in the neck crease, skin flap is raised in the subplatysmal plane (Fig. 46.33). The capsule of the gland should be left intact when the sialadenectomy is being done for a tumor, which might compromise the marginal mandibular nerve. The facial artery and nerve are identified as close to the gland as possible. After transection, they are elevated superiorly to identify and reflect the marginal mandibular nerve. Nowadays the facial artery is spared during surgery to allow free flap anastomosis during oncosurgeries (Fig. 46.34). The investing fascia is then divided at the lower border of mandible, and the gland is delivered out from between the anterior and posterior bellies of the digastric muscle. Anteriorly the gland is separated from the mylohyoid muscle, and lingual nerve, hypoglossal nerve, and Wharton's duct are identified. The lingual nerve shares the same facial sheath as the gland at the upper pole. This attachment of the lingual nerve to the gland represents its parasympathetic supply. The Wharton's duct is inferior to lingual nerve and is often surrounded by sublingual glands. As fascia and gland are mobilized upward from the surface of the hyoglossus, the hypoglossal nerve is identified more inferiorly. It is accompanied by ranine vein. Posteriorly the angular tract of fascia has to be cut with scissors to allow the gland in its fascial envelope to be drawn down without grasping the gland with instruments. Where necessary the upper pole may be mobilized via the mouth. An assistant can then depress the gland toward the submandibular wound to enable the operation to be concluded.

The duct and the branch of the lingual nerve supplying the submandibular gland are ligated and transected. The duct is divided close behind the papilla. During excision for inflammatory disease, the nerve is always separated from the gland with knife or scissors. However, if the nerve appears to be involved in a tumor, it is sectioned in front of and behind the gland and the cut ends sutured. The wound is closed in layers with drainage in the usual way.

46.10 Management of Minor Salivary Gland Tumors

Surgical resection of minor salivary gland tumors depends on the site of origin and extent of disease. This may range from a wide local excision of localized low-grade tumors to more radical excision, including marginal or segmental mandibulectomy and/or partial or total resection of the hard or soft palate, partial or total maxillectomy, infratemporal fossa dissection, and/or anterior craniofacial resection for larger and/or high-grade tumors. The V2 and V3 divisions of the trigeminal nerve are at potential risk for perineural spread of minor salivary gland malignancy and may facilitate an early skull base metastasis. Resection of the cranial base may be required in some cases to eradicate the tumor and obtain negative surgical margins [81].

46.10.1 Excision of Palatal Pleomorphic Adenomas [83]

Small pleomorphic adenomas on the palate can cause pressure resorption of the bone but do not cause true bony invasion. They are managed by local excision along with the periosteum. In the case of involvement of greater palatine foramen area, the lesion is freed until it can be drawn down, and the vessels clamped and cauterized under direct vision. If not, the vessel retracts into the canal and causes irritating bleeding. The wound is left to granulate secondarily.

46.10.2 Excision of Palatal Mucoepidermoid Carcinoma [83]

Low-grade mucoepidermoid carcinomas may be treated by the excision of a full-thickness disk of palate, including palatal and alveolar bone. Nasal and oral mucous membranes are sutured together around the defect in the soft palate. Primary reconstruction is avoided and an obturator is used instead (Fig. 46.35a, b).

46.10.3 Excision of Palatal Adenoid Cystic Carcinoma [83]

Spread along the perineurial tissues makes an inadequate surgical margin very likely after surgical management of ACC. A combination of surgery and radiotherapy is best. Surgical excision should be generous. Hemimaxillectomy including the orbital floor is a minimum, unless there is very good evidence that less will be sufficient. Where the soft palate and pterygoid region are involved, extended maxillectomy approach is essential to ensure adequate excision under direct vision.

46.10.4 Excision of Neoplasms of the Cheek and Lips

A primary excision with a margin of normal adjacent tissue can be used, but if there is any doubt, it can be preceded by a biopsy. Re-operation following incomplete extirpation

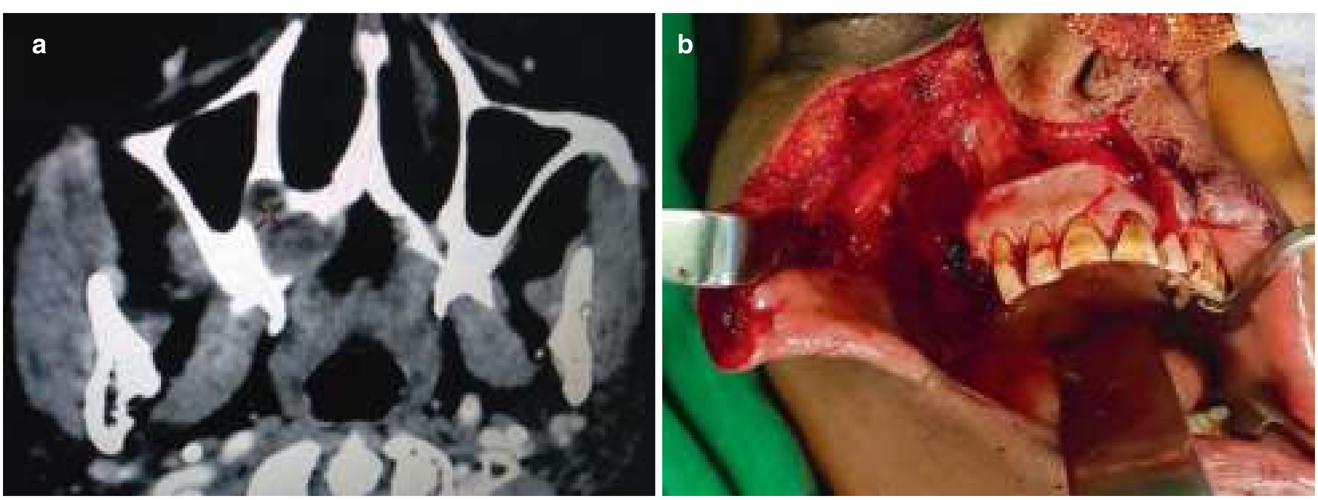

Fig. 46.35 (**a**) CT scan showing mucoepidermoid carcinoma of palate (red arrow). (**b**) Surgical excision of tumor using standard Weber-Ferguson incision

could mean the unnecessary sacrifice of tissue to ensure an adequate margin on the second occasion. Clinically aggressive neoplasms must be biopsied, since adequate treatment may involve radiotherapy and full-thickness excision and repair.

More aggressive tumors affecting the palatal salivary glands are managed by partial maxillectomy or total maxillectomy or extended maxillectomy based on the extent of disease.

46.10.5 Complications

- A hematoma may develop in the dead space after gland excision. It can be avoided by meticulous hemostasis and placement of suction drain to clear out any collection. In case a hematoma develops, it can be aspirated or sucked under aseptic precautions. However, it may not be completely effective. The patient can be just put on good antibiotic coverage, and it will resolve without getting infected.
- Trismus occurs due to masseter muscle spasm or inflammation in the TMJ. It generally resolves spontaneously and hence should be just managed symptomatically.
- Salivary fistula occurs uncommonly due to discontinuity between the residual salivary gland parenchyma and the salivary duct. In majority of cases, the problem is self-limiting. Management includes repeated aspiration, pressure dressings, wound care, an antisialogogue medication (glycopyrrolate), and patience.
- Facial nerve dysfunction results from traction injury to the facial nerve (neuropraxia) during dissection in parotid surgery. Complete recovery within a few months can be expected if nerve integrity has been maintained. In case the nerve is transected, it should be followed by immediate nerve grafting repair.
- Auriculotemporal syndrome of Frey is also called gustatory sweating. It manifests as flushing and sweating of the skin of upper cheek, temporal region, and forehead coincident with eating and smelling of food. Following damage to the auriculotemporal nerve or to communicating branches to the facial nerve, secretomotor parasympathetic nerves from the otic ganglion and also sympathetic fibers to the sweat glands traveling in the same nerve are divided. Following regeneration, fibers from otic ganglion come to supply the sweat glands. Minor's starch-iodine test is used for diagnosis [78]. It can be managed by simple treatment of antiperspirant application; 1% local application of glycopyrrolate is effective. The only effective cure is to divide the parasympathetic fibers from the glossopharyngeal nerve.

Sensory abnormalities associated with greater auricular nerve sacrifice, reflect as sensory deficit in the lower third of pinna including earlobe as well as adjacent preauricular and postauricular skin.

46.11 Recent Advances [84]

Robotic sialadenectomy of the submandibular gland has been done via a modified face lift approach. Virgilio et al. performed robotic sialadenectomy of the submandibular gland in five patients (two patients each with sialolithiasis and pleomorphic adenoma and one patient of ranula) with success. They used three robotic arms, two operative arms, and a facedown 30° endoscopic arm. The operative left arm is equipped with Maryland forceps and right arm with harmonic scalpel.

46.12 Conclusion

Salivary gland pathologies may be neoplastic, non-neoplastic, inflammatory, or non-inflammatory. Early surgical intervention after a good clinical, radiological, and histopathological diagnosis is need of an hour to minimize the postoperative complications. Early diagnosis and management with recent advanced technologies is the key factor in achieving excellent prognosis of the disease.

Acknowledgment Author wishes to thank Dr. Anshul Rai for Figs. 46.3, 46.4, 46.9, 46.13, 46.17a, b, and 46.20.

Author wishes to thank Dr. Kedar Saraf, Professor, Dept. of OMDR, SMBT Institute of Dental Sciences, Sangamner, Maharashtra, for Figs. 46.11a, b, and 46.12.

47 Obstructive Salivary Gland Disease and Sialendoscopy

Prithvi S. Bachalli and Aditya Moorthy

47.1 Introduction

Salivary gland diseases have been described in the literature for centuries. From the time of Hippocrates to the descriptions of parotid tumours in the sixteenth century and the anatomical descriptions of the ductal systems of the major salivary glands in the seventeenth century, we have assimilated knowledge of anatomy and pathology of these glands [1].

The conventional approach to infections of the salivary glands is medical management, occasional expression of the stone through the papilla, marsupialisation of the duct following removal of sialolith. Failing all, removal of the involved gland [2].

Minimally invasive surgery especially those in which endoscopes are utilized has gradually become popular over the last three decades. As a whole, the trend in surgery is to improve function and hasten recovery. To achieve these ends, a combination of technology and smaller incisions has been crucial. Hence there is an increasing interest to manage salivary gland diseases endoscopically [3].

Sialendoscopy is the endoscopic management of obstructive salivary ductal disease and has rapidly become the procedure of choice for such conditions.

47.2 Obstructive Salivary Diseases

Salivary gland diseases can broadly be classified into ductal and parenchymal disorders.

Some conditions, such as Sjögren's syndrome and juvenile recurrent parotitis, tend to have an overlapping component and thus are difficult to segregate.

Ductal obstructions can be commonly attributed to-

- Sialoliths,
- Strictures within the duct or at the punctum,
- Presence of mucous plugs, and
- Retrograde bacterial infection.

The majority of obstructive salivary gland disease can be attributed to the presence of stones or sialoliths. Almost 60–70% of reported obstructive salivary disease comprises of sialolithiasis [4], which occurs in about 1.2% of the population. Amongst the major salivary glands, the submandibular is most affected (87%) , then the parotid (10%), and the sublingual (3%) to a much lesser extent [5].

Although sialolithiasis has been reported as the most common cause of salivary ductal obstructions, strictures, mucous plugs and the rare foreign body can cause significant obstruction to ductal flow.

47.3 Sialendoscopy

Sialendoscopy is a minimally invasive technique which makes use of miniature endoscopes to diagnose and treat salivary gland pathologies, including sialolithiasis, sialadenitis and strictures.

It is fast becoming the investigating procedure of choice for such conditions. Sialendoscopy has grown as a subspeciality in the last three decades, since the first attempts to retrieve salivary stones endoscopically were carried out. It is slowly gaining popularity and awareness in the last decade and a half.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_47) contains supplementary material, which is available to authorized users.

47.4 Evolution of Sialendoscopy

It took a few centuries, after the discovery of the ductal systems, for the first endoscopy to be reported. In 1990, Konigsberger et al. reported the first successful salivary endoscopy using a 0.8-mm flexible endoscope. Katz removed a stone with a flexible scope using blind passage of a basket in 1991, and for over a decade, both Nahlieli et al. and Marchal described various types of sialendoscopy instruments and approaches [3].

The last decade and a half has witnessed significant development of minimally invasive techniques for diagnosing and treating salivary ductal obstructions. Like with other surgical fields, this has led to a paradigm shift from open procedures to minimally invasive and endoscopic techniques with the emphasis on gland preservation and restoration of function. The miniaturization of endoscopes and advancing technology have made exploration and visualization of salivary ductal system possible using sialendoscopes [4].

47.5 Indications and Contraindications

As mentioned previously, sialolithiasis is the most common obstructive condition affecting the salivary duct and therefore is where sialendoscopic/sialendoscopy-assisted retrieval of sialoliths is most indicated.

Ductal strictures which may be secondary to calculi or those at the papilla opening can be very effectively treated by serial dilatation with sialendoscopes of increasing diameter [4].

Juvenile recurrent parotitis (JRP) is an inflammatory condition affecting the parotid gland and is the second most common condition in children after mumps [6, 7]. The condition affects the paediatric population primarily especially the ages between 3 and 6 years and occasionally persists in adolescence [8]. As the cause is unknown, management has generally been conservative. Anatomical aberrations, such as kinks in the duct, dehydration and possible ascending bacterial infection, have been hypothesised as causes.

Dilatation and lavage as a consequence of performing sialendoscopy has provided relief from symptoms and reduction in the frequency of attacks, even though the mechanism is not fully understood. This condition has a tendency of spontaneous cessation at puberty.

Although in Sjogren's syndrome, where the parenchyma of the parotid gland is primarily affected, there is also an associated ductal pathology, namely, strictures. Here too dilatation via sialendoscopy can provide symptomatic relief.

Acute inflammation of salivary glands and ducts is a contraindication to performing sialendoscopy. The duct is essentially a condensation of surrounding epithelium and not a rigid structure. In such an inflamed state, the risk of creating a false passage or perforating the duct is significantly higher [4].

Management in such situations is conservative, mainly with the use of appropriate antibiotics and analgesics, incision and drainage of a collection, and removal of cause, such as a sialolith, if easily visible or accessible, to allow acute symptoms to settle before a formal sialendoscopy is carried out.

Trismus is a relative contraindication to performing sialendoscopy, as naturally, reduction in mouth opening makes it both difficult to introduce and manoeuvre the scopes.

47.6 Investigations

A simple ultrasound in the hands of an experienced sonologist usually provides adequate information prior to sialendoscopy. It is a non-invasive, economical investigation which can determine the presence and size of sialoliths, strictures, dilatation or fibrosis of the duct. Alternatively a CT scan can be considered to achieve the same result.

MR sialograms are particularly useful in identifying strictures or areas of stenosis. However, like conventional sialography the papilla needs to be dilated and cannulated to inject the dye. In the hands of an inexperienced operator, damage to papilla might make performing sialendoscopy impossible.

47.7 Armamentarium

The sialendoscope can be divided very simply into two systems: the Marchal All-in-one (Fig. 47.1) and the Modular system (Fig. 47.2).

As the name suggests, the all-in-one has an irrigation port, a working channel through which various instruments can be introduced, and fibre optics in the same unit. This scope serves as both diagnostic and as an interventional tool.

The modular sialoendoscope consists only of a telescope, attached fibre-optic cable and an eyepiece. Interchangeable sheaths of various diameters are available which fit onto the basic telescope [6]. This scope with the appropriate sheaths can be used for both diagnostic and interventional purposes.

The sheaths used in the modular system make it rigid and unfortunately also bulky; thus significant dilatation of the papilla is required to introduce the scope [6].

Unlike other endoscopes, sialendoscopes come with only a zero-degree viewing angle. The all-in-one is semirigid, with a 5–15-degree angulation at the tip to facilitate manoeuvrability especially while exploring branches of the duct.

Diagnostic scopes come with only an irrigation port, whereas a working channel is also provided in therapeutic scopes to introduce instruments such as wire baskets and graspers for entrapping stones, balloons for stricture dilation

Fig. 47.1 Marchal All-in-one sialendoscope

Fig. 47.2 Modular sialendoscope with sheaths

and a holmium laser fibre or a micro drill to fragment sialoliths [6].

Diameter of available scopes range from 0.9 to 1.6 mm, the smallest purely diagnostic and others having various sizes of the working channel to allow certain instruments only. This is a disadvantage of the all-in-one system in that the entire scope has to be changed if a larger instrument is required, whereas in the modular only the sheath can be changed [6].

Preliminary instruments, those that are used to dilate the papilla to facilitate the introduction of the scope, are also available. These include two types of dilators, papillotomy scissors, guide wires and hollow dilators [6] (Fig. 47.3).

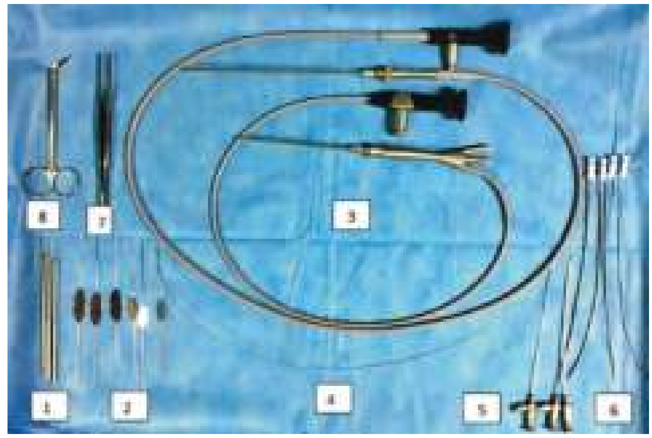

Fig. 47.3 Armamentarium. (1) Conic dilators, (2) Lacrimal probes, (3) Sialendoscopes, (4) Guide wire, (5) Sheaths for Modular sialendoscope, (6) hollow dilators, (7) vascular forceps, (8) papillotomy scissors

47.8 Anaesthesia and Technique

Anaesthetic of choice depends on the clinical and radiologically findings and the anticipated difficulty of the procedure. Local anaesthetic, with or without sedation, is usually adequate for a diagnostic procedure. In cases where sialolith retrieval is planned, either endoscopically or with a combined approach, general anaesthetic is usually preferable. Antisecretory agents like atropine and glycopyrrolate are avoided [6].

47.8.1 Positioning

Patient is placed supine with head fixed on a head rest and turned towards the surgeon. Shoulder extension is preferable. The monitor is placed opposite the surgeon. The assistant is next to the surgeon [6].

47.8.2 Identification, Cannulation and Dilatation of Punctum

The Wharton's duct punctum is comparatively more difficult to locate given the position is quite variable. There may even be a 'hood' of tissue obscuring the opening. In such situations, local anaesthetic can be infiltrated around the area which stiffens the opening, thereby aiding in location. Occasionally an incision might need to be placed on the floor of the mouth accompanied by minimal dissection to locate the duct. The Stensen's duct opening is far easier to identify. It is located on the buccal mucosa opposite upper second molar. Once the punctum is identified, the opening is serially dilated with conical dilator and probes of various sizes [6].

Fig. 47.4 Normal duct with vascular markings

47.8.3 Sialendoscopic Evaluation

Once the punctum is adequately dilated, the appropriate sialendoscope is introduced into the duct. The duct is normally a collapsed structure, and irrigation fluid is required to keep the lumen open to visualise the duct and to advance the scope (Fig. 47.4). Normal saline is the preferred choice of irrigant solution and is diluted with local anaesthetic if the patient is awake for the procedure.

The irrigant also serves an additional purpose as this also performs lavage of the duct, thereby washing out debris and mucous plugs which might be accumulated [6].

The endoscope is slowly and gently passed from the punctum till branches are identified and explored if possible. This point of division of the duct is known as the hilum and is considered the end point of sialendoscopy. Alternatively, the presence of pathology such as a sialolith or stricture may prevent complete exploration of the duct (Figs. 47.5 and 47.6). It is important to note that once the pathology has been treated, the entire duct must be explored so as to ensure there are no further causes of obstruction, including the withdrawal of the scope under vision [6].

As the scope is guided through the primary and secondary ducts, the colour and texture of the mucosa are noted which are an indicator of the presence of inflammation. In relation to sialoliths, the size, shape and position need to be assessed as these will determine the method of retrieval [6].

Between the submandibular and the parotid duct, the Stensen's duct is comparatively more difficult to navigate due to the presence of the masseteric bend.

Fig. 47.5 Sialolith

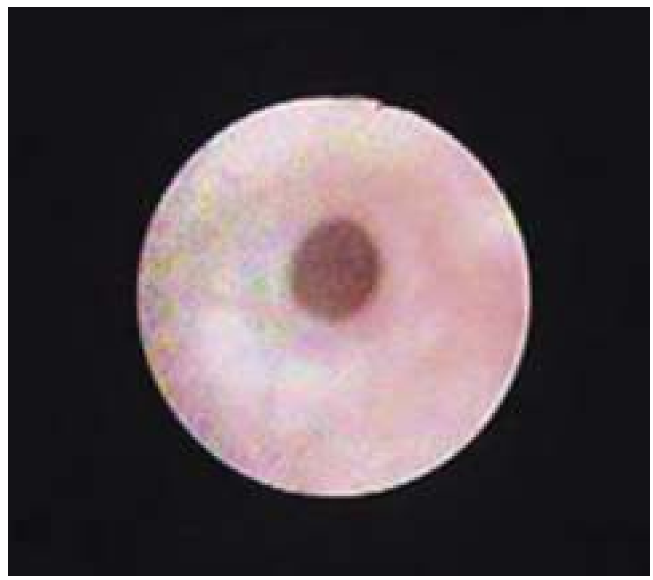

Fig. 47.6 Stricture

47.9 Diagnostic vs. Interventional Sialendoscopy

Indications for a diagnostic procedure include clinical symptoms, yet an unremarkable ultrasound and stricture at the papilla opening, to assess size and position of sialoliths.

Diagnostic sialendoscopy is a low morbidity, minimally invasive technique, which becomes the investigational procedure of choice for salivary duct pathologies in all age groups. Sialendoscopy has the advantage of offering a real-time ductal view. Diagnostic endoscopy is occasionally therapeutic, in minor obstructions caused by mucous plugs which can be relieved by lavage.

Interventional sialendoscopy makes use of a wide array of armamentarium including wire baskets (Fig. 47.7), balloon catheters and holmium laser to assist in sialolith retrieval (Fig. 47.8).

Sialoliths with sizes ranging between 3 and 4 mm are amenable for endoscopic retrieval. Here they may be entrapped and retrieved by use of a wire basket or dragged to the punctual opening where a small incision is placed to facilitate removal.

Fig. 47.7 Sialolith entrapped within wire basket

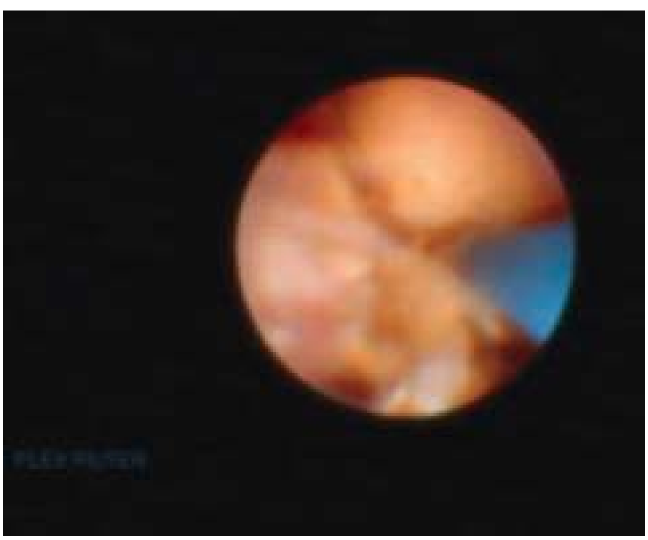

Fig. 47.8 Laser lithotripsy

Larger stones require a combined approach, whereby the position of the sialolith is identified and marked endoscopically and retrieved with an open surgical approach. The open approaches for submandibular sialoliths may be as small as a papillotomy or an extensive dissection of the floor of the mouth. The lingual nerve and iatrogenic ranula formation are important considerations when operating in this region. Large parotid stones require a SMAS flap, for the identification and protection of facial nerve branches and the duct, as well as reconstruction post-retrieval. Sialocele formation is an important consideration.

Hollow bougies of increasing diameter can threaded over a guide wire to widen strictures at the papillae. Balloons are another means of treating ductal strictures and once introduced through the working channel of the sialendoscope are inflated to dilate narrowed areas of the duct wall.

Stents are placed to maintain the patency of the duct and also to allow an incised duct to heal over with the aim of preventing stenosis. These stents are generally kept in place for up to 3 weeks. The authors have devised a salivary stent (Moorthy-Bachalli stent), made of polyurethane. These stents are available in sizes ranging from 3.5 French (diameter, 1 Fr = 0.3 mm) to 8 French and lengths from 5 to 7 cm with markings every centimetre. The stents also have a flange with prefabricated suture holes to facilitate suturing to the surrounding mucosa. An Ethilon 4-0 suture is preferred by the authors.

47.10 Complications

Like any other surgical procedure, open or endoscopic, sialendoscopy has its fair share of complications (Table 47.1).

Table 47.1 Complications of sialendoscopy

Complications	Management
Inability to locate papilla	Abort procedure/open approach to submandibular/parotid duct
False passage	If possible to locate duct-proceed, and abort procedure otherwise
Duct perforation	If possible to navigate beyond-proceed In case of floor of mouth or cheek oedema, then abort
Duct avulsion	Gland excision

47.11 Summary

When compared to other medical specialities, particularly otorhinolaryngologists, maxillofacial surgery is still in a primitive stage as far as the use of endovision is concerned. Hopefully an interest in areas like endoscopic management of salivary gland and temporomandibular joint diseases will narrow this gap.

Sialendoscopy is still in its infancy, in many parts of the world. Despite the challenges, growing awareness and the added attraction of minimally invasive surgery is steadily making it a popular choice for managing salivary ductal disease.

Part XVI

Maxillofacial Traumatology

Primary Assessment and Care in Maxillofacial Trauma

48

Saurabh Saigal and Manal M. Khan

48.1 Introduction [1, 2]

Maxillofacial injuries are common in polytrauma patients, and spectrum can be minor to life-threatening injuries. Primary assessment and management can be very important. They can involve facial soft tissues, facial bones, or both. Maxillofacial injuries can be due to various causes including road traffic accidents, assaults, and fall from height, industrial injuries, animal bites, sports injuries, burns, and war injuries. Life-threatening maxillofacial injuries can complicate the initial management of a trauma patient due to presence of concomitant injuries to airway, head, or cervical spine.

The mechanism for this injury is exemplified by an unbelted automobile passenger who is thrown into the windshield and dashboard. Trauma to midface can produce fractures and dislocations that compromise the nasopharynx and oropharynx. Facial fractures can be associated with hemorrhage, increased secretion, and dislodged teeth. Fractures of mandible, especially bilateral body fractures, can cause loss of normal airway and structural support. Airway obstruction can result if the patient is in supine position.

The term "golden hour" has to be kept in mind while handling the trauma patient which indicates that the injured patient has 1 h (60 min) from the time of injury to receive definitive care. After that there will be significant increase in the morbidity and mortality of the patient. "Chances of survival of the critically injured patient will largely determine after the first hour" [3].

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_48) contains supplementary material, which is available to authorized users.

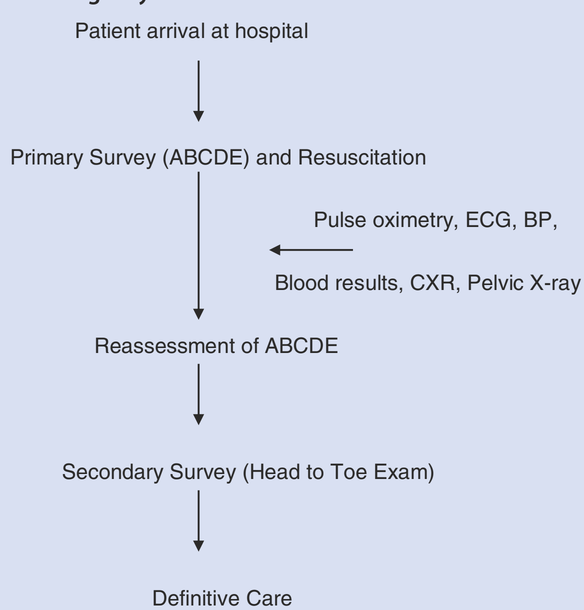
48.2 Triage [4]

Sorting of patients based on their need for treatment and the available resources to provide the treatment is triage. This sorting may be carried out by the paramedic team at the accident scene or receiving hospital who decides what level of care is required. It may be based on which patients need immediate, lifesaving interventions, which can wait and which are, in fact, beyond saving. Depending on the urgency of treatment required, maxillofacial injuries can be broadly placed into one of four groups (Table 48.1).

Appropriate triage and prompt evaluation, using the Advanced Trauma Life Support (ATLS) system, benefit patients [5].

Box 48.1 Step-by-Step Management of a Trauma Patient in Emergency Unit



K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_48

Table 48.1 Triage color coding

Group	Color coding	Description
Group 1	Red	Intervention required within few minutes. Immediate lifesaving management needed (airway compromise, severe uncontrolled blood loss)
Group 2	Yellow	Intervention required within few hours. Patient stable but urgent management needed (cranial fractures with open dura, contaminated wounds, and open fractures)
Group 3	Green	Intervention required within few days. Can wait a day or two (clean laceration and some fractures)
Group 4	Black	Intervention required within few weeks. Can wait for more days (most fractures)

48.2.1 Glasgow Coma Scale (Please Refer Table 7.5 in Chap. 7 of this book)

There are three variables used with the scale:

Best motor response (level of central nervous system function)
Best verbal response (ability of CNS to integrate information)
Eye opening (brainstem activity)

48.3 Primary Survey and Resuscitation [6]

The primary survey is a rapid, reproducible physical examination to evaluate every trauma patient and is designed to diagnose and treat immediately life-threatening conditions first. All patients are evaluated for physiologic or anatomic derangements that could lead to early mortality and morbidity. Treatment of problems identified during the primary survey begins without delay, before the survey is completed.

The sequence of primary survey is ABCDE:

1. **A**irway with cervical spine control
2. **B**reathing with ventilation
3. **C**irculation and hemorrhagic control
4. **D**isability management (neurological)
5. **E**xposure with environment control

Patient monitoring (pulse oximetry, electrocardiogram (ECG), blood pressure (BP), blood results, chest and pelvic radiographs) should run in parallel with the primary survey. Team approach is crucial for primary survey.

48.3.1 Airway with Cervical Spine Control

Airway assessment is first and foremost priority of primary survey. Patients with maxillofacial and head injuries are at high risk of compromised airway.

Causes of upper airway obstruction

1. Foreign body aspiration
2. Tongue fall position
3. Tracheal, laryngeal, facial, and mandibular fractures
4. Regurgitation of stomach contents

Maxillofacial injuries can cause airway obstruction because of:

- Bilateral anterior mandible fracture allows the tongue to fall posteriorly
- Downward and backward displacement of maxilla into nasopharynx, after midface fracture
- Blood clots and secretions
- Foreign bodies in the form of avulsed teeth or dentures

The chin lift or jaw-thrust maneuver is recommended to achieve patency of airway. The patient's head and neck should not be hyperextended, hyperflexed, or rotated to establish and maintain the airway. There may be associated cervical spine injury; all the cases are treated as they are having cervical spine injury unless diagnosed otherwise. Hence, cervical spine stabilization should be done.

48.3.2 Airway and Ventilatory Problems in Maxillofacial Trauma (Please Refer Chap. 7 of this book)

Early preventable deaths from airway problem after maxillofacial trauma often result from:

- Failure to identify the need for an airway intervention
- Inability to establish an airway
- Lack of backup or alternative airway plan in the setting of failed intubation attempts

- Failure to recognize an incorrectly placed airway
- Displacement of a previously established airway
- Failure to identify the need for ventilation
- Aspiration of gastric contents during dealing with airway

48.3.3 Airway and Ventilation Are the First Priorities

Airway compromise may be sudden and complete, insidious and partial, and/or progressive and recurrent. The early sign of airway or ventilator compromise is tachypnea or inability to speak words or sentences. "Talking patient" provides reassurance for that period of time that the airway is patent and not compromised. Failure to respond or an inappropriate response suggests an altered level of consciousness, airway and ventilator compromise, or both. Patient with the altered level of consciousness is at particular risk for airway compromise and aspiration, so he requires definite airway.

48.3.4 Objective Signs of Airway Obstruction

1. Observe the patient for agitation and obtundation, suggest hypercarbia, and cyanosis indicates hypoxemia due to inadequate oxygenation which can be identified by inspection of nail beds and circum-oral skin. However, cyanosis is a late finding of hypoxia. Pulse oximetry is used early in the airway assessment, to detect inadequate oxygenation prior to development of cyanosis. Look for retractions and use of accessory muscles of ventilation that, when present, provide additional evidence of airway compromise.
2. Listen for abnormal, noisy sound breathing which is usually snoring, gurgling, and crowing sound (stridor) and can be associated with partial obstruction of the pharynx or larynx. Hoarseness (dysphonia) implies functional, laryngeal obstruction.
3. Feel for location of trachea, and quickly determine whether it is in the midline position.
4. Evaluate patient behavior. Abusive and belligerent patient may in fact have hypoxia and should not be presumed to be intoxicated (suggestive of hypoxia, then only presume intoxication).

48.3.5 Airway Management [7, 8]

To assess airway patency and adequate ventilation quickly and accurately, pulse oximetry and end-tidal CO_2 measurement are essential. There are some measures to improve the oxygenation including airway maintenance techniques, definitive airway measures, or surgical airways. Because abovementioned measures include some movement of the neck, it is important to maintain cervical spine protection in all patients of trauma.

High-flow oxygen is required both before and immediately after airway management measures are instituted. A rigid suction device is essential and should be readily available. Nasal route for endotracheal route should not be chosen in patients with facial injury and midface injury. Patients who are wearing helmet and require airway management need their head and neck held in a neutral position. For this two-person procedure, one person provides manual inline stabilization from below, while the second person expands the helmet laterally and removes it from above. Then inline stabilization is re-established from above. And patient's head and neck are secured during airway management. Removal of the helmet using a cast cutter while stabilizing the head and neck can minimize cervical spine (C spine) motion in patients with known C spine injury [9].

Tracheostomy - Video 48.1.

Box 48.2 Need for Airway Protection

1. Severe maxillofacial fractures
2. Risk for obstruction
   - Neck hematoma
   - Laryngeal or trachea
   - Stridor
3. Risk for aspiration
   (i) Bleeding
   (ii) Vomiting
4. Unconscious

Box 48.3 Need for Ventilation or Oxygenation

1. Inadequate respiratory efforts
   - Tachypnea
   - Hypoxia
   - Hypercapnia
   - Cyanosis
2. Massive blood loss and need for volume resuscitation
3. Severe closed injury with need for brief hyperventilation if acute neurologic deterioration occurs
4. Apnea
   - Neuromuscular paralysis
   - Unconscious

48.3.6 Breathing with Ventilation

Next, the patient's breathing, ventilation, and oxygenation should be assessed, and any life-threatening derangements must be treated. Physical examination, pulse oximetry, and continuous end-tidal carbon dioxide monitoring should be used. For proper ventilation the lungs, chest wall, and diaphragm must all function adequately.

The most common interventions performed during the primary survey to support breathing are supplemental oxygen delivery, assisted or mechanical ventilation, and tube thoracotomy or chest tube insertion.

48.3.7 Ventilation

Sometimes it will happen that airway of the patient will be patent but ventilation will be inadequate, so look for the objective signs of inadequate ventilation**.** Ventilation may be compromised by airway obstruction, altered ventilatory mechanics, and central nervous system depression.

Following are the conditions where the ventilation may be compromised:

1. Direct trauma to the chest, like rib fractures, leading to severe pain during breathing and leads to shallow breathing and hypoxemia.
2. Elderly patients and other individual with pulmonary dysfunction are at significant risk for ventilator failure.
3. Intracranial injury can cause abnormal breathing patterns and compromised adequacy of ventilation.
4. Cervical spinal cord injury can result in diaphragmatic breathing and interfere with the ability to meet increased oxygen demands.
5. Complete cervical cord transection, which spares the phrenic and results in abdominal breathing paralysis of the intercostal muscles, and assisted ventilation may be required.

48.3.8 Objective Signs of Inadequate Ventilation

1. Symmetrical rise and fall of the chest and adequate chest wall excursion indicate the adequate ventilation, but asymmetrical rise and fall suggests splitting of rib cage or flail chest. Labored breathing may indicate an imminent threat to the patient's ventilation.
2. Listen for movement of air on both sides of the chest. Decreased or absent sounds over one or both hemithoraces should alert examiner to the presence of thoracic injury. Beware of rapid respiratory rate—tachypnea can indicate respiratory distress.
3. Use a pulse oximeter: This device provides information regarding patient's oxygen saturation and peripheral perfusion.

48.3.9 Circulation and Hemorrhage Control

Circulation must be assessed to determine the presence or absence of shock after addressing the highest priorities in the primary survey (airway and breathing). Shock is defined as inadequate organ perfusion and tissue oxygenation. In the trauma patient, shock is assumed to be hypovolemic/hemorrhagic, and resuscitation begins as soon as vascular access can be obtained. The possibility of neurogenic shock (e.g., spinal cord injury) or cardiogenic shock (e.g., pericardial tamponade) should also be considered. The focus of this segment of the primary survey should be assessing for the presence of shock, determining the cause (usually blood loss), and beginning resuscitation.

Signs of poor perfusion include a weak pulse, cool or clammy extremities, dry mucous membranes, pale skin, and confusion. A normal mental status examination confirms the presence of acceptable cerebral perfusion. The goal of resuscitation is to maintain tissue perfusion and homeostasis.

48.3.10 Bleeding

External or internal bleeding source should be identified. External hemorrhage is identified and controlled during the primary survey. Rapid external blood loss is managed:

- By direct manual pressure on the wound
- Tourniquets which are effective in massive exsanguinations from an extremity

Internal hemorrhage areas are chest, abdomen, retroperitoneum, pelvis, and long bones. Chest X-ray, pelvic X-ray, or focused assessment sonography in trauma (FAST) can be done to identify the source of bleeding.

48.3.11 Disability Management

The primary focus is on rapidly determining a patient's mental status and neurologic function via physical examination. The Glasgow Coma Scale (GCS) is a rapid and reliable way to quantify a patient's level of consciousness (Table 7.5). The GCS score allows for quick communication among clinicians about a patient's current mental status and can be important for decision-making. The neurologic assessment also includes an examination of the cranial nerves, pupils, and sensory and motor function.

48.3.12 Exposure with Environment Control

Exposure and environment are the final components of the primary survey. While lowering priority, they are still vital to the successful management of the trauma patient. The patients should be completely exposed so that injuries can be fully assessed. Decontamination may also be needed, depending on the nature of the trauma. Protection from hypothermia and continuous temperature monitoring are essential.

48.3.13 Monitoring of Adequacy of Oxygenation

Oxygenated inspired air is best provided via tight-fitting oxygen reservoir face mask with a flow rate of at least 11 L/min. Other methods (e.g., nasal catheter and non-breather mask) can improve the inspired oxygen concentration. Pulse oximetry is a noninvasive method of continuously measuring the oxygen saturation (O_2 sat) of arterial blood. It does not measure the partial pressure of oxygen (PaO_2), and depending upon the position of oxy-hemoglobin dissociation curve, the PaO_2 can vary widely. However a measured saturation of 95% or greater by pulse oximetry strongly suggests adequate peripheral artery oxygenation ($PaO_2 > 70$ mmHg).

Pulse oximetry requires intact peripheral perfusion and can't distinguish oxy-hemoglobin from carboxy-hemoglobin or methemoglobin, which limits its usefulness in patients with severe vasoconstriction and those with carbon monoxide poisoning. Profound anemia (Hb > 5 g/dL) and hypothermia (<30 °C) decrease the reliability of the technique. However, in most patient pulse oximetry is useful as the continuous monitoring of oxygen saturation provides an immediate assessment of therapeutic intervention.

48.3.14 Electrocardiographic (ECG) Monitoring

ECG monitoring of trauma patient is important.

Box 48.4

Injury indication	ECG changes
Blunt cardiac injury	Dysrhythmias including unexplained tachycardia, atrial fibrillation, premature ventricular contractions, and ST segment changes
Cardiac tamponade Tension pneumothorax Profound hypovolemia	Pulseless electrical activity (PEA)

48.3.15 Fluid Resuscitation

Warm resuscitation fluids should be given. IV fluid therapy with crystalloids should be initiated. A bolus of 1–2 L of an isotonic solution may be required to achieve an appropriate response in adult patient.

48.3.16 Urinary and Gastric Catheters

Urine output monitoring is important to manage the fluid therapy. Urine output reflects renal perfusion, and it is accomplished by insertion of indwelling bladder catheter.

Contraindications to the placement of Foley catheter and urethral injury should be suspected in the presence of:

1. Blood at the urethral meatus
2. Hemorrhage into the scrotum
3. High-riding prostate

A gastric tube is indicated to:

1. Reduce stomach distension
2. Decrease risk of aspiration
3. Assess for upper gastrointestinal hemorrhage from trauma

48.4 Secondary Survey [10–12]

Once the primary survey is completed, secondary survey is started. If additional personnel is available, then part of secondary survey can be conducted along with primary survey; however, it should be made sure that it does not interfere with primary survey, as primary survey is the first priority.

Secondary survey is a complete head to toe examination of the trauma patient which includes complete history taking and physical examination. During secondary survey, a complete neurologic examination is conducted. Patient's GCS score is identified, radiographs are obtained, and laboratory studies are conducted as indicated.

48.4.1 History Taking

A complete medical assessment includes history taking and understanding the mechanism of the injury. Often, patient is not in a condition to provide this history. In such cases, it should be obtained from the family members. The history taking involves identification of various allergies, present medications, past history of any illness, pregnancy, last meal taken, and the event of trauma. The mechanism of injury must be understood whether it's inflicted by a penetrating or blunt trauma or if the injury is thermal injury or due to hazardous environment.

48.4.2 Physical Examination

During physical examination in secondary survey, a sequence has to be followed, which is examination of head, maxillofacial structures, cervical spine and neck, chest, abdomen, perineum/rectum/vagina, musculoskeletal system, and neurologic system.

48.4.3 Four-Person Logroll

To examine the patient's back and remove the spine board, at least four persons are required for logrolling:

(a) Person one stands at the patient's head to control the head and C spine and two persons along the patient's sides to control the body and extremities.
(b) Three persons maintain the alignment of spine, as the patient is rolled.
(c) Fourth person examines the back and removes the board.
(d) Once the board is removed, patient is returned into the supine position while maintaining the alignment of spine.

48.4.4 Head

Secondary survey starts with examination of head which involves identification of injuries. The complete scalp should be examined for lacerations, contusions, and evidence of fractures. Other than these injuries, visual acuity, pupillary size, hemorrhage of conjunctiva and/or fundi, and ocular entrapment must be examined. These aspects must be re-evaluated once the periocular edema subsides.

Visual acuity examination must be done by asking the patient to read printed material such as handheld Snellen chart. To exclude ocular entrapment, ocular movement must be checked.

48.4.4.1 Classification of Brain Injury

Box 48.5

Severity	GCS score
Minor	13–15
Moderate	9–12
Severe	3–8

Intracranial lesions may be classified as diffuse or focal. The focal lesions include epidural hematomas, subdural hematomas, contusions, and intracerebral hematomas.

Signs of skull base fracture:

1. Hematoma or ecchymosis over the mastoid (Battle's sign)
2. CSF otorrhea or rhinorrhea
3. Hemotympanum
4. Subscleral hemorrhage

Computed tomography (CT) scan of the head should be carried out to accurately assess the neurologic injuries and detect mass lesions. CT scan helps in diagnosing:

– Intracranial hemorrhage
– Contusion
– Skull fractures
– Foreign bodies
– Brain shift
– Hydrocephalus

In a comatose patient, motor responses may be elicited by pinching the trapezius muscle or with nail bed or supraorbital pressure. Testing for doll's eye movements (oculocephalic) the caloric test with ice water (oculovestibular) and testing of corneal responses are deferred to a neurosurgeon.

48.4.5 Maxillofacial Structures

Maxillofacial examination includes examination of soft tissue, palpation of all the bony structures, checking of occlusion, and intraoral examination. Trauma to the maxillofacial region not associated with airway obstruction should be treated once the patient is stabilized after the management of life-threatening injuries.

48.4.6 Cervical Spine and Neck

Patients with maxillofacial trauma must be presumed to have an unstable cervical spine injury unless it is proven otherwise. The absence of any neurologic deficit does not exclude the presence of any C spine injury. A complete cervical spine radiographs and CT scan should be done to evaluate C spine injury. The patient wearing any kind of helmet must be removed with extreme care.

C spine injuries can result from one or a combination of the following mechanism of injury:

- Flexion
- Axial loading
- Extension
- Rotation
- Lateral bending
- Distraction

A complete examination of neck includes inspection, palpation, and auscultation. Inspection should be done to note any blunt injury over the neck. Carotid arteries should be palpated and auscultated for bruits. Penetrating injuries of neck are potentially fatal. If the wound is deep, they should not be explored in emergency department [13].

A cervical collar can be applied to the patients suspecting the cervical spinal injury. Its role is to immobilize the C spine. Cervical collars are divided into two groups: soft and rigid collars. Soft collars are generally used for whiplash injury; some surgeons prefer rigid collars. Rigid collars provide excellent immobilization in transverse and sagittal planes compared with soft collars. However patient's comfort is to be taken into consideration in selecting the collars. The Philadelphia collar is available in two pieces having front and back pieces; it is held together by Velcro straps to support the neck [14].

48.4.7 Chest

Chest examination includes inspection, palpation, percussion, and auscultation. Inspection of anterior and posterior chest can identify conditions like open pneumothorax and large flail segments. Contusions and hematoma over chest suggest occult injury. Palpation of entire rib cage, clavicle, and sternum helps in diagnosing fractures. Significant injury may present with pain, dyspnea, and hypoxia.

Auscultation of high anterior chest helps in diagnosis of pneumothorax, whereas posterior base auscultation reveals hemothorax. Cardiac tamponade can be identified by the presence of distant heart sounds and decreased pulse pressure. Presence of distended neck veins suggests cardiac tamponade and tension pneumothorax. A chest radiograph may confirm the presence of hemothorax or simple pneumothorax.

48.4.7.1 Classification of Chest Trauma

Immediate life-threatening chest injuries are to be identified and treated during primary survey.

These six life-threatening chest injuries include:

1. Open pneumothorax
2. Tension pneumothorax
3. Open pneumothorax
4. Flail chest and pulmonary contusion
5. Massive hemothorax
6. Cardiac tamponade

48.4.7.2 Managing Chest Trauma [15]

The basic principles of management remain the same with the universal sequence of airway, breathing, and circulation to be treated in that sequence.

48.4.7.3 Airway

It is necessary to recognize and address major injuries affecting the airway during the primary survey. Airway patency and air exchange should be assessed by listening for air movement at the patient's nose, mouth, and lung fields; inspecting the oropharynx for foreign body obstruction; and observing for intercostal and supraclavicular muscle retractions. Laryngeal injury can accompany major thoracic trauma. Although the clinical presentation is occasionally delayed, acute airway obstruction from laryngeal trauma is a life-threatening injury. Injury to the upper chest can create a palpable defect in the region of the sternoclavicular joint, with posterior dislocation of the clavicular head, which causes upper airway obstruction. Identification of this injury is made by listening for upper airway obstruction (stridor) or a marked change in the expected voice quality, if the patient is able to talk. Management consists of a closed reduction of the injury, which can be performed by extending the shoulders or grasping the clavicle with a pointed instrument, such as a towel clamp, and manually reducing the fracture. Once reduced, this injury is usually stable if the patient remains in the supine position.

48.4.7.4 Breathing

The patient's chest and neck should be completely exposed to allow for assessment of breathing and the neck veins. This may require temporarily releasing the front of the cervical collar following blunt trauma. In this case, cervical spine immobilization should always be actively maintained by holding the patient's head while the collar is loose. Respiratory movement and quality of respirations are assessed by observing, palpating, and listening. Important, yet often subtle, signs of chest injury or hypoxia include an increased respiratory rate and change in the breathing pattern, which is often manifested by progressively shallower respirations. Cyanosis is a late sign of hypoxia in trauma patients. However, the absence of cyanosis does not necessarily indicate adequate tissue oxygenation or an adequate airway. The major thoracic injuries that affect breathing and that must be recognized and addressed during the primary survey include tension pneumothorax, open pneumothorax (sucking chest wound), flail chest and pulmonary contusion, and massive hemothorax.

*Important***:** After intubation, one of the common reasons for loss of breath sounds in the left thorax is a right mainstem intubation. During the reassessment, be sure to check the position of the endotracheal tube before assuming that the change in physical examination is due to a pneumothorax or hemothorax.

48.4.7.5 Tension Pneumothorax

A tension pneumothorax develops when a "one-way valve" air leak occurs from the lung or through the chest wall. Air is forced into the pleural space without any means of escape, eventually completely collapsing the affected lung. The mediastinum is displaced to the opposite side, decreasing venous return and compressing the opposite lung. Shock results from the marked decrease in venous return causing a reduction in cardiac output and is often classified as obstructive shock (Fig. 48.1). The most common cause of tension pneumothorax is mechanical ventilation with positive-pressure ventilation in patients with visceral pleural injury. However, a tension pneumothorax can complicate a simple pneumothorax following penetrating or blunt chest trauma in which a parenchymal lung injury fails to seal or after a misguided attempt at subclavian or internal jugular venous catheter insertion. Occasionally, traumatic defects in the chest wall also can cause a tension pneumothorax if incorrectly covered with occlusive dressings or if the defect itself constitutes a flap-valve mechanism. Tension pneumothorax rarely occurs from markedly displaced thoracic spine fractures. Tension pneumothorax is a clinical diagnosis reflecting air under pressure in the affected pleural space. Treatment should not be delayed to wait for radiologic confirmation.

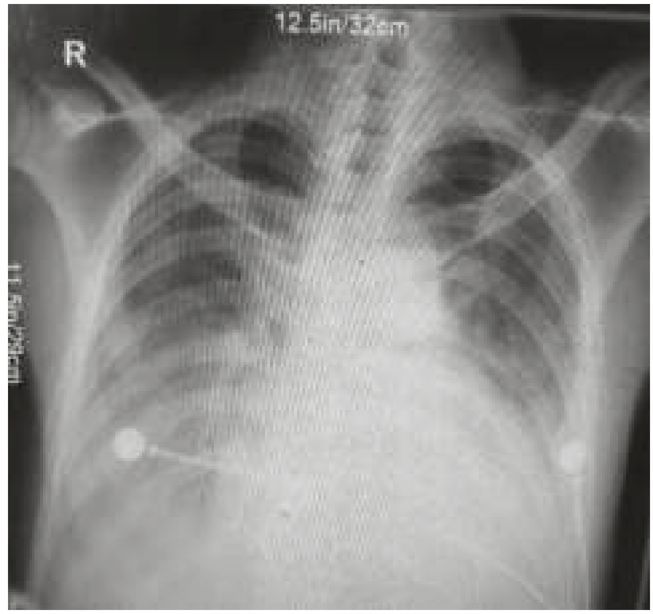


Fig. 48.1 Tension pneumothorax

> Tension pneumothorax is characterized by some or all of the following signs and symptoms:
>
> Chest pain
> Air hunger
> Respiratory distress
> Tachycardia
> Hypotension
> Tracheal deviation away from the side of injury
> Unilateral absence of breath sounds
> Elevated hemithorax without respiratory movement
> Neck vein distention
> Cyanosis (late manifestation)

Because of the similarity in their signs, tension pneumothorax can be confused initially with cardiac tamponade. Differentiation is made by a hyper-resonant note on percussion, deviated trachea, and absent breath sounds over the affected hemithorax, which are signs of tension pneumothorax. Tension pneumothorax requires immediate decompression and may be managed initially by rapidly inserting a large-caliber needle into the second intercostal space in the midclavicular line of the affected hemithorax. However, due to variable thickness of the chest wall, kinking of the catheter, and other technical or anatomic complications, this maneuver may not be successful [16].

When successful, this maneuver converts the injury to a simple pneumothorax; however, the possibility of subsequent pneumothorax as a result of the needle stick now exists, so repeated reassessment of the patient is necessary. Chest wall thickness influences the likelihood of success with needle decompression. Recent evidence suggests that a 5 cm needle will reach the pleural space >50% of the time, whereas an 8 cm needle will reach the pleural space >90% of the time. Even with a needle of the appropriate size, the maneuver will not always be successful. Definitive treatment requires the insertion of a chest tube into the fifth intercostal space (usually at the nipple level), just anterior to the midaxillary line.

In a tension pneumothorax, air from a ruptured lung enters the pleural cavity without a means of escape. As air pressure builds up, the affected lung is compressed, and all of the mediastinal tissues are displaced to the opposite side of the chest.

48.4.7.6 Open Pneumothorax (Sucking Chest Wound)

Large defects of the chest wall that remain open can result in an open pneumothorax, which is also known as a sucking chest wound. Equilibration between intrathoracic pressure and atmospheric pressure is immediate. Air tends to follow the path of least resistance; as such, if the opening in the chest wall is approximately two-thirds of the diameter of the trachea or greater, air passes preferentially through the chest wall defect with each respiratory effort. Effective ventilation is thereby impaired, leading to hypoxia and hypercarbia. Initial management of an open pneumothorax is accomplished by promptly closing the defect with a sterile occlusive dressing. The dressing should be large enough to overlap the wound's edges and then taped securely on three sides in order to provide a flutter-type valve effect. As the patient breathes in, the dressing occludes the wound, preventing air from entering. During exhalation, the open end of the dressing allows air to escape from the pleural space. A chest tube remote from the wound should be placed as soon as possible. Securely taping all edges of the dressing can cause air to accumulate in the thoracic cavity, resulting in a tension pneumothorax unless a chest tube is in place. Any occlusive dressing (e.g., plastic wrap or petrolatum gauze) may be used as a temporary measure so that rapid assessment can continue. Subsequent definitive surgical closure of the defect is frequently required [17].

48.4.7.7 Flail Chest and Pulmonary Contusion

A flail chest occurs when a segment of the chest wall does not have bony continuity with the rest of the thoracic cage. This condition usually results from trauma associated with multiple rib fractures, that is, two or more adjacent ribs fractured in two or more places (Fig. 48.2). The presence of a flail chest segment results in disruption of normal chest wall movement. Although chest wall instability can lead to paradoxical motion of the chest wall during inspiration and expiration, this defect alone does not cause hypoxia. The major difficulty in flail chest stems from the injury to the underlying lung (pulmonary contusion). If the injury to the underlying lung is significant, serious hypoxia can result. Restricted chest wall movement associated with pain and underlying lung injury is major causes of hypoxia. Flail chest may not be apparent initially if a patient's chest wall has been splinted, in which case he or she will move air poorly and movement of the thorax will be asymmetrical and uncoordinated. Palpation of abnormal respiratory motion and crepitation of rib or cartilage fractures can aid the diagnosis. A satisfactory chest X-ray may suggest multiple rib fractures but may not show costochondral separation. Initial treatment of flail chest includes adequate ventilation, administration of humidified oxygen, and fluid resuscitation. In the absence of systemic hypotension, the administration of crystalloid intravenous solutions should be carefully controlled to prevent volume overload, which can further compromise the patient's respiratory status.

The definitive treatment is to ensure adequate oxygenation, administer fluids judiciously, and provide analgesia to improve ventilation. The latter can be achieved with intravenous narcotics or local anesthetic administration, which

Fig. 48.2 Flail chest with pulmonary contusion

avoids the potential respiratory depression common with systemic narcotics. The options for administration of local anesthetics include intermittent intercostal nerve block(s) and intrapleural, extrapleural, or epidural anesthesia. When used properly, local anesthetic agents can provide excellent analgesia and prevent the need for intubation. However, prevention of hypoxia is of paramount importance for trauma patients, and a short period of intubation and ventilation may be necessary until diagnosis of the entire injury pattern is complete. A careful assessment of the respiratory rate, arterial oxygen tension, and work of breathing will indicate appropriate timing for intubation and ventilation [18].

48.4.7.8 Massive Hemothorax

Massive hemothorax results from the rapid accumulation of more than 1500 mL of blood or one-third or more of the patient's blood volume in the chest cavity (Fig. 48.3). It is most commonly caused by a penetrating wound that disrupts the systemic or hilar vessels. However, massive hemothorax can also result from blunt trauma. In patients with massive hemothorax, the neck veins may be flat as a result of severe hypovolemia, or they may be distended if there is an associated tension pneumothorax. Rarely will the mechanical effects of massive intrathoracic blood shift the mediastinum enough to cause distended neck veins. A massive hemothorax is suggested when shock is associated with the absence of breath sounds or dullness to percussion on one side of the chest. This blood loss is complicated by hypoxia. Massive hemothorax is initially managed by the simultaneous restoration of blood volume and decompression of the chest cavity.

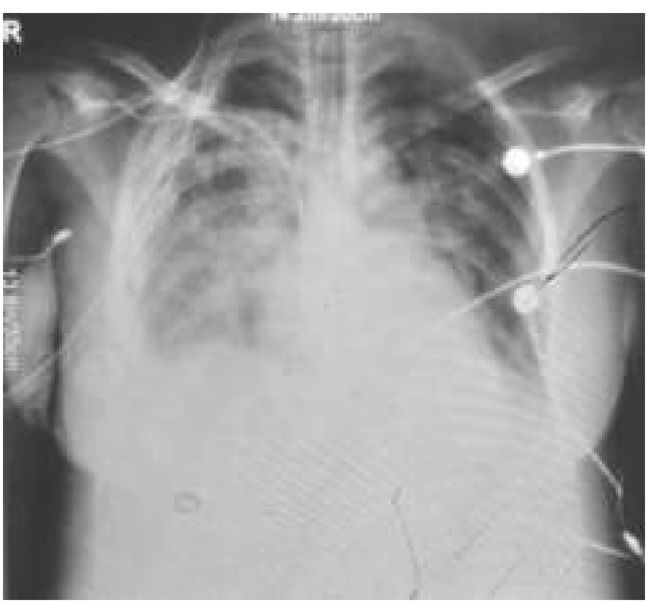

Fig. 48.3 Hemothorax

Large-caliber intravenous lines and a rapid crystalloid infusion are begun, and type-specific blood is administered as soon as possible. Blood from the chest tube should be collected in a device suitable for autotransfusion. A single chest tube (36 or 40 French) is inserted, usually at the nipple level, just anterior to the midaxillary line, and rapid restoration of volume continues as decompression of the chest cavity is completed. When massive hemothorax is suspected, prepare for autotransfusion. If 1500 mL of fluid is immediately evacuated, early thoracotomy is almost always required. Patients who have an initial output of less than 1500 mL of fluid, but continue to bleed, may also require thoracotomy. This decision is not based solely on the rate of continuing blood loss (200 mL/h for 2–4 h) but also on the patient's physiologic status. The persistent need for blood transfusions is an indication for thoracotomy. During patient resuscitation, the volume of blood initially drained from the chest tube and the rate of continuing blood loss must be factored into the amount of intravenous fluid required for replacement. The color of the blood (indicating an arterial or venous source) is a poor indicator of the necessity for thoracotomy. Penetrating anterior chest wounds medial to the nipple line and posterior wounds medial to the scapula should alert the practitioner to the possible need for thoracotomy because of potential damage to the great vessels, hilar structures, and the heart, with the associated potential for cardiac tamponade. Thoracotomy is not indicated unless a surgeon, qualified by training and experience, is present.

48.4.7.9 Cardiac Tamponade

Cardiac tamponade (Fig. 48.4) most commonly results from penetrating injuries. However, blunt injury also can cause the pericardium to fill with blood from the heart, great vessels, or pericardial vessel. The human pericardial sac is a fixed fibrous structure; a relatively small amount of blood can restrict cardiac activity and interfere with cardiac filling. Cardiac tamponade may develop slowly, allowing for a less urgent evaluation, or may occur rapidly, requiring rapid diagnosis and treatment. The diagnosis of cardiac tamponade can be difficult in the setting of a busy trauma or emergency room. Cardiac tamponade is indicated by the presence of the classic diagnostic Beck's triad: venous pressure elevation (distended neck veins), decline in arterial blood pressure, and muffled heart sounds. However, muffled heart tones are difficult to assess in the noisy examination area, and distended neck veins may be absent due to hypovolemia. Additionally, tension pneumothorax, particularly on the left side, can mimic cardiac tamponade. Kussmaul's sign (a rise in venous pressure with inspiration when breathing spontaneously) is a true paradoxical venous pressure abnormality associated with tamponade. Pulseless electrical activity (PEA) is suggestive of cardiac tamponade but can have other causes, as listed above [19]. Insertion of a central venous line with measurement of central venous pressure (CVP) may aid diagnosis, but CVP can be elevated for a

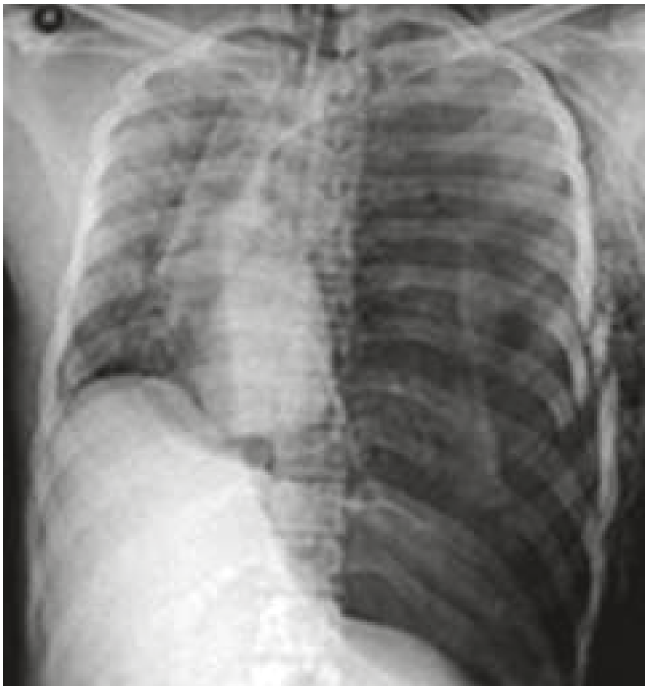

Fig. 48.4 Cardiac tamponade

variety of reasons. Additional diagnostic methods include echocardiogram, focused assessment sonography in trauma (FAST), or pericardial window. In hemodynamically abnormal patients with blunt or penetrating trauma and suspected cardiac tamponade, an examination of the pericardial sac for the presence of fluid should be obtained as part of a focused ultrasound examination performed by a properly trained provider in the emergency department (ED). FAST is a rapid and accurate method of imaging the heart and pericardium. It is 90–95% accurate for the presence of pericardial fluid for the experienced operator. Concomitant hemothorax may account for both false-positive and false-negative ultrasound exams. Prompt diagnosis and evacuation of pericardial blood are indicated for patients who do not respond to the usual measures of resuscitation for hemorrhagic shock and in whom cardiac tamponade is suspected. The diagnosis can usually be made with the FAST exam. If a qualified surgeon is present, surgery should be performed to relieve the tamponade. This is best performed in the operating room if the patient's condition allows. If surgical intervention is not possible, pericardiocentesis can be diagnostic as well as therapeutic, but it is not a definitive treatment for cardiac tamponade. However all patients with acute tamponade and a positive pericardiocentesis will require surgery to examine the heart and repair the injury. Pericardiocentesis may not be diagnostic or therapeutic when the blood in the pericardial sac has clotted. Preparation to transfer such a patient to an appropriate facility for definitive care is always necessary. Pericardiotomy via thoracotomy is indicated only when a qualified surgeon is available.

48.4.8 Abdomen [20]

Abdominal injuries must be identified and managed aggressively. It is not as important to arrive at a specific diagnosis as it is to recognize the injury which requires a surgical intervention. It is important to closely observe and re-evaluate the abdomen to identify the blunt injury. The safest management of penetrating wounds is a laparotomy.

Abdominal Trauma	
Blunt trauma	Penetrating trauma [21]
Direct blow, e.g., crushing injury to abdominal viscera and pelvis	Stab wounds commonly involve liver (40%), small bowel (30%), diaphragm (20%), and colon (15%)
Shearing injuries, e.g., laceration of the liver and spleen	Gunshot wounds commonly involve small bowel (50%), colon (40%), liver (30%), and abdominal vascular structures (25%)

The diagnostic peritoneal lavage (DPL) was used to diagnose blunt and occasionally penetrating abdominal trauma, but its use was decreased with the advancement of CT and USG. Focused assessment sonography in trauma (FAST) is very helpful to detect the presence of hemoperitoneum.

48.4.8.1 Focused Assessment Sonography in Trauma (FAST) [22]

The ultrasound machine and water-based gel are necessary to perform FAST.

Fast includes the following views:

1. **Pericardial view:** fluid within the heart should be black.
2. **Right upper quadrant view (RUQ):** diaphragm-liver interface and Morison's pouch.
3. **Left upper quadrant view (LUQ):** diaphragm-spleen interface and spleen-kidney interface
4. **Suprapubic view:** to see bladder

48.4.9 Perineum/Rectum/Vagina

Contusions, hematomas, lacerations, and urethral bleedings should be examined in the perineal area. The presence of blood at urethral meatus suggests urethral injury. Inspect the scrotum and perineum for ecchymosis or hematoma, also suggestive of injury to the urethra. In patients with perineal hematoma or high-riding prostate, Foley catheters should be avoided.

Rectal examination can be done to evaluate the presence of blood within the bowel lumen. In patients with the risk of vaginal injury, vaginal examination should be carried out. Pelvic compressions should be carried out to identify any pelvic fractures. Pelvic fractures can be suspected by the presence of ecchymosis over iliac wings, pubis, scrotum, or labia. The pelvic fracture can be divided into closed, open book, and vertical shear fracture. Hemorrhage control and fluid resuscitation will be in the initial management of major pelvic disruption associated with hemorrhage. Pelvic binder or sheet can apply sufficient stability for the unstable pelvis at the level of greater trochanters of the femur bone.

48.4.10 Musculoskeletal System

The patient must be completely undressed for adequate examination. Extremities should be inspected for deformities, abrasion, and contusions. Presence of tenderness on palpation of bones and abnormal movement helps in identification of occult fractures. Significant injuries of extremities can exist without fracture being evident. Ligament ruptures and a muscle tendon unit injury interferes with active motions. The musculoskeletal examination is incomplete without examination of the back of the patient.

Musculoskeletal injuries are a potential source of blood loss in patients with hemodynamic abnormalities. The proper splint application helps in blood loss control, reducing pain, and preventing further soft tissue injury. Splinting is required in the patients with joint dislocations.

Crush syndrome: it refers to the injured muscle which if left untreated can lead to acute renal failure. Traumatic rhabdomyolysis ranges from asymptomatic illness with elevation of creatine kinase level to a life-threatening condition associated with acute renal failure and disseminated intravascular coagulation (DIC). Early and aggressive fluid therapy protects the kidneys and prevents renal failure in patients with rhabdomyolysis.

Compartment syndrome: develops when the pressure within an osteofascial compartment of muscle causes ischemia and subsequent necrosis. Sometimes fasciotomy is required to manage the condition.

48.5 Conclusion

Management of airway is challenging in patients with maxillofacial trauma. Securing airway in these patients is dependent on the clinical status and the features of trauma. Before initiation of airway management, a series of steps are to be planned. For optimal care, one must have adequate knowledge of the specific attributes of difficult airway. Also, the expertise in techniques for managing the difficult airway, familiarity with devices, and recognition of failed airway are necessary. A multidisciplinary approach involving anesthesiologist, maxillofacial surgeon, and a trauma expert must be a practice for better outcome (please refer Chap. 7 for further reading).

49 Management of Soft Tissue Injuries in the Maxillofacial Region

Abhay Datarkar and Shikha Tayal

49.1 Introduction

Soft tissue injuries are one of the most commonly encountered injuries in head and neck region and present especially in the emergency department or surgical casualty. They can be isolated soft tissue injuries, or injuries having concomitant skeletal trauma. The frequent facial soft tissue injuries include simple lacerations, abrasions, contusions, bites, avulsions, and burns. These injuries are complicated by presence of vital anatomical structures like vessels, ducts, nerves, and muscles. Presence of foreign debris and hematoma further complicates the soft tissue injuries. The face is a region of high esthetics and functional importance. Hence, there are many factors that help to manage such injuries.

Factors that guide facial soft tissue injury management are:

(i) **Recognition of nature of the injury**—Helps in logical treatment planning that ultimately results in better esthetic and functional outcomes.
(ii) **Extent of injury**—Many facial soft tissue injuries that are relatively minor are treated in emergency department by the oral and maxillofacial surgeons. These wounds are managed by thorough cleaning, irrigation, debridement, primary suturing, and cleaning whenever needed. More complex wounds require special intervention by taking the patient into operation theatre and reconstructing using various grafts and flaps.
(iii) **Timing of the injury**—Any type of injury, by default, should be attended at the earliest to maximize the prognosis. The bottom line of many past and present literature is that the wounds of face and scalp should be primarily closed as soon as they are seen and as long as active infection is not present.

To achieve this, the surgeon needs to understand the etiopathogenesis, surgical anatomy, biomechanics of tissue wound, biology of wound healing, and the art of soft tissue repair.

49.2 Etiology

The most common etiology of facial soft tissue injuries varies according to the age, sex, and geographical distribution of the population. Facial soft tissue trauma tends to occur in certain areas of the head depending on the causative mechanism. It typically includes the T-shaped area that includes forehead, nose, lips, and chin, followed by the occiput and anterior temporal areas.

(a) **Falls** are by far the most common cause, accounting for 48–51% of the injuries [1, 2]. This etiology has a trimodal distribution. The first peak is 2–3 years, when toddlers begin to walk and fall into objects. There is smaller peak during the second and third decades and then a steady rise after age of 50 years. Alcohol consumption is a major factor for soft tissue injuries due to fall between 30 and 50 years. Medical comorbidities such as epilepsy are also the causative factor for falls in old age group.
(b) **Non-fall impacts**. Approximately 16% of facial soft tissue trauma is the result of a non-fall impact with structural element such a door, wall, or window frame. Other collisions with furnishings such as tables also counted. These types of injuries peak in children younger than 5 years. The common areas include the forehead, nose, and anterior temples.
(c) **Assaults** account for 16–32% of facial soft tissue injuries [1]. The assaults are most commonly caused by fists, kicks, and blunt instruments. The injuries due to assault occurs more frequently among young men on left side of face. Alcohol consumption is a factor in two-thirds of these patients.

Disclosure: Authors have no financial conflicts to disclose.

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_49

(d) **Road traffic accidents** cause 6–13% of facial trauma [2] where soft tissue injuries may occur alone or in combination with other fractures. The peak incidence is seen in young men at 15–24 years of age [3]. Impact from steering wheel, dashboard, and windshields results in most lacerations.

(e) **Sporting injuries** account for about 8% of facial soft tissue trauma [1], commonly occurring in young men. The forehead, nose, and teeth are the most likely areas to be injured. Concomitant facial fractures like nasal fractures, avulsive teeth injuries, and mandibular fractures are also common among these group of patients.

(f) **Others include occupational injuries, bites from humans or animals**, and other miscellaneous causes. Occupational injuries [3] account for 5% of facial trauma and are primarily seen in young men. The risk of dog bites is higher for children aged 5–9 years and decreases with age. The frequency of facial injuries is highest in children younger than 4 years, in whom nearly 65% of dog bite injuries involve the face. In adults, it is about 9%. Most dog bite injuries are from dogs known to person or occur near home. These injuries typically involve the cheek, lips, forehead, and nose.

49.3 Classification of Soft Tissue Injuries

Soft tissue injuries can be classified into multiple categories:

(A) **Based on mechanism of injuries**

(I) Mechanical or physical injuries:

- When injury is caused due to blunt force:
  1. Abrasions
  2. Contusions
  3. Lacerations
- When injury is caused due to sharp force:
  1. Incised wounds
  2. Chop wounds
  3. Stab/punctured wounds

(II) Thermal injuries:

- Due to excessive cold: e.g., frostbite
- Due to moist heat: e.g. burns and scald wounds

(III) Chemical injuries: Due to corrosive acids and alkalis

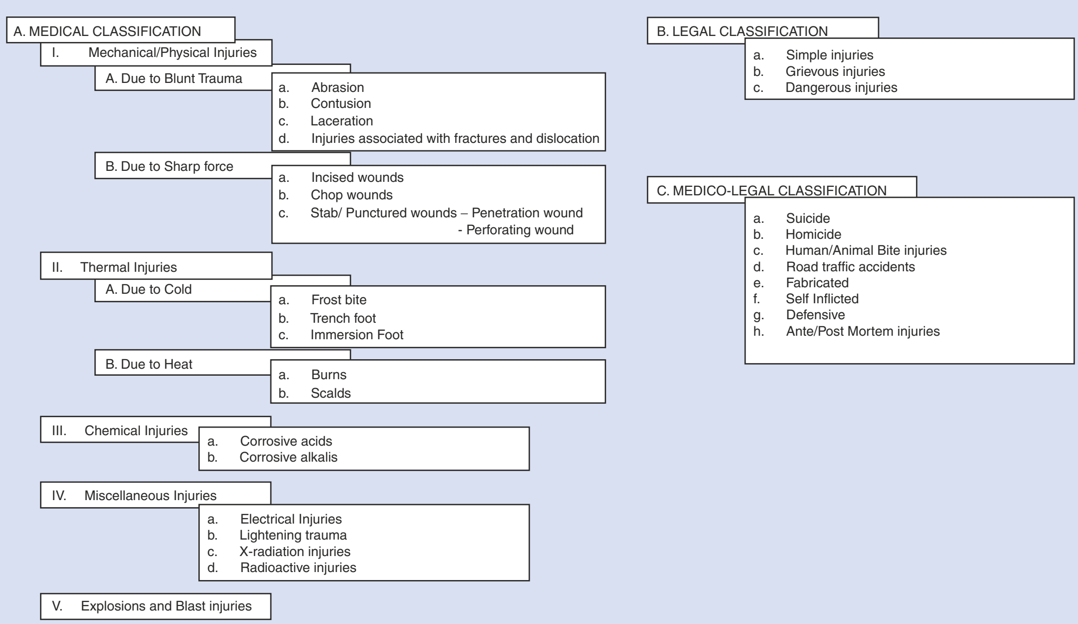
(IV) Miscellaneous: Electricity, lightning, etc.

(V) Explosions: Blast injuries

(B) **Legal classification**

1. **Simple**—soft tissue injuries without much tissue loss and can be managed conservatively. Heals rapidly without any permanent deformity.
2. **Grievous injuries**—described under Section 320 of Indian Penal Code as any injuries that endanger life and cause severe disfigurement or deformities like permanent hearing loss, vision loss, and severe head injuries. Tooth fracture or tooth loss following a blow in an interpersonal violence is also considered a grievous injury and penalized by the court of law. These injuries heal slowly and incompletely.
3. **Dangerous**—the grievous injuries that endanger life immediately after impact (Box 49.1).

Box 49.1 Classification of Soft Tissue Injuries



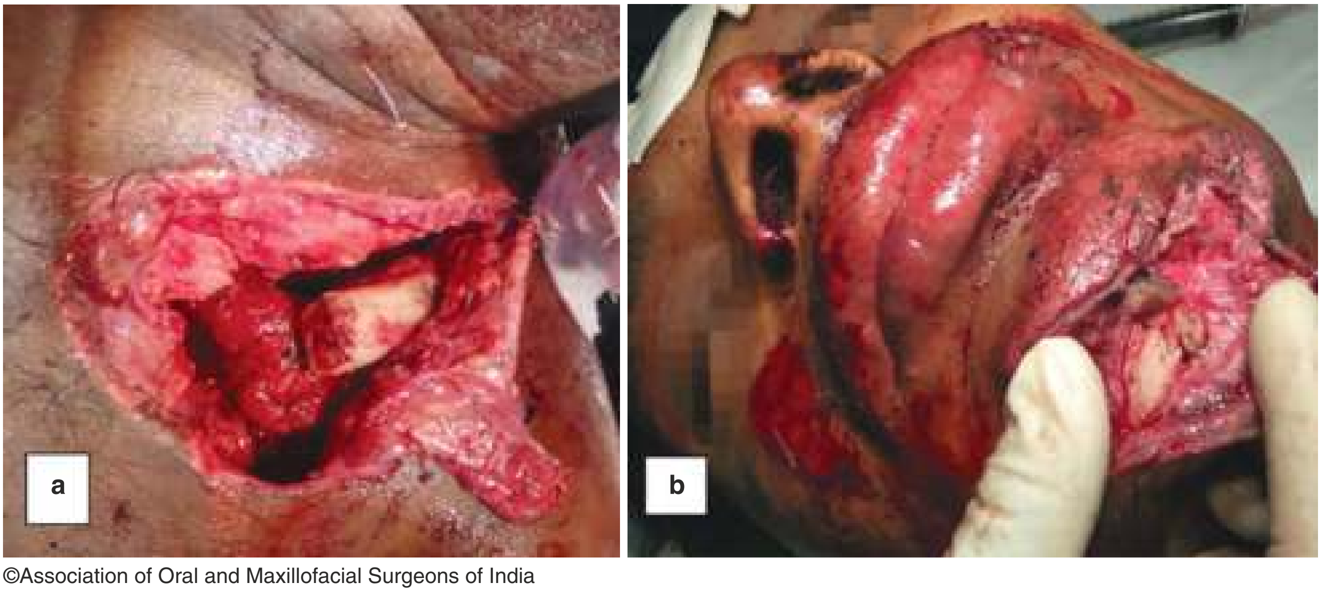


Fig. 49.1 (**a**) Showing open wound where fractured left clavicle is visible from the wound surface. (**b**) Open wound of maxillofacial region where underlying mandible is visible

(C) **Based on the communication of the injury with the external environment**

Closed wound: Only the underlying tissue and/or structures are damaged without breaking the skin. Examples of closed wounds include hematomas, contusions, and crush injuries. These types of wounds are not contaminated and, hence, heal on their own without any sequelae.

Open wounds: There is a break in the skin, which exposes the underlying structures to the external environment. Open wounds include simple and complex lacerations, avulsions, punctures, abrasions, accidental tattooing, and retained foreign body with a tendency to heal with scarring. These injuries require extensive exploration and debridement followed by a course of antibiotic regimen for uneventful healing (Fig. 49.1).

(D) **According to the facial subunit(s) involved**. The major esthetic subunits on the face are the scalp, forehead, nose, periorbital region, cheek, perioral region, auricle, and neck [4].

These major facial esthetic subunits are further divided into smaller subunits by location. The individual subunits must be reconstructed individually one by one in order to attain good esthetics (Fig. 49.2).

(E) **Based on additional injuries to the related structures**

(a) **Injuries to nerve**—The nerve injuries are most commonly encountered in cases of open wounds. The nerve injuries are further classified into neuropraxia, axonotmesis, and neurotmesis (Seddon's classification of nerve injuries [5]). Sunderland [6] further revised this classification of nerve injuries based on the histologic degree of nerve damage. There should be careful evaluation of sensory and motor components of the nerves in the involved region for proper treatment. The most commonly encountered nerve injuries in maxillofacial region are the facial nerve and trigeminal nerve.

(b) **Injuries to arteries and veins**—The face is a highly vascular region where even a small injury leads to significant bleeding. Any wound in maxillofacial region should be attended in emergency setting at the earliest due to chances of injury to the extensive vascular network which necessitates hemostasis.

(c) **Injuries to parotid duct**—Seen in cases of deep lacerations on cheek at the region of parotid duct. If undiagnosed and untreated, this injury can lead to cumbersome sequelae of parotid fistula. Parotid duct injury is suspected if the laceration involves an imaginary line joining the tragus of the ear to the upper lip. In such cases, exploration is performed to evaluate the injury, and suturing should be done using a stent to establish patency of the duct.

(F) **Rank and Wakefield classification** [7] **of wounds**

(a) **Tidy wounds**—The wounds that are inflicted by sharp instruments like surgical blades and contain

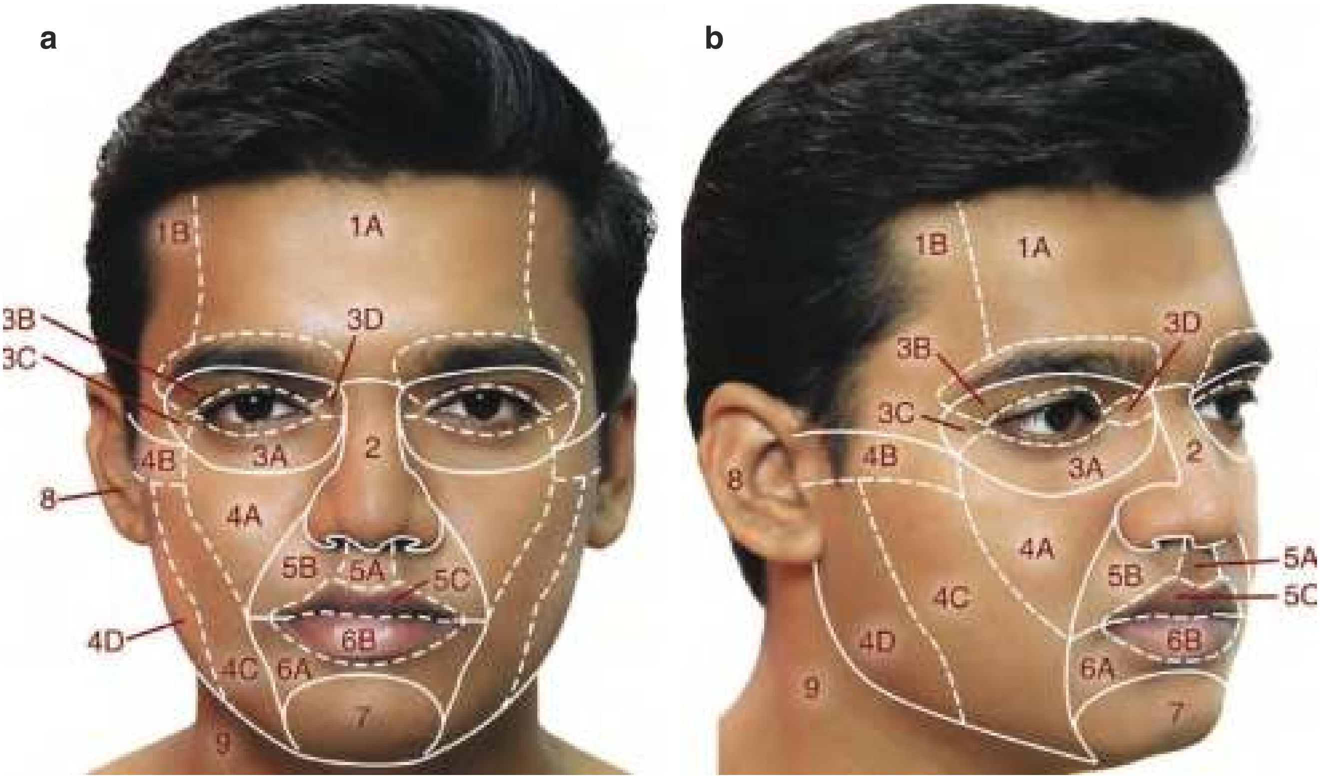

Fig. 49.2 Various facial esthetic subunits (Also see Fig. 86.3 in this book)

no devitalized tissue are called tidy. These wounds are closed primarily. Examples are surgical incisions, cuts from glass, and knife wounds.

(b) **Untidy wounds**—Untidy wounds result from crushing, tearing, avulsion, vascular injury, or burns and contain devitalized tissue. Such wounds must be managed by wound excision. The devitalized tissue is excised, and the untidy wound is converted into the tidy wound before proper closure is achieved. The chances of infection are high if inadequately managed.

(G) **CDC classification of surgical wounds**

A **surgical wound** is a wound created by incisions and placement of drains during surgeries.

Surgical wounds can be classified into four different categories depending on the bacterial load, the risk of infection, and where the wound is located on the body.

Class I: **Clean wounds**. They show no signs of infection or inflammation. They often involve the eye, skin, or vascular system. It is often due to non-penetrating (blunt) trauma.

Class II: **Clean-contaminated wounds**. Although the wound may not show signs of infection, it is at an increased risk of becoming infected because of its location. For example, surgical wounds in the respiratory tract like oropharynx and gastrointestinal tract may be at a high risk of becoming infected.

Class III: **Contaminated wound**. A surgical wound in which an outside object has come into contact with the skin and has a high risk of infection. For example, a gunshot wound may contaminate the skin around where the surgical repair occurs.

Class IV: **Dirty-contaminated or infected wounds**. The wounds that have been exposed to fecal material and have a high bacterial load.

This wound classification guides in choosing appropriate treatment as well as helps in predicting post-repair form and function.

49.3.1 Common Soft Tissue Injuries

The common clinical presentation of soft tissue injuries included abrasions, contusions, and lacerations.

1. **Abrasions**—(also known as gravel rash) (Fig. 49.3)—It is destruction of the superficial layer of skin only. It is caused by frictional forces that are light enough to erode only the superficial layer of epidermis. It can be scratches

Fig. 49.3 Showing multiple abrasions over face involving the supraorbital region, nose, upper lip, and chin

Fig. 49.4 Showing contusion wound over right cheek and periorbital ecchymosis of the right eye. The color changes can be appreciated intraorally

Fig. 49.5 Showing bilateral periorbital ecchymosis (raccoon eyes)

or linear type of abrasion, graze or sliding abrasion, pressure abrasions, and impact abrasions.

The healing of abrasions takes place from the periphery of the wound towards the center by new growth of epithelial cells. The wound is bright red in color for the first 12–24 h due to extravasation of blood which dries up to form a red scab. After 2–3 days, a reddish-brown scab is formed. After 4–7 days, epithelium grows and covers the defect under the scab, which gives it a dark brown to brownish-black appearance. After 7 days, the scab dries and ultimately falls off, leaving depigmented bright pinkish area underneath, which attains its normal pigmentation gradually over a period.

2. **Contusions (bruising)** (Figs. 49.4 and 49.5)—This is effusion of blood into the tissues, due to the rupture of small blood vessels at the site of impact. There is no destruction of the superficial layer of skin. The subtypes are (a) intradermal, (b) subcutaneous, and (c) deep.

   A bruise heals by disintegration of extravasated blood. The red cells in the wound are hemolyzed, and the hemoglobin molecule is broken down into hemosiderin, hematoidin, and bilirubin by the action of enzymes.

   This type of injury demonstrates a change in the color of the wound according to the time lapsed after injury: red at the time of injury, blue within few hours to 3 days, and bluish-black to brown color due to deposition of hemosiderin from the extravasated RBCs, by the 4th day. In 5–6 days, the wound appears greenish due to disintegration of hemoglobin to hemosiderin. Between 7 and 12 days, the wound appears yellow due to the presence of bilirubin which is the final disintegrated product from hemoglobin. The wound appears normal by 2 weeks. The various factors affecting the color of contusion include the depth of the bleeding, amount of extravasated blood, and overlying skin color.

3. **Lacerations**—It is the tear or split of skin, mucous membrane, muscle, or internal organs produced by the application of blunt force to a broad surface area, which

Fig. 49.6 Showing split lacerated wound over the nose, columella, lower lip, and chin

Fig. 49.7 Cut laceration having sharp clean cut edges

crushed or stretched tissues beyond the limits of their elasticity. They can be split lacerations (Fig. 49.6), stretch lacerations, shearing lacerations, and cut lacerations (Fig. 49.7).

4. **Incised wounds**—The wound is longer than it is deep. It is caused by the pressure and friction of any sharp object against the soft tissues (Fig. 49.8).
5. **Chop wounds (slash wounds)**—They are deep bigger wounds with gaping caused by a blow with the sharp-cutting edge of a heavy weapon, like an axe or chopper.
6. **Stab or punctured wounds**—Produced when the force is delivered along the long axis of a narrow or pointed object, such as knife, sword, chisel, scissors, nail, needle, spear, arrow, screw driver, etc. into the depths of the body. This type of wound is deeper than its length and width. These can be of the following types:
   (a) **Penetrating wounds**—When an object pierces the skin and enters a cavity of body or a viscus creating a localized path of entry leaving it an open wound (Fig. 49.9). In head and neck region, this type of injuries should be assessed for upper airway and bleeding as direct trauma to vital structures occurs along with facial bone fractures. Careful exploration of the wounds should be performed, and any impacted debris should be removed before closure.
   (b) **Perforating wounds or through-and-through puncture wounds**—Produced when the object enters the body at one surface and exits at another surface without causing much tissue loss. The wound of entry is larger with inverted edges, and the wound of exit is smaller with everted edges. They are considered to be sterile wounds (Fig. 49.10).
7. **Crush injury**—A crush injury typically occurs when the body part is crushed between two heavy blunt objects. Most severe trauma cases will have this type of injury. Crush injuries have ragged edges, varying amounts of devitalized tissue, and, sometimes, tissue loss.
8. **Avulsion injuries**—These involve significant tissue loss. Avulsion can be considered a very severe form of abrasion, wherein all layers of skin are torn off and the underlying structures are grossly exposed. The term avulsion can also mean complete loss of a small body part such as eyelid, fingertip, part of ear, etc.

Fig. 49.8 Showing incised wound extending from dorsum of the nose till pre-auricular region; caused by knife in a case of assault

Fig. 49.9 Showing penetrating wound. (**a**) Only the entry site is seen over the right temporal region. (**b**) The object remains dislodged within the body cavities

Fig. 49.10 Showing gunshot wound injuries. (**a**) Picture showing entry wound over pre-auricular region. (**b**) Showing exit wound over right infraorbital region on opposite side

9. **Burn injuries**—Burns are injuries to tissues caused by heat, friction, electricity, radiation, or chemicals. Most burns are from hot objects (including fluids) and fire. Burns cause severe skin damage where the cells die. Burns are highly painful injuries which require specific treatment as distinct from other injuries depending on the degree of burn.
   The clinical presentation of burns depends largely on the depth of injury. Superficial burns (first degree) are confined to the epidermis. They are characterized by severe pain, dryness, and redness of skin. Superficial partial-thickness (second degree) burns extend into the papillary dermis. The skin is moist and red and blanches with pressure. Blisters are common in this type of injury. Deep partial-thickness burns extend into the reticular dermis. The skin is dry and appears yellow or white with minimal blistering. Full-thickness burns extending to the entire depth of dermis are classified as 3rd degree. These are very severe injuries. The skin is stiff, leathery, and brown, but pain is not a common feature. Fourth-degree burns involve charring of skin and affect the deeper structures like fat and muscle. The skin is dry, black, and painless.

49.4 Initial Evaluation and Assessment

All trauma patients should be assessed and managed initially according to the principles of Advanced Trauma Life Support. Soft tissue injuries of the head and neck region can be accompanied by significant swelling and bleeding leading to airway compromise. The patient also should be assessed for associated ophthalmologic, intracranial, and cervical spine injuries.

49.5 History and Examination

Once the patient has been evaluated for life-threatening injuries and stabilized as necessary, a thorough and focused history and physical examination of the head and neck should be performed. History includes timing and mechanism of injury.

Early treatment of soft tissue injuries is associated with optimal esthetic outcomes. Determining the mechanism of injury may help the surgeon in managing the wounds with special consideration. For example, crush injuries may result in a larger area of compromised tissue than appreciated on initial examination. Tissue that appears healthy initially may subsequently necrose and may require serial debridement.

The site(s), depth, and nature of all wounds should be noted. Presence of nonviable tissue, gross contamination, and any foreign body like dirt and debris are important to discern.

Palpation helps to identify the presence of underlying bony injuries. Palpation can be done through the open wound itself.

49.6 Management of Soft Tissue Injuries

The principles of management of soft tissue injuries include the control of bleeding, copious irrigation of the wound, debridement of devitalized tissue, and removal of foreign bodies before closure.

(a) **Control of bleeding**—Blood loss is minimized by applying local pressure using hands and pressure dressings. The wound should be examined thoroughly with suction, irrigation, and meticulous dissection to identify the offending vessel, if any. If local pressure fails to achieve hemostasis, local hemostatic agents can be used. Local anesthesia with adrenaline helps in control of pain as well as bleeding through its vasoconstrictive action. If generalized oozing is still present which is hampering the ability of a surgeon to close the wound, systemic measures like injectable vitamin K, tranexamic acid, or ethamsylate can be given, provided the blood investigations (INR, BT, CT) are within normal limits.

(b) **Copious irrigation** serves to dilute and wash out the contamination present in a wound. All grossly contaminated wounds should be copiously irrigated with sterile saline. The fluids may be warmed to 37 °C to promote cellular activity. The cleanser should be nontoxic and have a neutral pH. Alkaline soaps are best avoided. Antiseptics are generally not recommended for cleansing. They are applied on the wound after wound cleansing. The most commonly used antiseptic is Povidone-iodine 10% solution. An alternative solution for this purpose is Cetrimide 15% in combination with chlorhexidine gluconate 1.5%.

(c) **Broad-spectrum antibiotic prophylaxis** is warranted in grossly contaminated wounds and bite wounds and in immunocompromised patients.

(d) **Tetanus vaccination** [8]—Prevention of the local wound infection especially in crushed injuries, contaminated wounds, and bite wounds is a main concern. Tetanus prophylaxis in wound management is required as per the accepted international protocols.

(e) **Wound excision** (also known as **wound debridement** or **toileting of the wound**)—Serial debridement of contaminated and untidy wounds done to remove all the necrotic tissues like devitalized muscles, tendons, and fascia and comminuted bony fragments that have lost the soft tissue cover of periosteum and are hanging within the wound, in order to aid in uneventful and optimum healing. The blunt contused margins of skin are also

Fig. 49.11 Showing wound excision and serial debridement of an extensive untidy wound gradually healing secondarily

excised using sharp scissors, and the wound margins are freshened up. The toilet of any wound should be done in a systematic layer-wise manner from superficial to deep (Fig. 49.11).

(f) **Closure**—Ideally, facial soft tissue injuries should be closed as early as possible. Primary closure of a wound should be completed within 8 h of injury when possible [9]. Early intervention and closure decreases the risk of infection as well as optimizes the functional and cosmetic result. Basic principles of suturing should be met, which include precise approximation and eversion of the skin edges, avoidance of excessive tension, and layer-wise closure to prevent dead space and fluid accumulation.

If gaping of the lacerated margins or tissue loss is present that cannot be closed primarily, the tissue can be managed by regular dressing and allowed to heal secondarily. Revision surgeries to improve esthetics and function are performed after minimum of 9 months.

(g) **Reconstruction** [10]—Done in cases of extensive degloving injuries. There are several options for soft tissue reconstruction using flaps. Starting from local, regional, distant flaps and free microvascular flaps, depending on the type, location, and extent of the injury (Box 49.2).

Box 49.2 Reconstructive Options for the Head and Neck Region

CLASSIFICATION SCHEME OF VARIOUS RECONSTRUCTIVE FLAPS

Based on **CIRCULATION**

a. **Axial** – flap with one blood vessel. Further classified as fasciocutaneous, musculocutaneous, venous and direct. E.g. – Radial forearm flap, nasolabial flap, submental flap etc.

a. **Random** – multiple random tributes of small vessels.

According to **SOURCE OF HARVEST**

a. **Local** – area adjacent to the wound
b. **Regional** – Same region e.g. – head and neck
c. **Distant** – Region away from the wound
d. **Free Flaps** – Flaps having their own blood supply, connected to the defect using microvascular technique.

Based on the **MODE OF TRANSFER** of flap

a. **Rotational** – a semicircular type of flap pivoting onto the defect.
b. **Transpositional** – flap that moves laterally around the adjacent defect.
c. **Advancement** – Flap moved forward into the wound defect. E.g.. –VY flap
d. **Interpolational** – the flap moved laterally into the defect but not adjacent. Undermined to reach the area.

According to **THE THICKNESS** of the flap

a. **Full thickness flap** – offers better esthetics

a. **Partial thickness flap**

Based on **COMPOSITION** of the flap

a. Dermal
b. Muscle
c. Fascia
d. Tendon
e. Bone
f. Various combinations

49.7 Wound Dressings

Wound dressings are sterile pads used to cover the wounds. Lister [11] introduced antiseptic dressings by soaking gauze in carbolic acid. The dressings should be clean and provide a warm and moist environment for the successful wound healing. The dressings should be frequently changed in order to keep the wound free from bacterial load. Antibacterial ointments must be applied over the wound to keep it lubricated and free from bacteria. The dressings are selected on the basis of two concepts: occlusion and absorption. The reasons for placing a wound dressing are enumerated in Box 49.3.

Box 49.3 Purposes of Dressings

Purposes of applying dressings over wounds

(i) Protection the wound from elements of nature
(ii) Prevention of bacterial contamination
(iii) Application of compression where required
(iv) Absorption of exudate
(v) Facilitation of hemostasis
(vi) Prevention of further inadvertent trauma to wound site

In selected cases, the dressing is modified to achieve additional purposes such as

(vii) Relief of pain
(viii) Application of topical antibiotic
(ix) Removal of slough and foreign bodies from the wound

Studies [12] have demonstrated that the rate of epithelialization under a moist occlusive dressing is twice that of a wound that is left uncovered and allowed to dry. An occlusive dressing provides a mildly acidic pH and low oxygen tension on the wound surface, which is conducive for fibroblast proliferation and formation of granulation tissue.

However, wounds that produce significant amounts of exudate or have high bacterial counts require a dressing that is absorptive and prevents maceration of the surrounding skin. These dressings also need to reduce the bacterial load while absorbing the exudate produced. Placement of a pure occlusive dressing without bactericidal properties would allow bacterial overgrowth and worsen the infection.

The various types of dressings [13] can be enumerated as in Table 49.1.

49.8 Other Therapies

1. **Hyperbaric oxygen therapy**—uses oxygen as a drug and the hyperbaric chamber as a delivery system to increase PO2 at the target area. It involves inhalation of 100% oxygen at 1.9–2.5 atm, for sessions of 90–120 min each. Treatments are given once daily, five to six times per week and should be given as an adjunct to surgical or medical therapies. Clinical evidence of wound improvement should be noted after 15–20 treatments.

Table 49.1 Types of wound dressing materials

Kind of dressing	Examples	Properties	Indications
Protective	Gauze	Inexpensive, readily available Highly permeable and nonocclusive Dry dressing—can stick to the wound if used primarily	As secondary dressing over another material
	Polymeric films (Opsite, Tegaderm)	Transparent, waterproof dressing Semi-permeable, thin, highly elastic	Surgical incisions
Absorbent	Hydrogels	Mostly contain water Provide a moist and cool environment	Wounds with mild exudates Not for heavily exudating or infected wounds
	Hydrocolloids	Composed of methylcellulose, pectin, and gelatin Absorb fluids and convert them into a gel that covers the wound Provides pain relief as the gel covers nerve endings	Light to heavily exuding wounds such as burns Must not be used on infected wounds
Bioactive	Antimicrobial dressings	Soft, paraffin dressing impregnated with chlorhexidine (Bactigras) or framycetin (Sufratulle) Actively prevent bacterial contamination	Flat, shallow wounds such as skin graft donor sites, superficial burns, and abrasions
		Require a secondary dressing over it **Scarlet Red**, a relatively nonocclusive dressing that is impregnated with *O*-tolylazo-*O*-tolylazo-β-naphthol Xeroform—hydrophobic dressing containing 3% bismuth tribromophenate in a petrolatum base, which helps mask wound odors and has antimicrobial activity against *Staphylococcus aureus* and *Escherichia coli*	Skin graft harvest sites in burn care
	Collagen dressings	Activate matrix metalloproteinases and promote new collagen formation	Chronic non-healing wounds Burn wounds

Mechanism of action—HBO therapy can increase tissue PO2 ten times higher than usual. The higher PaO2 is sufficient to supply the tissue with all its metabolic requirements even in the absence of hemoglobin. This elevated level lasts for 2–4 h after termination of HBO therapy and induces synthesis of endothelial cell NO synthase as well as angiogenesis. Oxygen stimulates angiogenesis, enhances fibroblast and leukocyte function, and normalizes cutaneous microvascular reflexes, thus aiding in healing of chronic, complicated, non-healing wounds.

2. **Negative pressure-assisted wound therapy**—Argenta [14] and associates originally described the use of negative pressure to assist in wound closure in 1997. By applying subatmospheric pressure to wounds, they demonstrated removal of chronic edema, an increase in local blood flow, and stimulation of granulation tissue. This technique may be used on acute, subacute, and chronic wounds. The wound is filled with a foam substance. A drainage tube is inserted into, or laid on, the foam, and the part is then covered with impermeable film. Suction is applied at around 125 mmHg between changes of dressing.

49.9 Necrotizing Fasciitis

It is a rapidly spreading necrotizing soft tissue infection, also known as flesh-eating disease. It is one of the most challenging infections faced by the maxillofacial surgeons due to its diagnosis and management. The most common bacteria responsible for the fascial necrosis are hemolytic *Streptococcus* and *Staphylococcus*.

It is foul-smelling with loss of skin and superficial subcutaneous tissue, having patchy blackish necrosis and frank pus along with the raw surface of the wound, margins of which are pale and spreading in nature. If it involves the skin of scrotum, it is known as Fournier's gangrene.

The prompt diagnosis and aggressive treatment is the key to manage this complicated condition. Removal of the offending factors like carious tooth and infected foreign material is the prime step followed by aggressive debridement and desloughing involving the normal tissue margins under the antibiotic coverage and adequate anesthesia. Once the wound is free of the active infection, showing healing margins with no evidence of pus, it is reconstructed with the skin grafts (Fig. 49.12).

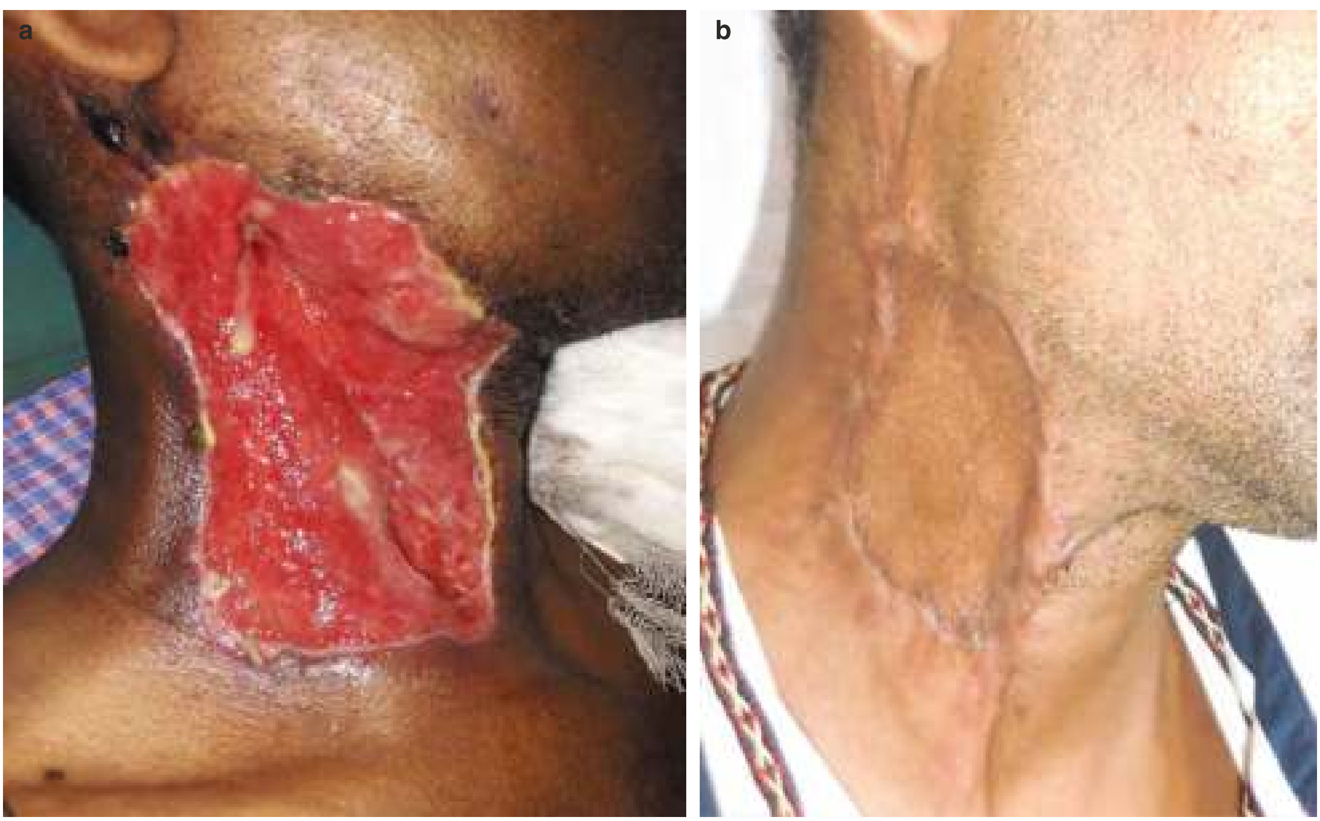

Fig. 49.12 Depicting a case of necrotizing fasciitis of the right side of the neck due to infection from right mandibular third molar. The patient was promptly and aggressively managed by sequential debridement followed by anterolateral thigh skin graft

Table 49.2 Phases of wound healing

Phases of wound healing	Time period	Mechanism of healing
Inflammatory phase	Immediate till 5th day	• Immediate vascular response • Cellular infiltration—Polymorphonuclear leukocytes initially, followed by monocytes within 24 h, which become dominant by the 5th day and actively engaged in phagocytosis • Formation of new blood vessels at the edges of wound (neovascularization) • Synthesis of granulation tissue
Proliferative phase	Established by 5th day	• Cellular proliferation—Macrophages are preponderant • With time, the number of fibroblasts increases that are active in synthesis of extracellular collagen and proteoglycans (collagen synthesis) • The fibroblasts in the wound are closely followed by the endothelial buds of capillaries. The wound is filled with vascular granulation tissue containing new capillaries, fibroblasts, macrophages, and mast cells • An intrinsic increase in the mechanical strength of the wound at the end of this phase
Maturation phase		• Extensive remodeling as a result of a decrease in the numbers of fibroblasts and macrophages concurrent with a decrease in vascularity • Increase in wound strength • Formation of scar tissue

49.10 Principles of Soft Tissue Healing

The three phases of repair in soft tissue wounds are overlapping and include

- The inflammatory phase
- The proliferative phase
- The maturation phase (Table 49.2)

Any alteration in the local environment of the wounds or the systemic status of the patients can influence the normal process of wound healing.

49.11 Types of Wound Healing

The various types of wound healing include:

1. Primary intention
2. Delayed primary closure
3. Secondary intention

1. **Primary intention**—occurs when full-thickness wound edges are approximated shortly after the primary wound has been created. This type of closure is generally avoided in grossly contaminated wounds, in wounds that cannot be completely debrided, and in wounds where further tissue loss is anticipated as in blast injuries.
2. **Delayed primary closure**—Primary closure is delayed to allow host inflammatory and immune responses to control contamination. It is typically completed 3–4 days after the initial injury but depends on the particular characteristics of the wound. Serial debridements may be performed until the full extent of tissue devitalization is determined.

Table 49.3 Factors that negatively influence wound healing

Local factors	Systemic factors
Presence of foreign bodies Venous insufficiency Ischemia/ hypoxia to tissues Radiation Salivary contamination Scarring Hematoma	Smoking Comorbidities like diabetes Systemic condition—malnutrition, chronic illness, deficiency of vitamins Prolonged drug use—corticosteroids, cytotoxic chemotherapy

3. **Secondary intention**—healing is by natural biologic processes without surgical intervention, and it usually occurs in large wounds associated with soft tissue loss or avulsion. It involves epithelialization and collagen deposition for wound healing. Contraction is the most important phenomenon in the spontaneous closure of large open wounds.

49.12 Complications in Wound Healing

Complications in the normal process of wound healing may occur due to presence of various local and systemic factors which exert a negative impact (Table 49.3).

One of the frequently observed complications is “abnormal wound healing” which presents in different forms such as keloids and hypertrophic scars. These are proliferative scars characterized by excessive net collagen deposition. Keloids and hypertrophic scars (Fig. 49.13) differ histologically from normal scars. The clinical appearance of the two types of scar is described in Table 49.4.

Keloids and hypertrophic scars contain collagen bundles aligned in the same plane as the epidermis. Tension

Fig. 49.13 Showing. (**a**) keloid type of scar and (**b**) hypertrophic scar healing

Table 49.4 Difference between keloids and hypertrophic scar

Keloids	Hypertrophic scar
Contain disorganized type I and type III collagen bundles	Primarily contain well-organized type III collagen fibers
The collagen bundles are thicker and form a nodelike structure in the deep layer of skin	Contain islands of aggregates of fibroblasts, small vessels, and collagen fibers throughout the dermis
Cannot be prevented and are often refractory to medical and surgical intervention	Often preventable
Occur above the clavicles, on the trunk, on the upper extremities, and on the face	Prolonged inflammation and insufficient resurfacing (e.g., burn wounds) promote hypertrophic scarring
Grow beyond the borders of the original wounds and rarely regress with time	Raised scars within the confines of the original wound and frequently regress spontaneously
Appear to be genetically predisposed	Represent a reversible hyperproliferative scar phenotype that regresses when the original stimulus (skin tension, stimulatory growth factors) are removed
First-line treatments include pressure therapy and intralesional corticosteroid injections. Intralesional 5-fluorouracil, bleomycin, and verapamil used according to the established treatment protocols. Refractory cases after 12 months of therapy should be considered for surgical excision in combination with adjuvant therapy. Excision alone results in a high recurrence rate of 50–100% and enlargement of the keloid. Immediate postoperative electron beam irradiation or brachytherapy with iridium-192 reduces recurrence rates.	Pressure and silicone therapy combined with selective localized corticosteroid injections in resistant areas. Bleomycin, 5-fluorouracil, and verapamil can be used as adjuncts to corticosteroid therapy. Laser therapy to reduce scar thickness, resurface scar texture, and treat residual redness, telangiectasias, or hyperpigmentation. Early surgery is indicated if the scar causes functional impairment. Scar contracture release procedures in the neck and axilla are best performed with flaps to improve functional and cosmetic outcomes. Widespread large hypertrophic scars may require serial excision or tissue expansion.

over the edges of the wound signals the formation of activated fibroblasts resulting in excessive collagen deposition.

Scars perpendicular to the underlying muscle fibers tend to be flatter and narrower, with less collagen formation than when they are parallel to the underlying muscle fibers. As muscle fibers contract, the wound edges become reapproximated when they are perpendicular to the underlying muscle and tend to gape if placed parallel to it, leading to greater wound tension and scar formation.

49.12.1 Prevention of Hypertrophic or Keloid Scars

The four strategies that reduce adverse scarring immediately after wound closure are:

- Layer-wise closure as to avoid gaping within the layers of the wound
- Closure without tension
- Hydration of the wound with clean dressing
- Use of pressure garments

Postsurgical taping of the wound for 3 months can reduce scarring. Moisturizing lotions and moisture-retentive dressings (silicone sheets and gels) can reduce the thickness, discomfort, and itching and improve the appearance of the scar.

49.13 Recent Advances in Soft Tissue Management

1. Use of **growth factors**—intimate role in the regulation of all phases of wound healing, i.e., chemotaxis, proliferation, matrix synthesis, inflammation, and angiogenesis. The enhancement of soft tissue wound healing can be done by various methods. Topical application of growth factors in a vehicle or by direct seeding of cells topically on the wound can enhance healing. Placement of growth factors or cells can also be done with a fibrin sealant or glue. Use of platelet-rich plasma (PRP) by degranulation of platelets with the secretion of its contents of growth factors into the surrounding fibrin matrix or, more recently, use of tissue-engineered equivalents of skin or mucosa can provide a scaffold that enhances healing.
2. **Gene and stem cell therapy**—in which the gene encoding for the therapeutic growth factor or protein is directly transfected into host cells. This is a promising approach for the treatment of acute and chronic wounds.
3. **Tissue engineering**—In 1987, the National Science Foundation bioengineering panel defined tissue engineering as "the application of the principles and methods of engineering and the life sciences toward the development of biologic substitutes to restore, maintain, or improve function."
   They include—*Bioengineered Skin substitutes vis* [15]

   (a) *Epidermal substitutes*—These are autografts taken from split-thickness skin grafting or from cell line bioreactor expansion and grown in laboratory until enough tissue is produced to be transferred to the wound later.
   (b) *Dermal substitutes*—When the wound is deep and the dermis is destroyed, epidermal substitutes are not enough to ensure wound healing. The dermis is replaced by the one manufactured in the laboratory from the patient-specific cells. This dermis is essential to maintain mechanical resistance and occlude the surface of the wound.
   (c) *Bilayer substitutes*—Integra, developed in 1981, was the first acellular bilayer and has been used successfully to treat burns and chronic wound patients.

49.14 Conclusion

Proper assessment and classification of soft tissue injuries is the primary step in management. Early intervention and closure of soft tissue injuries is associated with optimal functional and esthetic outcomes as well as decreases the risk of complications. The basic principles of management of soft tissue injuries include the control of bleeding, copious irrigation of the wound, debridement of devitalized tissue, and removal of foreign bodies before closure. Administration of antibiotics and tetanus prophylaxis play a vital role in management of contaminated wounds. Wound dressings are mandatory to protect wounds postoperatively and facilitate ideal healing. Soft tissue injuries resulting in loss of tissue must be reconstructed using flaps which may be local, regional, distant, or free microvascular flaps, depending on the type, location, and extent of the injury. Innovative options such as growth factors, stem cell therapy, and bioengineered skin substitutes may be considered.

49.15 Case Scenarios

Case Scenario 1

A 23-year-old male patient met with a road traffic accident and suffered from a perforating injury over the nose, extending to right infra-orbital region. After initial resuscitating of the patient and ruling out the head injury component, the patient was taken up for the management of soft tissue and hard tissue injuries under general anesthesia. Through the existing lacerated wound, open reduction and internal fixation was done within 48 h of the trauma. Simultaneously, the soft tissue closure was performed layer-wise. Closure of the muscle layer was performed followed by the subcutaneous tissue and finally the skin (Fig. 49.14a–e).

Case Scenario 2

A case scenario of a 67-year-old male patient who reported to the department of Oral and Maxillofacial Surgery. He was a victim of ballistic injury while he was working in a marketplace. The penetrating pathway of the bullet could be traced

Fig. 49.14 Case scenario 1(a–e): Soft tissue management of a road traffic accident victim

having an entry site over left cheek. An extensive and careful exploration was performed in the OT under general anesthesia after the sections of 3D CT face were obtained (Fig. 49.15a–g). The comminuted fracture of the mandible was reconstructed using reconstruction plate. The bullet was found to be lodged in the carotid triangle just above the bifurcation of the common carotid artery.

Soft tissue management in such type of ballistic injuries becomes very critical. Since the bullet is a foreign material, it has to be removed from the soft tissues. The approach could either be through the entry wound but due to deep seating of the bullet into the neck and proximity of vital structures, one should always think of an extensive approach. The neck dissection was carried out in this case to remove the bullet from the bifurcation of common carotid artery in as atraumatic manner as possible. Bidigital palpation is a crucial step to locate the foreign body in this region. One interesting fact about such injuries is that though they are extensive with crushed and comminuted fractures and they are sterile due to the heat generated by the velocity of the bullet along its path. Such injuries are less prone to infection.

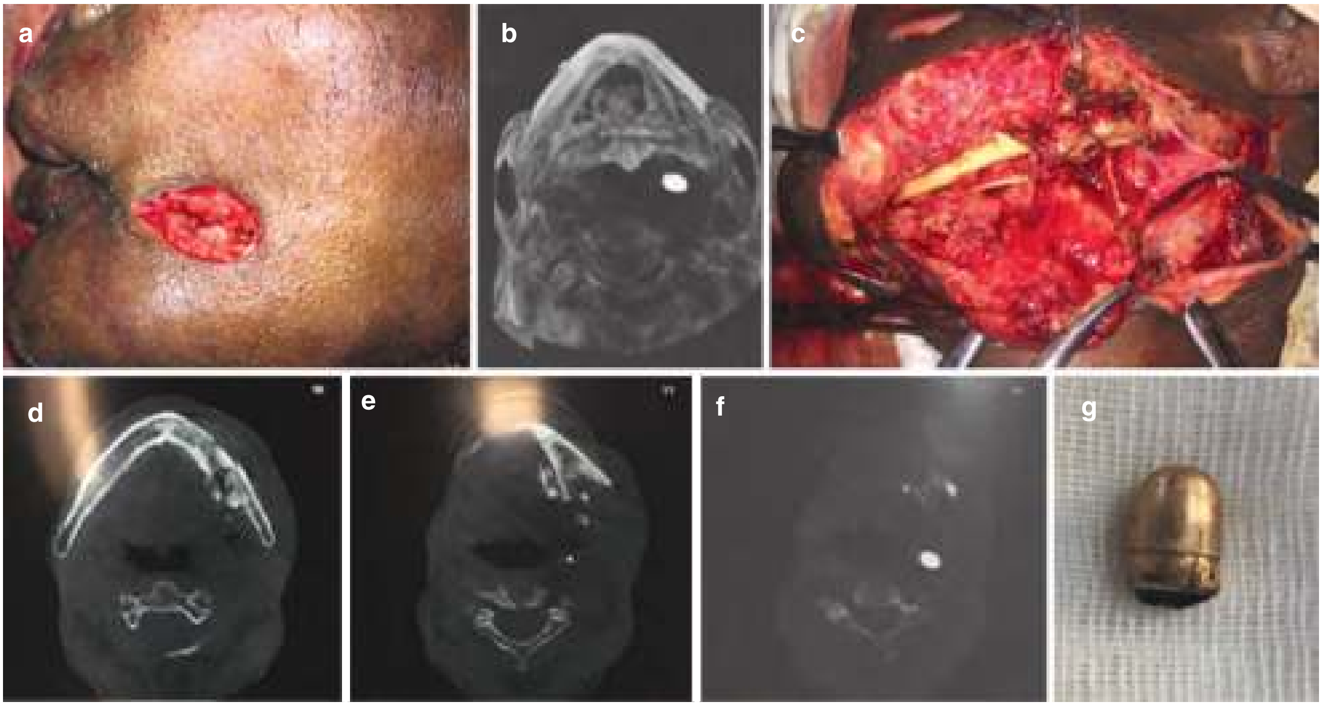

Fig. 49.15 (a–g) Case Scenario 2: Soft tissue management in a ballistic injury

Proper surgical toilet with wound irrigation followed by careful debridement remains the mainstay of treatment of all types of soft tissue injuries.

50 Dentoalveolar Injuries and Wiring Techniques

Omkar Anand Shetye

50.1 Definition

Dentoalveolar fracture is defined as a fracture in the bone surrounding the teeth without any extension to the basal bones of the maxilla or mandible [1, 2].

50.2 Incidence

Dentoalveolar injuries commonly occur in the age group of 8–12 years. They generally involve teeth, soft tissues, and/or associated bone. Traumatic dental injuries account for a total of 92% of maxillofacial injuries of which 92% involves only the soft tissues and 8% involve the maxillofacial bones [2].

50.3 Introduction

Trauma is the foremost etiological factor that leads to a loss of significant number of teeth annually. The recent advancements in the field of preventive dentistry as well as the development of myriad evidence-based techniques to restore the lost form and function of teeth have made it possible for the dental surgeon to successfully facilitate the improvement in the quality of life of trauma-afflicted patients. Time elapsed post-trauma plays a major factor in determining the outcome of the intervention. Apart from reestablishing the premorbid position of the traumatized tooth in its socket, the goal of the treatment is directed toward achieving the pre-traumatic occlusion and intra-arch contour [3].

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_50) contains supplementary material, which is available to authorized users.

50.4 Diagnosis and Treatment Planning

The foundation of diagnosis and management of traumatic dental injuries solely lies on the pillars of a detailed patient history and a clinical examination. **When, Where, and How** forms the "Trauma Triad" of history taking in traumatic dental injuries [4].

When—Time interval between injury and treatment may significantly affect the prognosis for cases of pulp exposure, displacement, and avulsion type of injuries.

Where—The place of injury. The chances of the injury getting infected on a playground compared to an injury that has occurred at home in relatively cleaner surroundings. The place of injury has medico-legal repercussions if the assault or accident has occurred at the place of work. Depending on the cleanliness of the wound, the clinician can also consider protection against tetanus.

How—This may give an indication of concomitant injuries like soft tissue injuries secondary to the trauma [5].

History of immediate local measures employed to reduce the severity of injury helps in eliciting information regarding the original condition of the injured area [6].

History of any systemic disorders that may interfere with treatment or post-operative healing including a history of tetanus vaccination has to be obtained before starting the treatment [7].

"Outside-in" examination (examining the facial structure in three concentric rings paying more attention to the innermost ring) helps in achieving the desired management protocol. Level of consciousness should be assessed prior to the clinical examination [6].

The potential for aspiration, airway compromise, and neurosensory deficit warrants the need for a thorough evaluation of all maxillofacial injuries before managing dental injuries [3].

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_50

In a patient with missing tooth fragment or prosthesis, a chest radiograph and abdominal radiograph may be helpful in locating the missing structures and their management. Owing to its anatomic position, the right bronchus is often the site of foreign body dislodgement [3, 6].

50.5 Clinical Examination

Clinical examination of the patient has to be divided into the following subsets [8]:

- Extra-oral soft tissue
- Intra-oral soft tissue
- Jaws and alveolar bone
- Teeth (displacement and mobility)
- Percussion and pulp testing [3]

50.5.1 Extra-oral

Asymmetry of the face following trauma could be due to injury to the facial skeleton or swelling. Areas of ecchymosis and hematoma may indicate fracture of the underlying osseous structure. Laceration, contusion, and abrasion of the overlying skin are common with dentoalveolar injuries (Figs. 50.1, 50.2, and 50.3). Mild antiseptic soap should be used to clean the extra-oral abrasions or a saline wash can be used while being careful to not inoculate injury site further with debris or foreign body [4, 8].

50.5.2 Intra-oral

Buccal mucosa lacerations should raise suspicion for a Stensen's duct injury. The lips, floor of the mouth, and tongue are areas which are at a risk of being penetrated or sites for secondary injuries [3].

50.5.3 Jaws and Alveolar Bone

Bimanual palpation of the maxillary and mandibular dentition and evaluation of occlusion should reveal areas of discrepancy or mobility. The direction of dislocation of the apex of primary tooth should be diagnosed since these teeth are in close approximation to the succedaneous teeth. Palpating from the vestibular approach makes this diagnosis easier. Sublingual ecchymosis/hematoma (Coleman's sign) at the floor of the mouth is suggestive of underlying mandibular fractures. Step deformity, crepitation, malocclusion, and gingival lacerations raise suspicion for possible bone defects [7, 9].

Fig. 50.1 Mandibular anterior lingually displaced dentoalveolar fracture with degloving vestibular wound and ragged lip lacerations

Fig. 50.2 Maxillary anterior palatally displaced and extruded dentoalveolar fracture with associated upper lip injury. Note incisal fractures of the upper lateral incisors (see also Fig. 50.8)

Fig. 50.3 Maxillary anterior teeth complete avulsion with associated upper lip injury

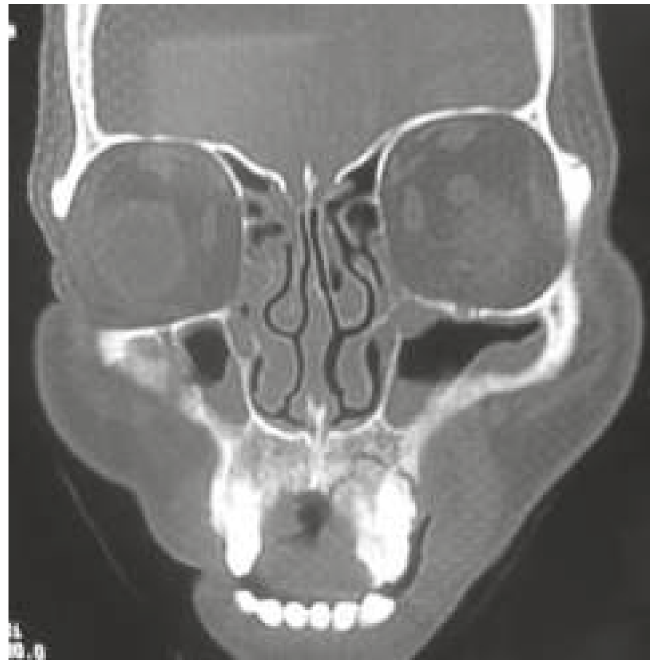

Fig. 50.4 Coronal CT image showing left maxillary high dentoalveolar fracture

50.5.4 Percussion and Pulp Testing

Percussion test is performed with the end of the handle of an examination mirror. Pain to percussion of a tooth is indicative of damage to the periodontal ligament. Dullness to percussion in one or several adjacent teeth can be indicative of partially luxated teeth or en bloc fracture of tooth or alveolar bone. The percussion test should be started on a non-injured tooth to ensure a reliable response through visual analogue scale [6, 8].

To evaluate the tooth injury thoroughly, pulp vitality is a must. A positive response indicates that the pulp is alive, whereas a negative response indicates that the pulp is dead. Following injury, the tooth may be in a state of shock and may give a false response. Hence pulp testing should also be performed during the subsequent visits to acknowledge the change in response [5].

Electric vitality testing depends on a number of factors including the stage of eruption of tooth, the presence of a restoration or decay, and the ability to isolate the tooth and keep the area clear of blood and saliva [8].

Laser Doppler flowmetry (LDF) is a relatively new pulp testing apparatus. It employs a laser beam directed at the coronal-labial aspect of the pulp which is scattered by pulp blood cells that in turn produce a Doppler frequency shift. The fraction of light scattered back is detected and processed to elicit a signal. The basic theory is that the pulp revascularization process can be monitored. Studies have shown that in cases in which electrometric tests were negative and LDF displayed vascular perfusion, the LDF accuracy of pulp vitality reached 100% [3].

All the teeth should be tested for abnormal mobility both horizontally and vertically. It should be remembered that primary teeth undergoing physiologic root resorption and therefore always exhibit a certain degree of mobility. The typical sign of an alveolar fracture is the movement of adjacent teeth when the mobility of a single tooth is tested [6].

50.6 Radiographic Examination

Radiographic techniques are available to evaluate dentoalveolar trauma.

Radiographic examination is essential to determine damage to underlying structures and should include intraoral periapical (IOPA), occlusal, panoramic radiographs (OPG), and cone-beam computed tomography (CBCT) imaging [3, 4].

If conventional CT imaging is done as part of the trauma series, fine axial and coronal cuts will also show the dentoalveolar injuries (Fig. 50.4)

IOPA radiograph provides vital information about root fracture and dislocation of teeth. At times it is difficult to adequately evaluate a fracture on an IOPA radiograph, due to variations in tube-tooth-film geometry. Post-treatment radiographs can confirm the proper repositioning of avulsed or luxated tooth into alveolar bone.

Occlusal radiographs provide a larger field of view, and a steep occlusal exposure is of special value in the diagnosis of root fracture and lateral luxations with displacement of crown [8].

OPG is a useful screening tool and can demonstrate fractures of the mandible and maxilla as well as fractures of alveolar ridges and teeth.

Radiographic evaluation of foreign bodies within soft tissues of the lips and cheeks is done by taking radiographs with the film placed labial to the alveolus. A reduced radiographic exposure time (approximately 1/3rd of the normal) is used.

CBCT scanning is extremely useful in diagnosis of maxillofacial, alveolar bone, and teeth fractures with the advantage of high-resolution three-dimensional images with low radiation.

The etiology of pediatric and adult dentoalveolar injuries were shown in Box 50.1 and Box 50.2 respectively. Box 50.3 and Box 50.4 represents the classification of alveolar bone fracture and classification of alveolar bone fracture based on location and displacement respectively.

Box 50.1: Etiology of Pediatric Dentoalveolar Injuries

Pediatric patients [9]

- Bicycle injuries
- Falls
- Sports injuries
- Car crashes
- Child abuse
- Iatrogenic injuries(dental extractions, endoscopy, oral intubation)
- Industrial accidents

Box 50.2: Etiology of Adult Dentoalveolar Injuries

Adult patients

- Motor vehicular accidents
- Interpersonal violence
- Sports injuries(contact injuries)
- Falls
- Work-related trauma

Box 50.3: Classification of Alveolar Bone Fracture:

Traumatic alveolar bone [9]

Type I: Areas surrounding a single tooth

Type II: Entire dentoalveolar segment dislocation

Box 50.4 Alveolar fracture can be classified by their specific location and movement of displacement [10]

Class I: Edentulous segment fracture

Class II: Little or any displacement of fractured dentulous segment

Class III: Moderate to severe displacement of fractured dentulous segment

Class IV: Multiple fracture lines with combination of fracture of the dentulous segment

Box 50.5: Classification of Dental Injuries and Surrounding Structure

Classification based on level of involvement [11]

1. Fracture involving enamel
2. Fracture involving enamel and dentin
3. Fracture involving enamel, dentin and pulp
4. Fracture involving enamel, dentin, cementum
5. Crown/ root fracture
6. Luxation of tooth
7. Intrusion and extrusion (Fig. 50.5a,b) (Box 50.6)
8. Avulsion (Fig. 50.5c) (Boxes 50.7 and 50.8)

Fig. 50.5 (**a**–**c**) Clinical images showing tooth (a) intrusion, (b) extrusion, and (c) avulsion

Box 50.6: Management of Intruded Tooth (Fig. 50.6)

Diangelis et al. [12, 13]

Fig. 50.6 IOPA showing an intruded upper right canine

Permanent Teeth

1. In closed apex
   – Intrusion <3 mm—allow eruption
   – Intrusion between 3 and 7 mm—surgical or orthodontic repositioning
   – Intrusion >7 m m
     (a) Surgical extrusion with flexible splint for 4–8 weeks
     (b) RCT using Ca $(OH)_2$ medicament 2–3 weeks after surgical extrusion
2. In open apex
   (a) Wait till the tooth erupts for 3 months
   (b) Place an orthodontic extruding appliance

Primary Teeth

Treatment is debatable

Immediate extraction of the involved tooth

or

More conservative approach

Box 50.7: Principle of Avulsion

- Primary should not be replanted
- Permanent teeth should be replanted as soon as possible and stabilized for 7–10 days up to 2 weeks [14, 15].

Box 50.8: Primary Management of Avulsion by the Patient

What the patient can do:

- To hold the tooth by its crown and not to touch the root surface.
- To rinse the tooth immediately with saliva, tap water or saline solution and reimplant the tooth.
- If the patient cannot replace the tooth, it should be held in the buccal vestibule (only if patient is fully conscious).
- Gentle irrigation with saline or gauze soaked with saline may be employed to remove blood clots or foreign objects from the surface of the root.

What the patient should not do:

- No effort should be made to mechanically cleanse the root of the tooth because this would damage the remaining periodontal ligament.

50.6.1 Storage and Transportation Media

If the tooth cannot be reimplanted within 5 min, it should be stored in a medium that will maintain its vitality and periodontal ligament fibers [14–16].

Transportation media for avulsed teeth include

1. Viaspan: a specialized tissue storage media used when transporting liver for transplantation.
2. Hanks balanced salt solution: both hanks solution and viaspan are physiologic with compatible pH and osmolality. The relative availability and cost-effective hanks solution makes it medium of choice in storage of avulsed teeth.

Commercial products are designed especially for storing avulsed teeth. It has shelf life of 2 years without refrigeration (Box 50.9).

3. Milk: is a readily available medium. It is the medium of choice in the absence of hanks balanced salt solution or viaspan. Milk will only prevent further cellular demise and is used specifically when the teeth has been outside the oral cavity for less than 20 min.

Box 50.9: HBSS Contents

Contents of Hanks balanced salt solution [19]

- Sodium chloride
- Glucose
- Potassium chloride
- Sodium bicarbonate
- Sodium phosphate
- Calcium chloride
- Magnesium chloride
- Magnesium sulfate

Box 50.10: Reagent for Root Surface Therapy

Agents used for root surface treatment to prevent resorption

- Citric acid
- Doxycycline
- Tetracycline
- Fluorides
- Enamel matrix derivative (emdogain)
- Diphosphonates

4. Saliva: is an excellent transport medium and is as effective as saline. It does not matter if the tooth is stored in another person's saliva.
5. Tap water: has been commonly recommended storage solution but due its hypotonicity, it leads to rapid cell lysis and increased inflammation on replantation.
6. Contact lens solution: a compilation of information from a study Blomlof et al. [17] indicates that Hanks buffered saline, isotonic saline, and pasteurized bovine milk may be the most favorable known storage media. If none of these are available, human saliva or contact lens solution is acceptable short-term substitute storage liquid.
7. Culture mediums like minimum essential eagles medium and Dulbecco's storage media [18] have been used as they contain amino acids, vitamins, and bicarbonates that help to maintain the vitality of cells.
8. Propolis: a beehive product which has an excellent anti-inflammatory and anti-bacterial effect has been used as a storage medium.
9. Green Tea: its polyphenol derivative have antioxidative, anti-carcinogenic, anti-mutagenic, anti-inflammatory, antimicrobial, and antiviral effect.
10. Patients own serum have shown to maintain the vitality of periodontal ligament cells up to 1 h.

    Morus rubra (red mulberry), egg white, coconut water, rehydrating solution like Gatorade and ricetral, lens solution, probiotic solutions, saliva officinalis, honey milk, and ascorbic acid have been used as a transportation medium for avulsed tooth.

50.7 Treatment at the Clinic

Traumatically avulsed teeth when out of the mouth for a short period should be reimplanted as soon as possible. After normal reattachment, survival is prolonged. Avulsed teeth which remain out of the mouth for more than 2–3 h generally resorb rapidly and should not be reimplanted indiscriminately.

The outcome of replantation depends on the stage of root development and extra-oral time. If the avulsed tooth has a closed apex and extra-oral time is less than 60 min (early replantation), the reimplanted tooth will have the best prognosis. The ideal time to begin root canal treatment is within 10–14 days post-replantation and before splint removal.

There is a statistically significant association between extirpation within 14 days and an increased likelihood of successful periodontal healing and prevention of external inflammatory root resorption.

It is generally agreed that $Ca\ (OH)_2$ has a beneficial effect in the outcome because of its antibacterial properties, ability to dissolve necrotic tissue, and its ability to prevent or control inflammatory resorption. The anti-inflammatory and antibacterial action may decrease root resorption by directly inhibiting resorptive cells (Box 50.10).

50.7.1 Delayed Replantation (more than 60 min)

Delayed replantation of avulsed tooth with closed apex has a poor long-term prognosis. The periodontal ligament gets necrotic and healing is delayed. The goal of delayed replantation is to promote alveolar bone growth so as to encapsulate the reimplanted tooth. The eventual outcome is ankylosis.

In children below age of 15 years, if ankylosis occurs and when the infra position of the tooth crown is more than 1 mm, decoronation is recommended to preserve the contour of the alveolar bone.

Root canal treatment (RCT) can be carried out on a tooth prior to reimplantation or it can be carried out within 14 days of reimplantation. The tooth is immersed in 2% sodium fluoride solution for a minimum of 5 min up to 20 min.

Avulsed teeth having open apices and extra-oral time less than 60 min are also reimplanted and stabilized for 7–10 days and up to 2 weeks. The goal of reimplanting developing (immature) teeth in children is to allow for possible revascularization of the tooth pulp.

If there is evidence of the pulpal infection or inflammatory response, the pulp should be removed and Ca $(OH)_2$ placed immediately, aiming to stimulate apexification and halt the inflammatory process.

It is believed that delayed replantation of avulsed teeth with open apices have a poor long-term prognosis. The periodontal ligament gets necrotic and is not expected to heal. Osseous replacement, resorption, or ankylosis will occur. Therefore some authors have concluded that such teeth should not be reimplanted.

The recent guidelines recommend replantation to maintain alveolar ridge contour as ankylosed roots get transformed to bone during the remodeling process. RCT can be performed on the tooth prior to replantation through an open apex (Fig. 50.7a–c).

50.7.2 Stabilization

Stabilization of an avulsed tooth can be achieved using a variety of materials like wires, arch bar wired to the teeth,

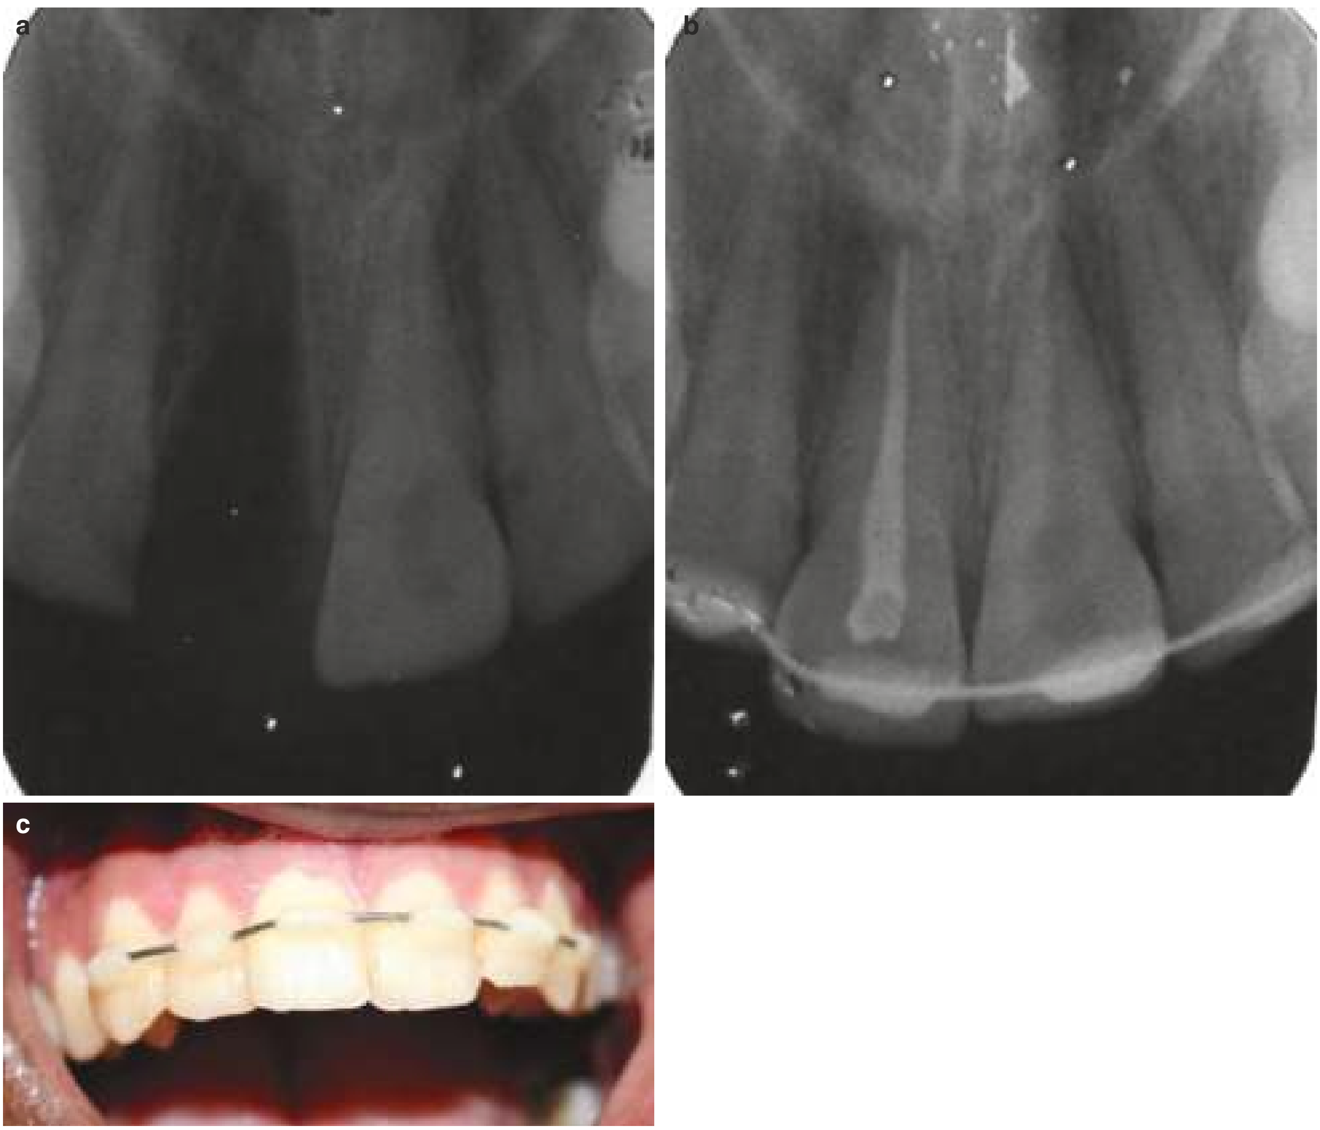

Fig. 50.7 (**a**–**c**) Shows a case of avulsed upper right central incisor in a 24-year-old man, which presented after few hours of avulsion. The tooth was transported in milk by the relatives. A RCT was carried out and the tooth reimplanted and stabilized with wire and composite splint (**a**, IOPA showing avulsed incisor; **b**, IOPA with tooth reimplanted; **c**, shows the clinical image after splinting)

orthodontic band and brackets attached by acid etch technique, combined with orthodontic band and acrylic appliance, or periodontal pack.

They are generally maintained for 7–10 days after replantation to allow gingival reattachment.

Studies by Andreason [20] (1985) have shown that prolonged splinting may be inadvisable because it enhances ankylosis.

The socket should be left undisturbed before replantation. If the alveolar bone has collapsed, a blunt instrument should be inserted carefully into the socket in an attempt to reposition the wall. It should be lightly aspirated if a blood clot is present.

In general, stabilization for reimplanted teeth is required for 7–14 days. The periodontal ligament fibers should have healed sufficiently after the first week to remove the splint. However, the patient should be advised not to bite directly on the reimplanted tooth for 3–4 weeks after injury.

50.7.3 Technique

50.7.3.1 Wire Acid Etch Composite Splint

A wire of moderate stiffness (round 0.030 in. stainless steel) is adapted to the facial surface at least one or more stable teeth on either side of the reimplanted teeth.

The physiologic movement imparted to the reimplanted tooth during function is increased when fewer teeth are included in stabilization of the avulsed tooth.

The facial surface of the avulsed and adjacent teeth is acid etched, and wire is cemented to them with composite.

The wire is generally curved along the middle third of the labial surface of the teeth. 90° terminal bends toward the gingiva are made at the labiodistal angles of the most posterior teeth to be splinted in order to avoid sharp edges and stability. The terminal ends should be about **2 mm** long to reduce the possibility of lateral displacement of the wire [21, 22].

Splinting periods for traumatic dental injuries [6]

Traumatic dental injuries	Splinting period
Subluxation	2 weeks
Extrusive luxation	2 weeks
Avulsion	2 weeks
Lateral luxation	4 weeks
Intrusion(if surgically repositioned)	4–8 weeks
Root fracture(middle third)	4 weeks
Root fracture(cervical third)	4 months

50.7.4 Complications

1. Pulp necrosis
2. Pulp chamber or root canal obliteration
3. Internal resorption
4. External resorption—three types:
   (a) Surface replacement
   (b) Replacement resorption (ankylosis)
   (c) Soft tissue replacement [23]

50.8 Alveolar Process Fracture

Fracture of the alveolar process usually involves the teeth.

↓

Place the segment into position (closed reduction) (Fig. 50.8)

↓

Open reduction/ raise the flap if reduction not possible (Fig. 50.9 a, b)

Fig. 50.8 Shows the case in Fig. 50.2, which has undergone closed reduction and fixation by arch bar. Full intrusion and reduction was not achieved. The occlusal discrepancy was planned to be corrected later by RCT and necessary prosthetic work

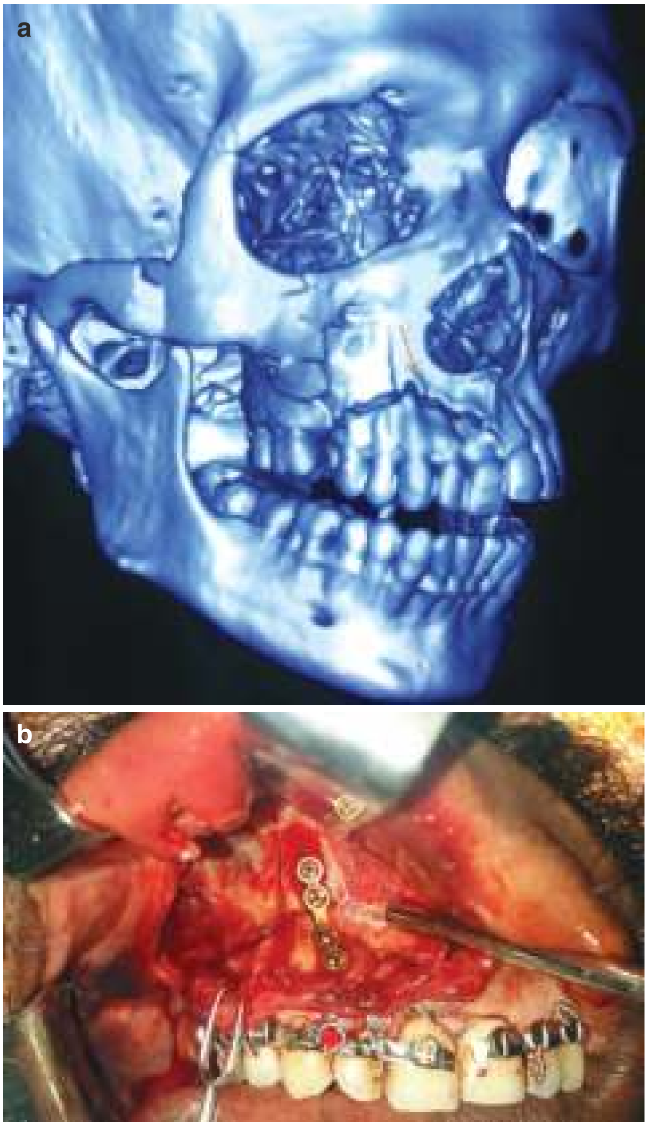

Fig. 50.9 (**a**, **b**) Shows a case of high alveolar process fracture segment in the maxillary right side with associated split between central incisors. Under GA, the extruded displaced alveolar segment was repositioned after placement of split arch bars and bridle wiring between the central incisors. The segment was fixed with mini plate and screws, taking care not to injure the tooth roots. Due to root anatomy, only a single plate was fixed after reduction. Post-operative IMF was given for 2 weeks, for additional stability and to help the healing process

50.9 Management of Dentoalveolar Fracture

The goals of treatment should be:

(a) Anatomic reduction
(b) Re establishment of premorbid occlusion
(c) Early return of function
(d) Preservation of premorbid arch form and facial contour [24]

50.9.1 Treatment Options

1. Arch bars (Fig. 50.8)
2. Loop wiring
3. Orthodontic bands
4. Acrylic/metallic splints
5. Acid etch composite

Model surgery on the plaster models is performed to recreate the normal anatomic relationship of the fractured segment and allow fabrication of accurate splint [9].

50.9.2 Specific Treatment Options

Class I fractures that involve a non-displaced, edentulous alveolar segment often do not require treatment other than a soft diet and observation. If there is concern about the stability of the fracture during the healing process, stabilization may be used.

Class II fractures that involve a displaced dentulous segment and need reduction may require a great deal of force to realign the fractured segment. Posterior fragments are always displaced to the lingual area. Large forceps may be helpful to apply a force suitable to reduce the bony fragment. Reduced fragments are held in place by MMF or splints.

Class III fractures of a moderately or severely displaced dentulous segment may be too difficult to reduce adequately. There may be scant room into which the irregular, displaced segment needs to be replaced. It may be necessary to burr or rasp down the displaced segment or the opening in the remaining bone to successfully reduce the fracture. This is usually accomplished by use of a power drill with a suitable size bur or a fine rhinoplasty rasp. The amount of tissue that is removed should be limited so that the sufficient bone to bone contact remains for bony union as the fracture heals. Maintenance of class III fractures in a reduced fashion may be accomplished with arch bars, MMF, and/or variety of splints.

Class IV fractures that extend into one or more non alveolar fracture lines are usually less challenging than class III fractures because (1) the bone segments are larger, (2) the treatment of the associated fractures gives excellent exposure, and (3) usually no barrier exists to reduction. Plates, screws, arch bars, MMF, and/or variety of splints may be used [7].

50.9.3 Wiring Techniques

In MMF, wires are passed interdentally between teeth in both the jaws followed by tightening of these wires together in a cross arch fashion which serves to stabilize the fracture segments.

Over the period of last century, MMF techniques have evolved dramatically, and more recently, many more easier and effective methods have been introduced like MMF screws, eyelet wiring, and Erich arch bars to name a few. Although it is a quick and efficient way of securing MMF, yet, this technique is criticized for extended periods the patient needs to be closed mouth, difficulty in maintaining oral hygiene, lack or deficient nutritional support via oral route and inability to use this treatment modality in medically compromised patients like epileptics or in immediate post-operative period due to increased risk of aspiration.

Fig. 50.10 Armamentarium for wiring

50.9.4 Armamentarium and Principles (Fig. 50.10)

A soft stainless steel wire of 0.35–0.5 mm diameter is utilized and pre-stretched to 10% of its original length to prevent loosening of wire once tightened. Overstretching beyond this point should be avoided as this will make the wire brittle and susceptible to breakage.

50.9.5 Principles

Basic principles to be followed are [25]:

1. Continuous tension on the wire while twisting and tightening.
2. Force should be apically directed while tightening.
3. Utilizing a clock wise direction for all tightening/ twisting.
4. Only half a turn to be given at a time at the end.
5. Once the tail is cut, it is turned and placed into the inter-proximal embrasures.
6. Once all the wires are in place, move the finger around the arch bar/wire to check for any sharp edge/margin/ wire ending.

50.9.6 Technique

50.9.6.1 Bridle Wire [26, 27]

First advocated by Hippocrates, bridle wire remains one of the oldest yet a conventional method of treating mandibular fractures. This technique represents a temporary way of stabilizing the fractured segments, preventing them from flaying apart.

Advantages include stabilization of the two fractured segments preventing further damage to the adjacent soft tissues, maintenance of the airway patency (especially advantageous for the fractures of the anterior mandible), decrease pain, and reducing damage to the neurovascular bundle from immobilizing the fractured fragments, thereby preventing gross movements and also decreasing muscle cramping.

Technique

Following administration of local anesthesia , a 24–26 gauge wire is passed around the neck of the teeth adjacent to the fracture site on either side (Fig. 50.11a). With both ends being secured in the wire holder (Fig. 50.11b), the fractured segments are manually reduced anatomically, and the wire is tightened in a clockwise fashion till further reduction is achieved (Fig. 50.11c), and the fracture is stabilized

50.9.6.2 Gilmer's Direct Interdental Wiring [26, 27]

This technique represents an easy and fastest method of immobilization.

Technique

A 15 cm pre-stretched wire is passed through the interdental embrasure of the tooth on one side from buccal to lingual. This wire will pass around the tooth and emerge out buccally through the interdental embrasure from the other side. Both ends are held together and twisted to achieve a 3 cm tail (Fig. 50.12a–c). Multiple teeth (at least 5–6) in either jaw are utilized. Following manual fracture reduction and placement of teeth with premorbid occlusion, the tails from opposite arch are twisted together in a cross arch or zigzag fashion to achieve immobilization (Fig. 50.12d). The cut ends of the tail are secured into the interdental spaces. Once all the wires/tails are twisted, complete immobilization is achieved.

The only drawback of this technique is that, in cases of broken /loose wire, all the cross arch wires will have to be removed and redone post placement of twisted wire.

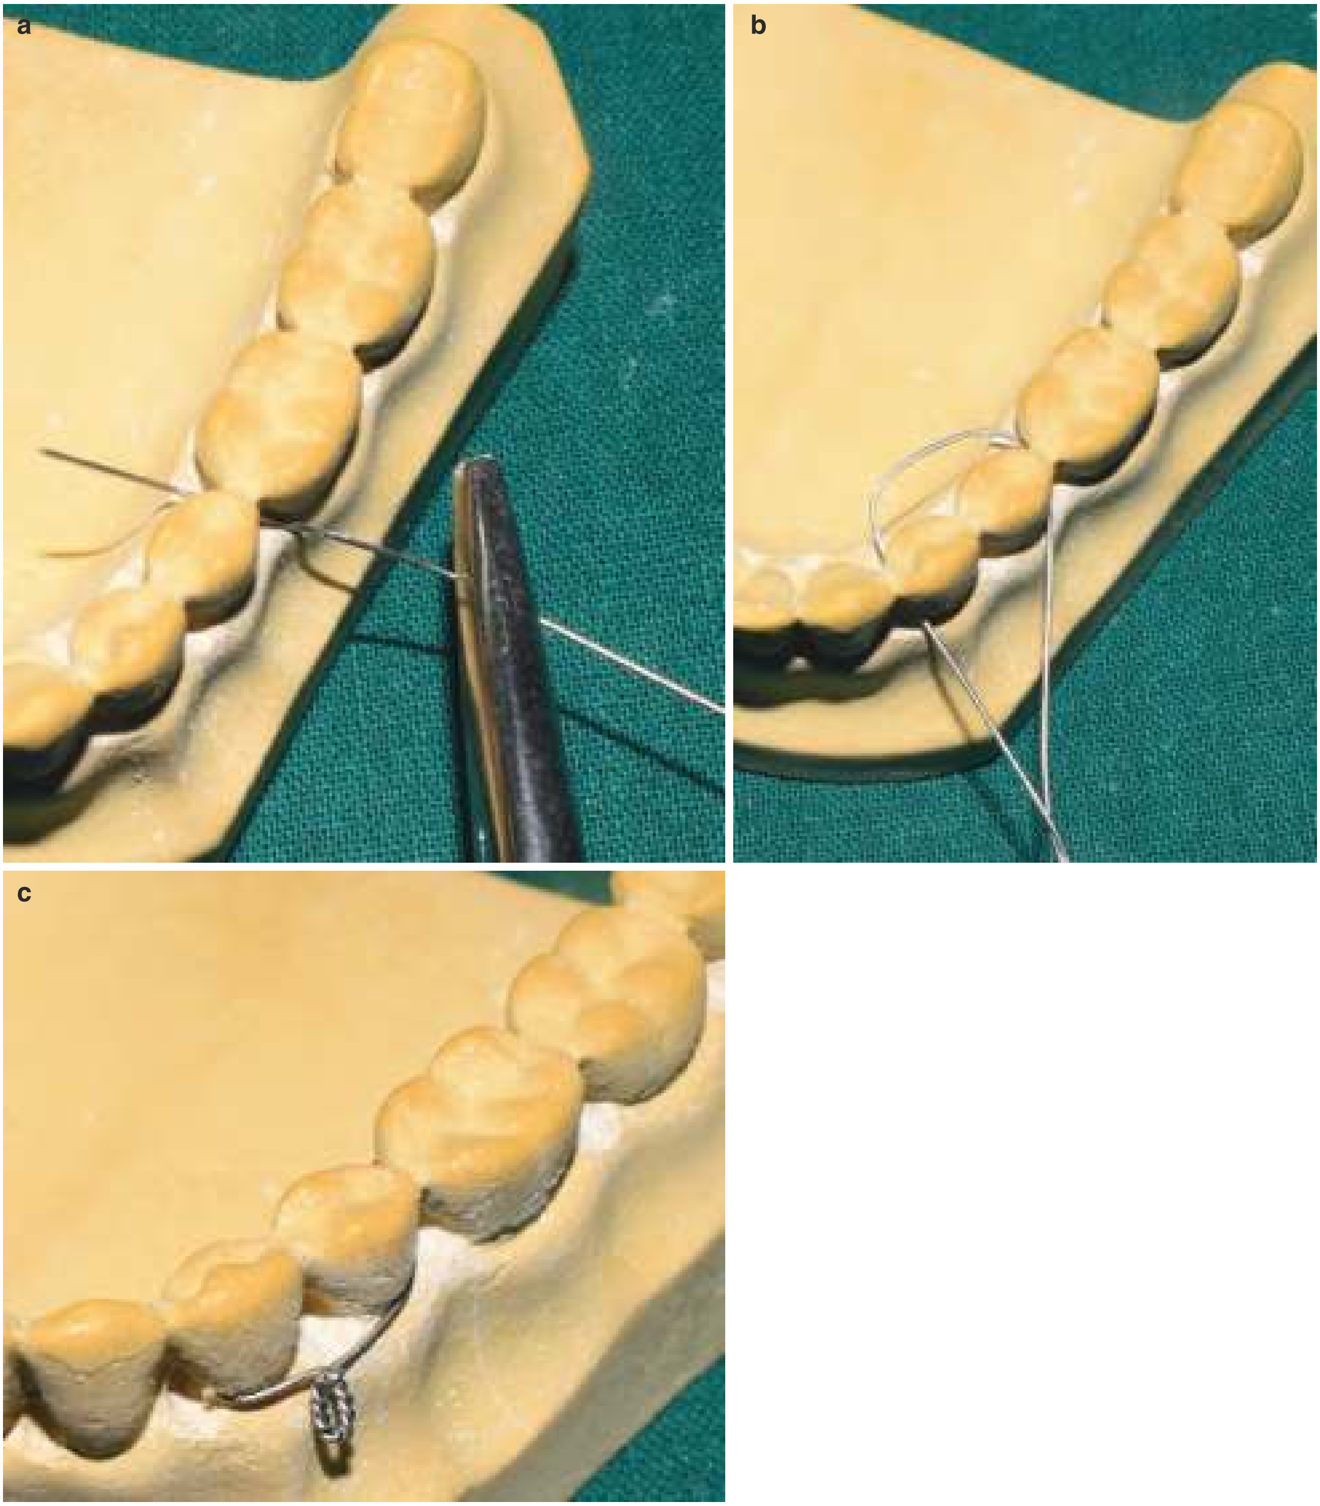

Fig. 50.11 Shows sequential steps bridel wiring. (**a**) Passing of the wire through the tooth embrasure. (**b**) Formation of the wire loop assuming the fracture line is between the two premolars. (**c**) Twisting of both the ends to stabilize the fracture

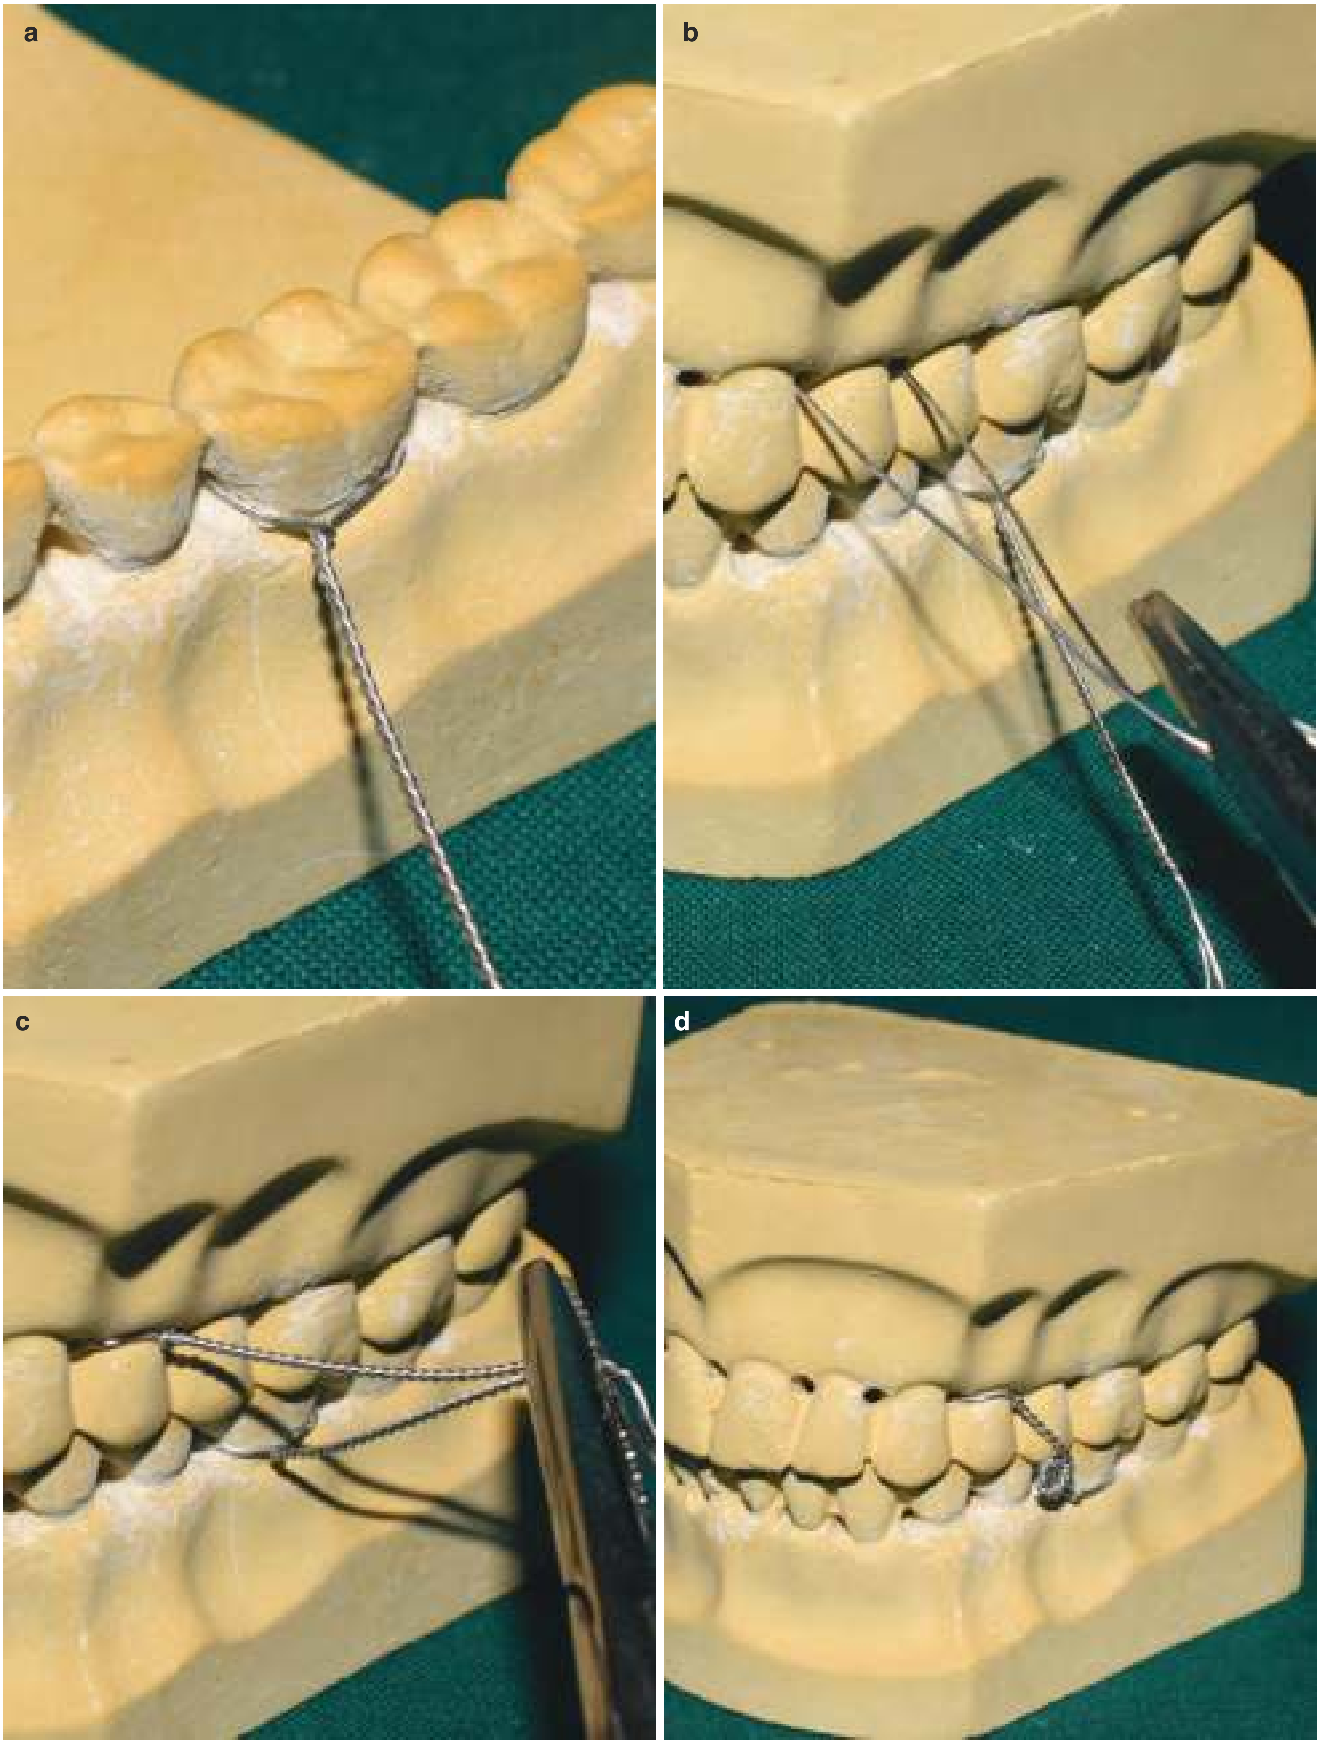

Fig. 50.12 (**a**–**d**) Shows technique of direct Gilmer wiring. Formation of the loop around the tooth in the lower and upper arch followed by twisting both the wires together in order to achieve MMF

50.9.6.3 Interdental Eyelet Wiring (Ivy Loop Method) [26, 27] (Video 50.1)

Yet another easy and quick method of securing MMF was advocated and popularized by Dr. Robert H.Ivy, Philadelphia, USA.

Technique

A pre-stretched 26 gauge/0.35 mm diameter wire was made into an Ivy loop utilizing the middle segment of the wire by twisting it around a metallic rod of 3 mm diameter. 3–4 turns are given to achieve adequate stability to the loop. Both the ends of the wire are then cut in an oblique fashion (Fig. 50.13a).

Both the ends are passed through the interdental space to emerge lingually/palatally so that the loop lies buccally (Fig. 50.13b). Following this, one end of the wire is passed from distal interdental space of the same tooth to emerge buccally. This same wire is passed through the loop and secured to the other end of the wire which is passed mesially from the lingual/palatal side to the buccal side of the adjacent tooth side (Fig. 50.13c,d) . Both the ends are tightened (Fig. 50.13e), and the tail end cut short and secured into the dental space mesially to prevent damage to the adjacent soft tissues.

Stability of the MMF is based on the adequate number of Ivy loops placed in both the arches and secured.

In the maxillary arch, loops can be placed between two molars, two premolars, or between lateral incisor and canine or two central incisors. In the mandibular arch, loops are best placed between two molars, two premolars, or between lateral incisor and canine.

Modifications

1. In 1975, Hallam modified the Ivy loop by addition of another loop proximal to the first for the purpose of ligature/tie wire (Fig. 50.14)

   Although an interesting modification yet the disadvantage observed was that due to increase in length and in patients with short vertical dimension, both the proximal loops would meet one another making the placement of MMF extremely difficult.
2. **Clove hitch**

   This technique helps in placement of an Ivy loop in cases of missing teeth or a single isolated tooth. It is the easiest way to secure MMF where placement of an arch bar or any other technique of securing MMF is difficult due to lack of supporting teeth.

Technique of Clove Hitch

The one end of the wire that has an Ivy loop forms a loop around the lone-standing tooth (Fig. 50.15a) . Continue the wire around the tooth forming another loop for the second time (Fig. 50.15b) . The end of the wire is under the first loop (Fig. 50.15c), and both the ends of the wire are pulled together and tightened (Fig. 50.15d).

50.9.6.4 Continuous or Multiple Loop Wiring [26, 27]

It was first described by Col. Stout in 1943. It represents an easy and simple technique which requires minimal instrumentation. This technique utilizes multiple loops on the buccal surface of the tooth which can be used for both MMF using wire as well as elastic traction for the purpose of fracture reduction. One major advantage of this technique is the use of differential traction force that can be achieved and applied for fracture reduction before securing it with wires for MMF.

Technique

A 30 cm-long pre-stretched wire is placed on the buccal side of the teeth with the anterior end placed as anteriorly as possible while the posterior end extending up to the last tooth to be used. The wire is passed through the interdental space of the posterior most teeth and emerged through its mesial side. The wire is then passed over the buccal wire and passed back into the same interdental space. A 3 mm diameter rod can be used parallel to the buccal wire for adequate loop diameter as well as uniformity of the loop (Fig. 50.16a). Once the wire is passed back through the same interdental space, it then emerges out from the mesial interdental space of adjacent tooth (Fig. 50.16b). This continues till the anterior most teeth where both the ends of the wire are twisted together, cut, and placed into the interdental space (Fig. 50.16c,d). Each loop is then twisted, and loops are made of uniform diameter. In cases of securing MMF, the loops are turned toward the occlusal surfaces of the teeth, but in cases of elastic traction, they are turned in the opposite direction toward the gingiva [27].

Modification

This technique needs modification when some teeth are missing. Herein, once the loop at the mesial end of the tooth adjacent to the missing tooth is formed, both of the free ends of the wires are held together and twisted till the distal end of the next tooth. Once the desired length is achieved, the loop is again formed at the distal end, and the looping continues till the anterior most teeth.

50.9.6.5 Risdon's Wiring [26, 27]

Indications

It is an alternative to an arch bar for a fractured mandible that needs fixation.

Technique

A 25 cm-long wire is passed through the posterior most tooth in the quadrant to emerge bucally, followed by twist-

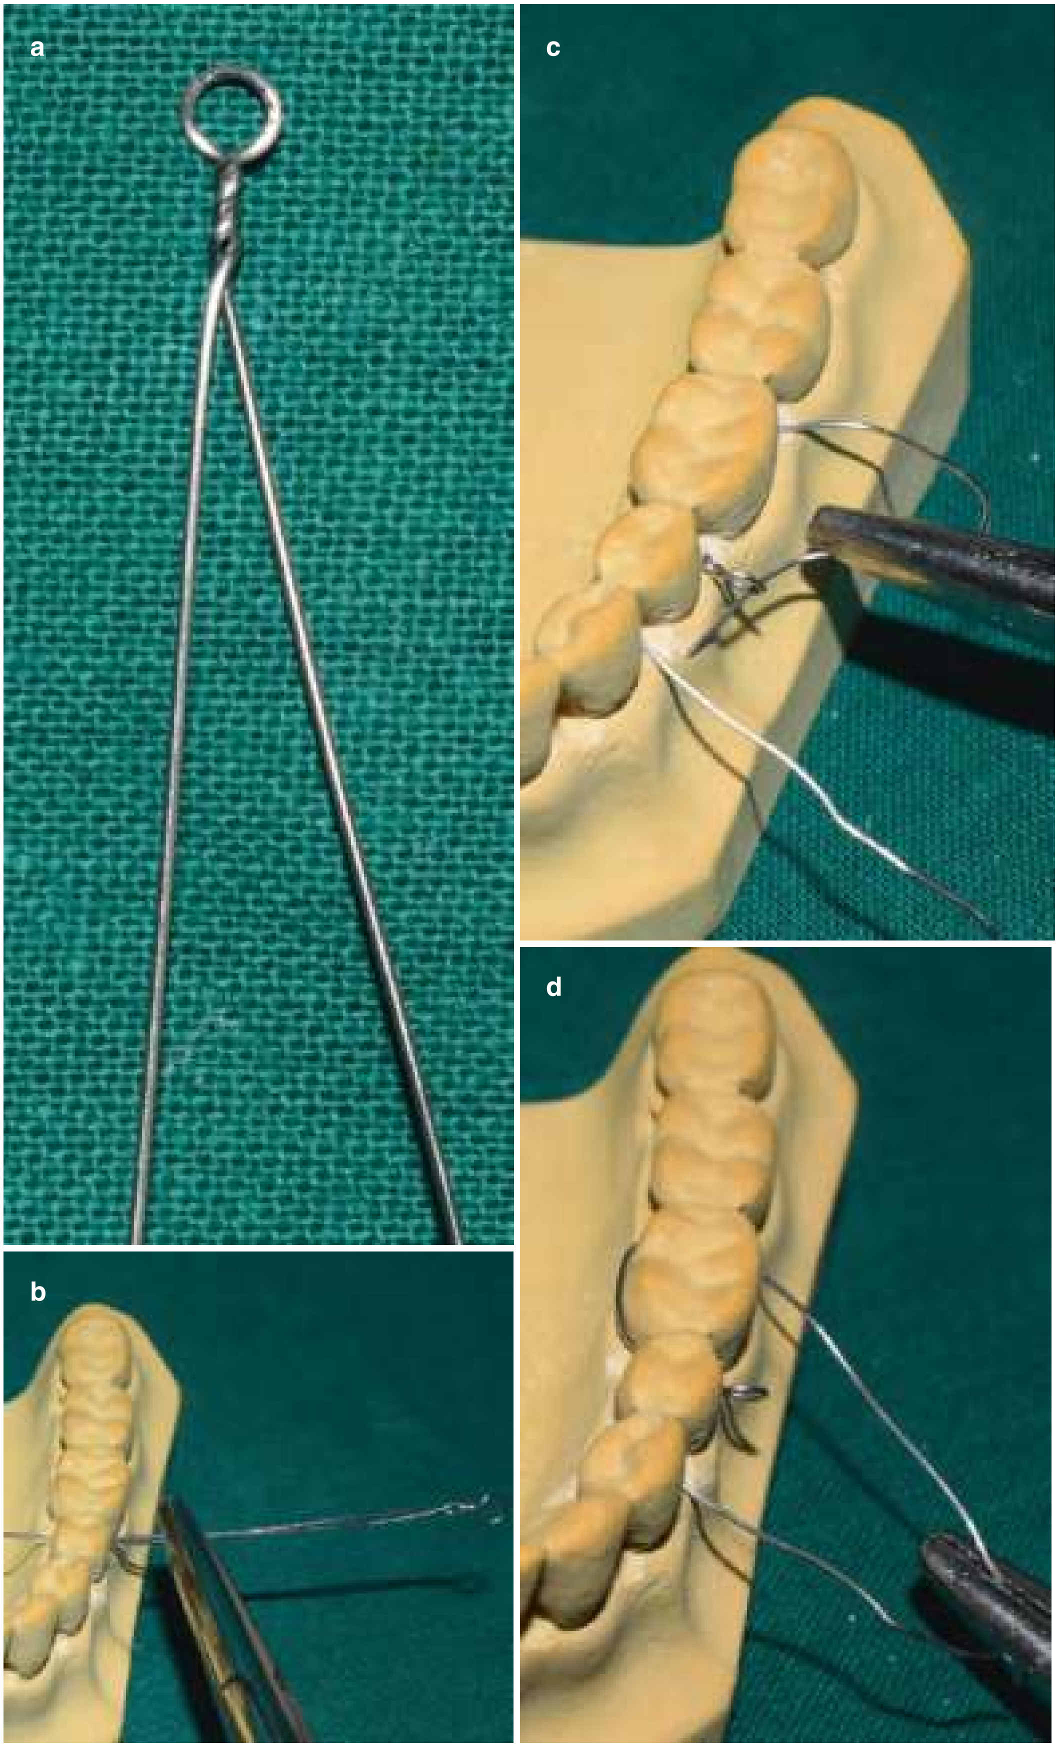

Fig. 50.13 Shows steps in Ivy loop technique. (**a**) Photograph of an Ivy loop. (**b**) Both the ends are held together an passed through the tooth embrasure of the premolar and molar. (**c**) One end passed is passed through the mesial of premolar and other through the distal of molar to emerge buccally. (**d**) Distal end is passed through the loop on the buccal side to emerge mesially. (**e**) Both the ends of the wire are held together and twisted

Fig. 50.13 (continued)

Fig. 50.14 Shows a modification of Ivy loop

ing the wire up to its full length till the midline (Fig. 50.17a). Another wire is passed from the opposite quadrant of the same arch and twisted in a similar manner. Both the ends of this twisted wire are tightened at the midline after reducing the fracture segments (Fig. 50.17b,c). Once anatomic reduction is achieved, additional wires are used to stabilize this long wires by passing around the embrasures of the teeth and looping around the wire segment (Fig. 50.17d) [26, 27].

50.9.6.6 Obwegeser Wiring [26, 27]

Technique

This technique utilizes a 30 cm-long wire that is bent into a continuous "W" arcade form as depicted in Fig. 50.18a. The elevated portion of the arcade acts to form the loop, whereas the depressed portion adapts to the contour of the teeth palatally or lingually. The distal end of the wire arcade is kept long enough so that it will follow the buccal contour of the arch, when it is passed through the interdental space of the most posterior tooth from lingual/palatal to buccal side. The elevated ends of the

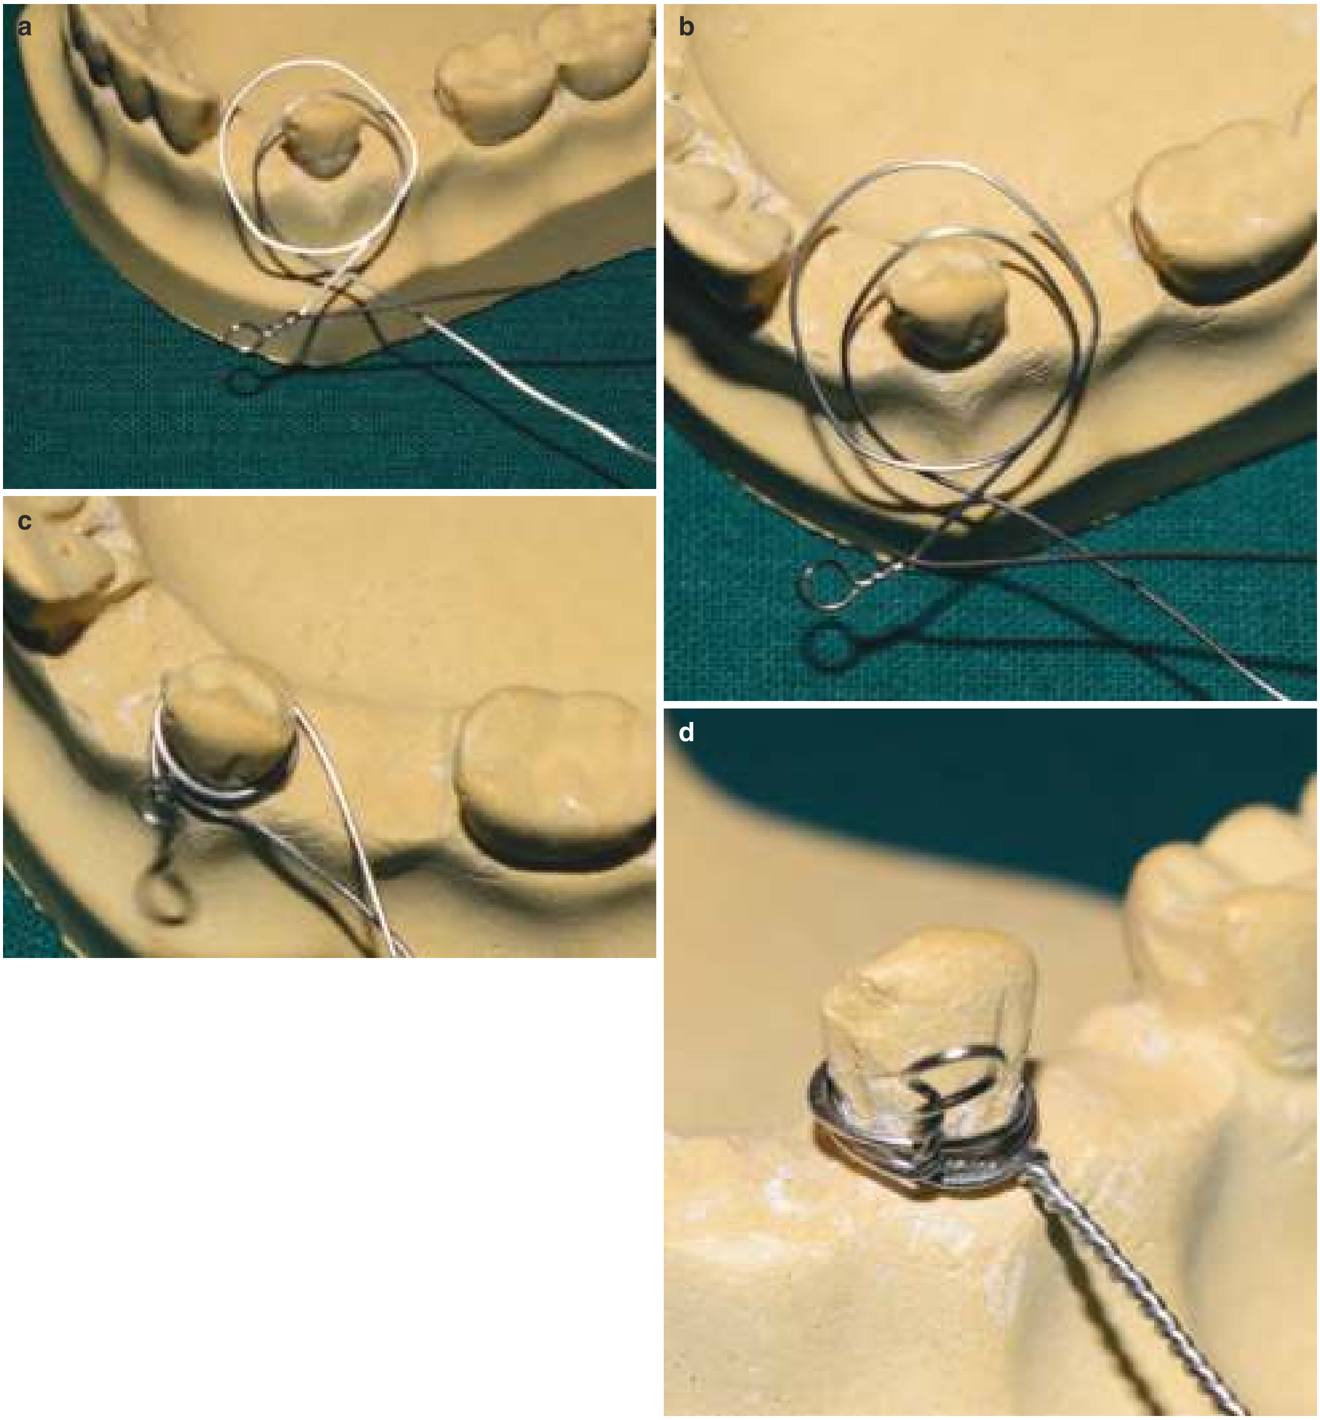

Fig. 50.15 Showing clove hitch technique. (**a**–**c**) Single loop is passed around the lone-standing tooth followed by second loop under the first one, pulling both the ends together. (**d**) Showing clove hitch wiring technique

arcade have a ligature wire attached to it (Fig. 50.18b), which only suffices the arcade to be pulled through to the interdental space to emerge buccally (Fig. 50.18c,d). The long wire is then passed through this loop (Fig. 50.18e), and a modified hemostat is used to twist this wire to form uniform loops. At the mesial end, both the ends of the wire are held together and twisted (Fig. 50.18f). The loops can be used for both elastic traction and wires for securing MMF.

The disadvantage of this technique is that it is very cumbersome and adequate expertise is needed to carry out this technique.

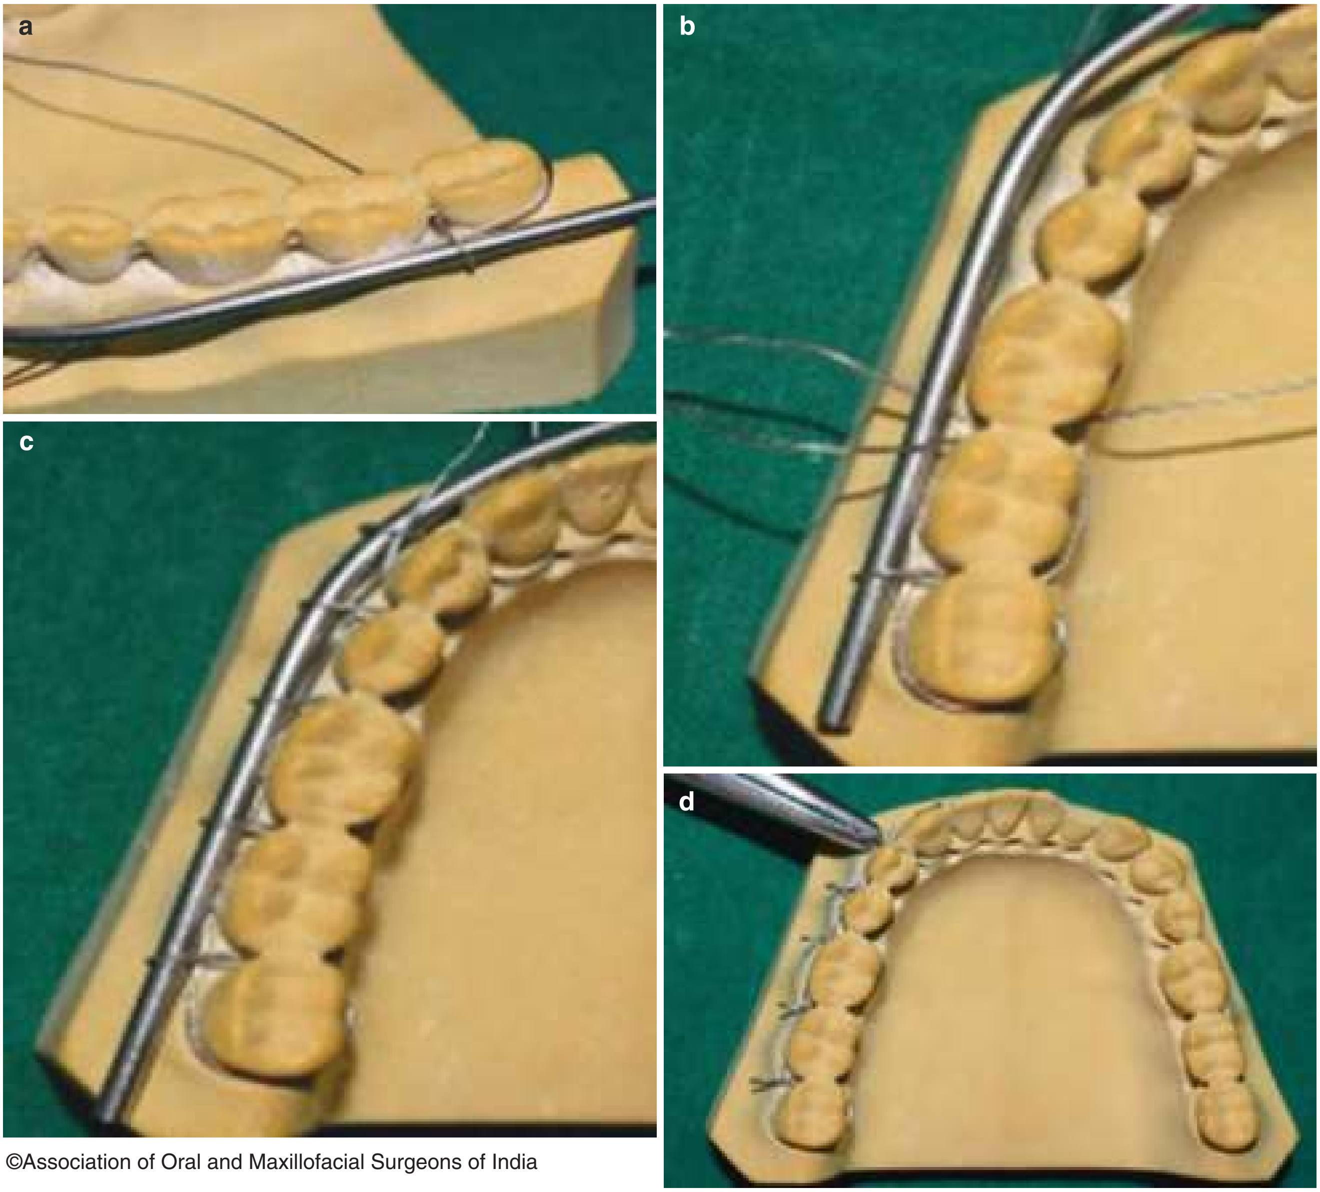

Fig. 50.16 (**a**, **b**) Showing continuous or multiple loop wiring technique, a rod is held parallel to the buccal surface of the teeth, and the wire is passed through the distal most tooth embrasure to emerge buccally and looping around the rod. (**c**, **d**) Continuous loops till the midline are made followed by pulling the buccal rod out to achieve loops

50.9.6.7 Arch Bar [26, 27] (Video 50.2)

Commercially available arch bars are usually customized or prefabricated. In most clinical scenarios, prefabricated arch bars like Erich's, Jelenko, Winter's, or Schuchardt's suffice the need for placement.

Indications

1. Partially edentulous patients where placement of eyelets is not an option due to insufficient number of teeth.
2. The teeth present are far apart making MMF impossible.
3. For alignment of avulsed teeth/displaced dentoalveolar fracture into proper arch form.
4. Reduction and immobilization of dentoalveolar component/ fracture.
5. As a part of integrated treatment for suspension for treatment of maxillofacial fractures.

Technique

Ideal placement is as close to the interdental spaces, which are then secured with 26 gauge wire. This close placement helps to reduce the arch bar to tooth contact and allows for better adaptability of the arch bar to the arch contour, thereby reducing loosening of arch bar.

In most cases, arch bars are placed from distal of first molar, in one quadrant to the other, maintaining a minimum of two teeth on either side of the fracture line in a dentate patient.

The wire is passed from one interdental space and moved around the tooth to emerge buccally from the other side (Fig. 50.19a). Placement of arch bar by securing it with wire begins (Fig. 50.19b) usually at the midline and proceeds posteriorly or from one end (molar) to another (Fig. 50.19c,d) in order to avoid excess in the center and to achieve uniformity throughout the length of the arch bar. The wires are usually twisted in between the cleats and placed into the interdental space to avoid damage to surrounding soft tissues.

The cleats of the arch bar always face gingivally. MMF is usually secured using 24 gauze wires in box pattern.

Figure 50.19e is showing a model with upper and lower arch bar placement secured with wires, while Fig. 50.19f is showing a clinical photograph of arch bar placement.

Advantages

- Easier to manipulate and maintain the intra-arch form.
- Acts as a tension band, resisting forces acting at the alveolar level of the fractured component.
- Multiple vectors can be provided by using elastics and VW cross bracing in reducing the fracture displacement to achieve premorbid occlusion.

Disadvantages

- One of the major drawbacks is the lack of vertical stop in the anterior region when an arch bar is used. In the posterior region, the opposing teeth act as a vertical stop for occluding teeth which isn't the case with anterior region as the anterior upper teeth may slide over the lower when elastics are stretched between the maxillary and mandibular teeth resulting in extrusion of anterior teeth. This problem can be circumvented, by drilling a hole using a bur in the gingival area apical to the mucogingival junction through the buccal and lingual cortices.

An additional 24 gauze wire is passed from the buccal side of this hole to emerge lingually. The lingual end of the wire is then passed through the interdental space of the tooth to emerge buccally. Both the ends of the wire are then twisted to prevent extrusion.

In the anterior maxilla, anterior nasal spine can be used for additional suspension of the arch bar to prevent downward pull exerted by the elastics.

- Increased operating time.
- High probability of penetrating injuries to the operator.
- Compromised oral hygiene and periodontal tissue damage.
- Post-treatment removal is a traumatic experience.

Complications

Post reduction of the dentoalveolar fracture, the incisal edges of the fractured teeth bearing segment will remain above the normal occlusal plane. This discrepancy can be corrected by application of apical pressure to this segment through MMF, circummandibular wiring, suspension from ANS, lateral piriform, buttress, or using the eye of the maxillomandibular fixation screw.

50.10 Maxillomandibular Fixation (MMF) Screws [28] (Video 50.3)

50.10.1 Introduction

A self-drilling or tapping maxillomandibular fixation screws by Arthur et al. [29] in 1989 reduced the intra and post-operative problem associated with the arch bars.

50.10.2 First Generation

Screws were modified monocortical self-tapping screws that were kept at 4–5 mm above the mucosa for subsequent wire

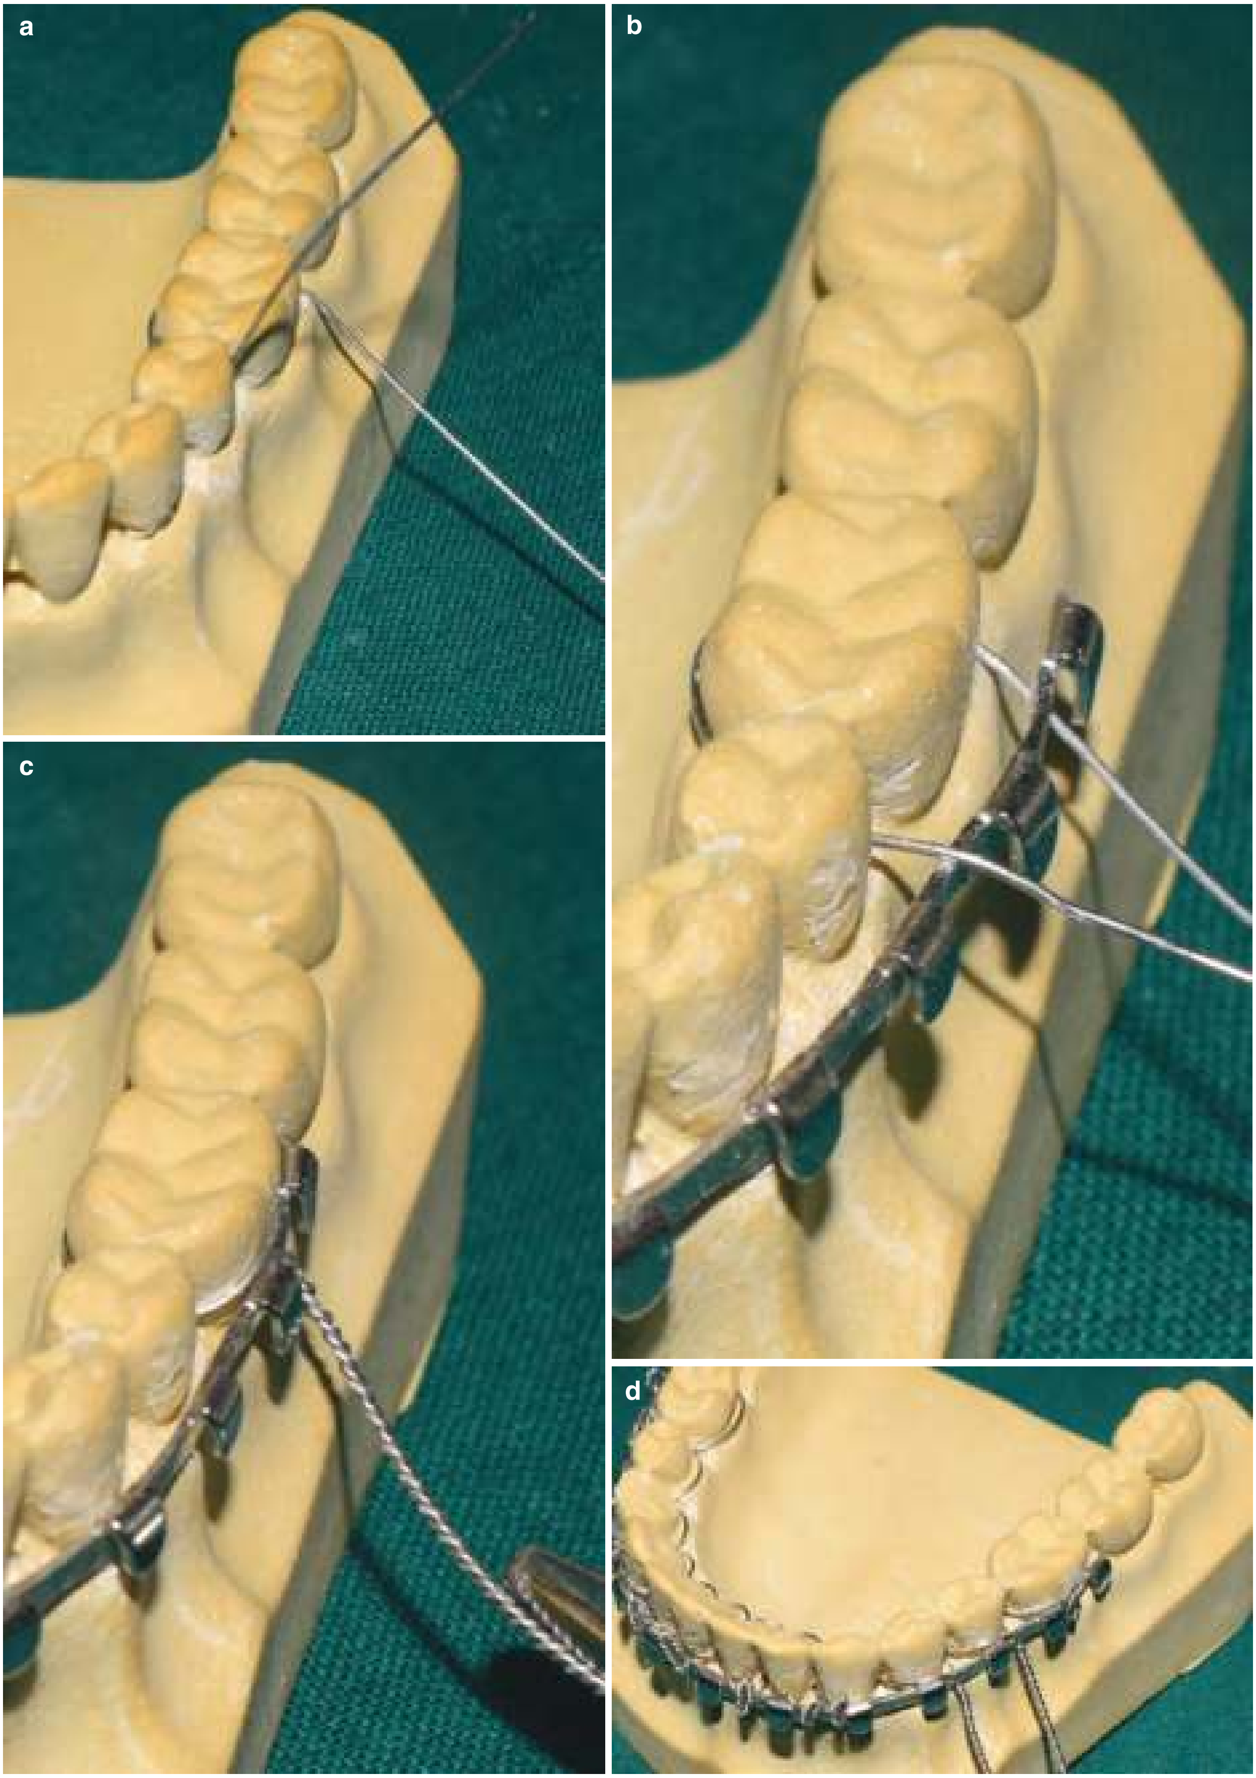

Fig. 50.19 (**a**–**d**) Showing technique of arch bar placement. The wire is passed through the embrasure or emerge buccally. The wire on the mesial side of the tooth is passed above the arch bar, where as the distal end wire is passed below the arch bar to secure it by twisting. (**e**) Showing a model with upper and lower arch bar placement secured with wires. (**f**) representing a clinical photograph of arch bar placement

Fig. 50.19 (continued)

splinting. Surgical preparation of the site needed prior to insertion. They were usually wider in diameter with grooves/flutes.

50.10.3 Second Generation

Screws were self-drilling or self-tapping screws which were spool shaped. The central part of the screw head is perforated with one of two channels perpendicular to its axis aiding in the passage of ligature wires. The top of the screw heads is smoothly finished at the contact zone with overlying mucosa.

Clinician should consider fracture location, dentition, surgical exposure, and the quantity of bone for placement of these IMF screws.

Ideal radiographic images obtained are orthopantomogram and CT axial scan to analyze and plan placement of these screws.

Sites include anterior vestibule and anterolateral (canine and premolar regions) as they provide sufficient bone depth, clearance from adjacent tooth, and easy accessibility. Screws should be placed above the root apices as subapical placement leads to mucosal overgrowth (Fig. 50.20a–d).

Ideally one screw should be placed on either side of the fracture line. However, in severely displaced cases, it is advisable to use multiple screws on either side to achieve vectors in different directions.

50.10.4 Advantages

1. Cost-effective
2. Easy placement
3. Lesser operating time
4. Less incidences of penetrating injuries
5. Lesser appliances inside the oral cavity
6. Minimum damage to periodontium
7. Easy maintenance of oral hygiene

50.10.5 Disadvantages

1. Iatrogenic damage to tooth roots
2. Root fracture
3. Ingested hardware
4. Screw loosening resulting in malocclusion [30]
5. Pulpal necrosis
6. Root resorption
7. Tooth loss
8. Soft tissue growth over the screw head [31]

Fig. 50.20 (**a**–**d**) Showing clinical steps in placement of MMF screw. Technique for placement of MMF screws. Marking is done between the root apices followed by drilling and placement of MMF screw, one in each quadrant. The wire is passed through the eye of the opposing arch and secured to achieve intermaxillary fixation

50.11 Conclusion

Dentoalveolar fracture mostly involves teeth, soft tissues, and associated bones. With the recent advancements in the field of dentistry, the oral and maxillofacial surgeon can restore the lost form and function of teeth to facilitate the improvement in quality of life in trauma-afflicted patients.

51 Principles of Internal Fixation in Maxillofacial Surgery

Abhilasha Yadav

51.1 Introduction

Road traffic accidents (RTA) are one of the primary etiologies of craniomaxillofacial fractures. Open reduction and internal fixation (ORIF) is the most important treatment modality to restore the compromised form and function. Adequate reduction and fixation with miniplate osteosynthesis is the essential component of management.

51.1.1 Association of Osteosynthesis (AO Principles)

The following are guidelines for internal fixation based on the four basic principles formulated by AO in 1958.

(A) **Anatomic reduction:** Fracture reduction and fixation to restore normal anatomy
(B) **Stable fixation:** Fracture fixation with relative or absolute stability, as required by the patients injury and type of fracture
(C) **Preservation of blood supply:** By gentle reduction and careful handling along with preservation of vascularity of soft tissues and the bone
(D) **Early and active mobilization:** Rehabilitation of the injured part and the patient as a whole with early and safe mobilization

51.2 History

1. Plating of fractures can be traced back to 1895 when a metal plate was first introduced by Lane for internal fixation. It was abandoned due to its drawback of corrosion [1].
2. Subsequently Lambotte in 1909 and Sheman in 1912 introduced plates for fixation, but due to insufficient strength, their designs were abandoned [1].
3. Eggers in 1948 developed a plate which was structurally weak resulting in instability of fixation [1].
4. In maxillofacial surgery, the interest in rigid fixation began with the treatment of fractures of edentulous mandible, as the fractures located in edentulous mandibular segments were easier to manage.
5. Keys to fast and economic bone healing are optimal reduction of fracture ends and maximum stabilization of fracture area. Simplest way to achieve these goals is to apply the principles of axial compression of fracture ends. This principle was first advocated by Belgian Surgeon Davis in 1994 and later adopted by ASIF (association for the study of internal fixation).

   According to him, there was a need for compression between the fragments of fractures. He used a plate called coaptens to achieve this goal, which increased stability and suppressed interfragmentary motion. The mode of healing initiated by this is called soudure autogene (autogenous welding) now known as primary bone healing.
6. In 1967, mandibular compression screw (MCS) was used in oral and maxillofacial surgery (OMFS) in edentulous fractured mandible while performing first compression osteosynthesis. Self-tightening/automatic MCS plate was developed by Luhr in 1968. Later, dynamic plates were advocated for surgery of long bones with subsequent application in mandibular fractures.

51.2.1 Evolution of Fixation Methods

History of development of fracture management modalities [2–4] (Table 51.1)

51.3 Concept of Bone Healing

51.3.1 Secondary Bone Healing (Fig. 51.1)

51.3.1.1 Stage I: Inflammation Induction

Immediately after fracture, hematoma formation occurs; hematoma plays a vital role in the angiogenesis of the healing fracture. Subsequently, inflammatory cells, stem cells, and fibroblasts initiate inflammatory response and enhance angiogenesis. Cytokines which helps in bone repair are released in this phase and hematoma is removed. Within 3 days, thin layer of fibrous tissue covers the periosteal surface of fractured bone. The cortical bone adjacent to fracture site becomes necrotic which later gets remolded by multinucleated osteoclast.

51.3.1.2 Stage II: Fibrocartilaginous (Soft) Callus Formation

Dense fibrous tissue, cartilage, and fibrocartilage formation occurs due to organization of subperiosteal hematoma; soft callus is composed of internal (endosteum of marrow cavity and lining of Haversian canal) and external components (periosteum and organizing hematoma) and continued proliferation of osteoblasts; fibrocartilaginous tissue begin to calcify as the periosteal and endosteal circulation develops. The conversion of chondrocytes to osteocytes occur and the entire callus is converted to immature woven bone.

51.3.1.3 Stage III: Hard Callus Formation

After 3–4 weeks of fracture, the hard callus begins to form and osseous union of the fractured cortical bone starts.

51.3.1.4 Stage IV: Remodeling

The trabeculae orient themselves in the direction of functional pressures after bone formation.

51.3.2 Primary Bone Healing (Contact and Gap Healing)

Healing without callus formation is called as primary bone healing. When there is direct apposition of cortical bone surfaces, contact healing occurs. Osteoclasts widen the Haversian canals on either side of the fracture and move toward each other. The cortical bridging occurs in 8 weeks and is usually completed in 16 weeks. In gap healing also primary bone healing occurs; gap as wide as 100 μm can be filled with mature lamellar bone (Fig 51.2).

51.4 Biomechanics of Facial Skeleton [5]

51.4.1 Mandible Fractures

The mandible is a class III lever with:

- Condyle as fulcrum.
- Bite load as a resistance force.
- Masticatory muscles as applied force.

Simple beam mechanics described the traditional biomechanical properties of mandible, which represents compression at inferior border and tensile forces on the superior border with an applied anterior load (Fig. 51.3). The "neutral axis" is the line of zero stress where the tensile forces become compressive, and it is approximately at the level of the inferior alveolar canal. Compression and tension will be produced in symphysis region due to torsional forces.

The muscles inserting on the mandible and forces exerted by these muscles during function, determine the tension and compression zone in cases of fracture mandible.

The direction of the muscular forces acting on the mandible by temporalis, lateral pterygoid, pterygomasseteric sling, and suprahyoid musculature is shown by arrows in Fig. 51.4. For successful treatment of facial fractures in the form of rigid fixation, the understanding of biomechanics of facial injury is very important.

©Association of Oral and Maxillofacial Surgeons of India

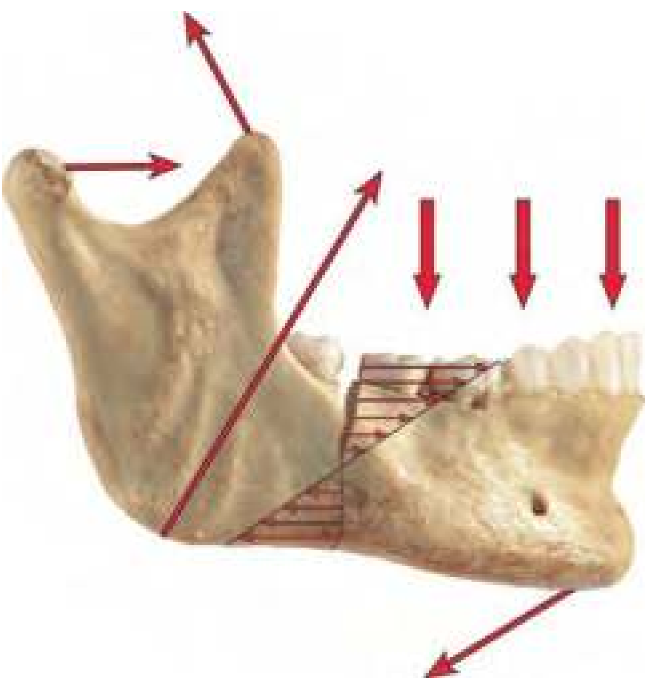
Fig. 51.3 Tensile and compressive force mechanism



©Association of Oral and Maxillofacial Surgeons of India

Fig. 51.4 Direction of muscular forces

51.4.2 Midface Fractures

Midface generally does not show muscle forces acting on them except for zygomatic bone, on which masseter exerts the primary force which can create notable bony displacement causing inferior and medial displacement especially in the presence of temporalis fascia disruption (Table 51.2).

Table 51.2 The four articulations of zygoma with their functions in management of fracture

Frontozygomatic suture	Received greatest tensile forces and is the important site for fixation
Infraorbital rim	Thin bone, least important site for fixation
Zygomaticomaxillary buttress	Best site for fixation to counter the force of masseter muscle
Zygomaticotemporal suture	Least important site for plating

51.5 Functions of Plates

51.5.1 Compression

Compressing together the main fragments of a single plane fracture can result in absolute stability, i.e., the complete abolition of interfragmentary movement. Interfragmentary compression in single plane, as in diaphyseal fractures, can be achieved by exploiting the eccentric loading capabilities of the dynamic compression family of plates.

The screw is inserted in a neutral mode, and plate was fixed to the right-hand fragment. In an eccentric (load) mode, a screw is then inserted into the left-hand fragment. As the load screw is fully inserted, it engages and slides down the sloping surface of the plate hole, and the screw and bone move toward the fracture, compressing it.

If the plate that exerts axial compression is exactly contoured to the anatomically reduced fracture surface, there will be some gapping of the opposite cortex when the plate is tensioned by tightening the load screw. This is due to the compression being maximal immediately beneath the plate and not evenly distributed over the whole area of the fracture plane. The solution to this problem is to "overbend" the plate so that its center stands off 1–2 mm from the anatomically reduced fracture surface. Slight gaping of the cortex will occur directly underneath the plate when the neutral side plate is applied to the bone. The tightening of load screw causes tension in the plate and compresses the fracture evenly across the full diameter of the bone.

51.5.2 Neutralization

A primary lag screw fixation, exerting interfragmentary compression, can be vulnerable to disruption by physiological bending and/or rotational forces. Such a primary fixation is usually protected by the use of a plate, spanning from one main fragment to the other—this "neutralizes" the disruptive forces. All such forces are then transmitted via the plate and bypass the primary lag screw fixation.

51.5.3 Tension Band

If a body with a fracture is loaded at each end, over a bending point (fulcrum), tension (distraction) forces are generated, maximal on the side opposite the fulcrum, and angulation occurs. However, if an inelastic band, such as a plate, is anchored to the tension side of the body, same load will generate compression across the fracture interface. This is known as the tension band principle.

51.6 Fixation Methods and Devices [6] (Table 51.3)

Commonly used devices used for fixation are wires, staples, pins, and screws [6].

51.6.1 Material

Most commonly used materials are titanium (Ti-6Al-4V) and stainless steel (316L). Stainless steel has been used because of its greater biocompatibility and corrosion resistance. Since 1980 titanium was used in maxillofacial surgery.

51.6.2 Rigid Fixation

The internal fixation is defined as the placement of wires, plates, screws, rods, pins, and other hardware to stabilize the fracture fragments.

51.6.2.1 Rigid Internal Fixation (RIF)

RIF is defined as "bone fixation of any form in which biomechanical forces are either countered or used to stabilize the fragments of fracture and permits loading of bone to permit active action" [7].

51.6.2.2 Examples of RIF

Examples of RIF are the use of bone plates and screws, two lag screws, and use of reconstruction plate with three screws on each side of the fracture fragment. Use of long compression plate is also included in the rigid internal fixation examples.

Table 51.3 Fixation methods and devices

Fixation methods			
Wires	Staples	Pin	Screws
	Pneumatically driven staples	Kirschner wires	Cancellous screw
	Prebent staple legs		Cortical screw

Healing: In the rigid internal fixation, no callus formation is formed during bone healing. The fracture bones heal by a process of Haversian remodeling. This primary or direct bone union requires immaculate immobilization between osseous fragments, i.e., minimum gap between the rigid fixation. Examples of rigid fixation for fracture mandible are shown in Fig. 51.5a,b.

51.6.3 Nonrigid Internal Fixation

It is a kind of fixation that is not strong enough to prevent interfragmentary motion completely. Thus interfragmentary motion is the differentiating factor between rigid and nonrigid fixation. Any mobility between fragments stabilized through internal fixation on active usage of skeletal structure signifies nonrigid fixation.

Fig. 51.5 (**a**, **b**) Techniques of rigid fixation for mandibular fracture. (**a**) Fixation with single miniplate and tension band; (**b**) fixation with two miniplates

Transosseous wiring across a fractured mandible is a good example of nonrigid fixation. The wire is unable to neutralize torsion/or shear forces and requires other fixation methods like MMF (maxillomandibular fixation).

Healing: The bone healing that occurs under the condition of mild mobility between fragments is called as secondary bone healing. There is deposition of periosteal callus in such circumstances, followed by resorption of fragment peripheries and tissue differentiation through various stages from fibrous to osseous healing.

51.6.4 Semirigid Fixation

Semirigid fixation is based on load-sharing osteosynthesis. Semirigid fixations include the use of:

– Lag screw
– Miniplates and microplate
– Locking plates
– Resorbable plates
– Three-dimensional plates

51.6.5 Load-Bearing Versus Load-Sharing Fixation (Table 51.4)

Table 51.4 Load-bearing versus load-sharing fixation

	Load-sharing fixation	Load-bearing fixation
Definition/ explanation	Internal fixation of inadequate stability to withstand the functional loads across the fracture	Fixation that is capable of withstand the entire load applied during the functional activities to the mandible
Indication	1. Simple linear fractures 2. Mandibular fractures	1. Mandibular comminuted fractures 2. Loss of segment of mandible due to injury 3. Fracture with very less boney interface because of atrophy
Material used	Stainless steel, titanium 2.0 mm miniplating systems	Stainless steel, titanium 2.3 mm, 2.4 mm, 2.7 mm diameters, mandibular reconstruction bone plate
Complications	Due to inadequate bone stock adjacent to comminuted fractures, load-sharing plates should be avoided	Failure by either screw loosening or plate fracture

51.7 Classification of Plating System [8]

(A) Luhr vitallium maxillofacial systems
  (I) Mandibular compression screw system
  (II) Mini system
  (III) Micro system
  (IV) Mandibular reconstruction system
(B) Champy's system
(C) AO/ASIF maxillofacial implant system
  (I) DCP, EDCP
  (II) Reconstruction plates
(D) The Würzburg titanium system for rigid fixation

51.7.1 Locking Plate-Screw Systems

In the late 1950s, AO group put forth the tenets which are followed in traditional plates and screws. This included exposure of fracture with anatomic reduction and internal fixation of fracture fragments with the desired result of anatomic bone union [9]. The stability of these plates is achieved by locking the plates by the screws.

Conventional screw – bone plates system requires plate to adapt precisely. In the absence of this contact, the tightening of screw will draw the segments of the bone toward the plate which results in change of the occlusion and bony segments.

On the other hand, the locking plate-screw system does not require the intimate contact of plate to the underlying bone in all the areas. The screw tightening locks the plate and thus stabilizes the bone segments without compressing the bone to the plate. Alteration in reduction is impossible after screw insertion.

According to Herford and Ellis [10], the locking plate and screw system are simple to use. Like compression plate it does not require plate to be compressed to the bone.

Klotch et al. [11] also concluded that the locking plates require less time due to less bending and faster application with good results.

Locking plate and screw come in two designs, i.e.:

– Threaded locking plate and screw (Conventional)
– Tapered locking screw and plate (New generation)

The threaded locking plate - screw system features corresponding machined threads incorporated in both the screw and plate. Whereas, the tapered locking screw - plate system has a screw head which is tapered in shape with machined threads, with the plate either having no machined threads or a single machined thread incorporated into its design. This facilitates a more flexible locking mechanism which allows for screw angulation of upto 10 degrees, in comparison to the threaded locking system which needs absolute perpendicular screw placement [12].

51.7.2 Reconstruction Plates

The rigid plates with 2.7 mm bicortical screws were introduced by AO/ASIF in 1972 [13].

The main advantage attributed to the non-locking reconstruction plate, is its "load bearing" principle. Scolozzi and Richter [14], used the 2.4 mm AO Titanium plates for the management of mandible fractures, with good outcomes and very less complications.

They are available in different shapes for specific areas like angle reconstruction plate (Fig. 51.6), condylar reconstruction plate (Fig. 51.7), and straight reconstruction plate with different lengths.

Indications

1. Large defect of mandible after massive trauma
2. After mandible resection due to tumors or osteoradionecrosis
3. Commonly used in comminuted fractures of mandible, sometimes in combination with miniplates
4. To support the bone grafts in mandibular reconstruction

The advantages of rigid fixation with grafting include immediate jaw function and excellent stabilization of graft. The main disadvantage at the graft site is disuse osteoporosis or "stress shielding." This phenomenon occurs when rigid plates absorb the mandibles functional stress. To protect the long bones from stress, the plate's modulus of elasticity will have to exceed in comparison with the bone to which it is attached. Osteoporosis and reduction in bone strength are the result of protection from stress or shielding in long bones [15].

Fig. 51.6 Angle reconstruction plate

Fig. 51.7 Condylar reconstruction plate

51.7.3 Lag Screw Fixation

In oral and maxillofacial surgery, Brons and Boeriing introduced lag screw fixation for the first time in 1970. According to them two lag screws prevent rotational movements of the fracture fragments in oblique mandibular fractures [16].

51.7.3.1 The Principle of Lag Screw

The lag screw principle is used whenever two wide contact surfaces of the bone should be pressed together (for mandibular oblique sagittal fractures or onlay graft fixation).

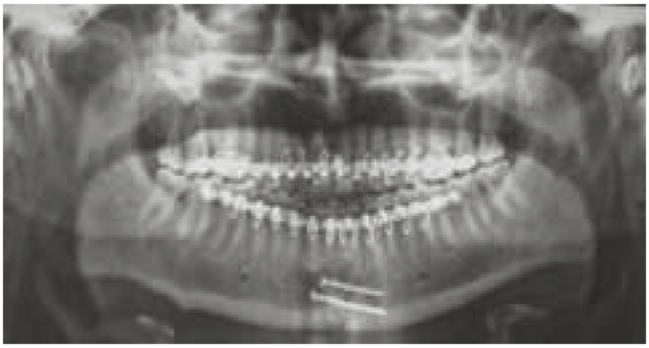


Fig. 51.8 Orthopantomogram showing fixation with lag screws

Through the outer cortex or onlay graft, the drilling of the hole was carried out of the identical diameter to that of screw so that the screw slips through the outer cortex. The lag screw drill, which is of the same diameter as the screw, will simultaneously create a conical countersink to provide an optimal fitting of the screw head. The inner cortex is then perforated with the normal surgical drill, and the screw is inserted. It grips the inner cortex and, when tightened, exerts great force to pull the outer segment into close contact with the inner one. This principle can be used in oblique sagittal mandibular fractures, with the placement of at least three screws, or in combination with the plate, lagging only one or two of the total minimum number of screws (Fig. 51.8).

51.7.3.2 Absolute Rigid Fixation Provided by Lag Screw

Lag screw should be selected in patients having sufficient bone available for placement of two screws; dissolution of the bone around the screws results in cases of micromotion. The lag screw should be placed in the direction perpendicular to the line of fracture to avoid displacement or overriding during tightening of the screws.

Advantages of lag screws over bone plates:

1. Lag screws require less hardware hence cost-effective.
2. Absolute rigid fixation.
3. Quick and easy to use.
4. Accurate reduction.

Disadvantages

As the lag screw fixation relies on compression of bone fragments and if intervening bone is unstable due to comminution or missing, there will be segment overriding or fracture gap shortening, resulting in malocclusion.

51.7.4 Comparison of Lag Screw Fixation Methods with Different Methods of Fixations [17–19]

1. Single lag screw with arch bar, without MMF is sufficient enough in the treatment of anterior mandible indirectly reducing the cost and requiring less hardware and time of healing [17].
2. Lag screw fixation and plating showed excellent outcome in anterior mandible fracture; lag screws technique is difficult but associated with less postoperative complications [18].
3. In mandibular angle fracture, the lag screw demonstrates smaller inter-fragmentary gap in comparison with miniplate fixation [19].
4. Lag screw osteosynthesis is more advantageous for ramus height restoration in comparison with miniplates and Kirschner wires, in patients with condylar process fractures [20].

51.7.5 Champy's System [21]

Different treatment principles using monocortical miniplates without axial compression for treatment of mandibular and midface fractures were introduced, namely, by Michelet et al. in the late 1960s, which they published in 1973.

Michelet's work has been elaborated by Champy et al. for the management of mandibular angle fracture by the use of intraoral monocortical miniplates. The ideal line of osteosynthesis has been followed by Champy for plates fixation (Fig. 51.9).

It is based on the principle of neutralizing unfavorable traction strains while at the same time allowing transmission of favorable compression forces. The biomechanical validity of Michelet principles was confirmed in a series of multidisciplinary experiments performed in Strasbourg, France, between 1971 and 1974 [21].

Advantages

1. Smaller incision required
2. Less soft tissue dissection
3. Less palpable
4. Decrease stress shielding effect
5. Less chance of dental injury because of monocortical screws
6. Less chances of infection

With this type of fixation, there is adequate stability to allow direct bony union and is called as functionally stable fixation. There are many fixation techniques used in oral and maxillofacial surgery (OMFS) which are not rigid fixation truly but classified as functionally stable fixation.

Fig. 51.9 Champy's ideal line of osteosynthesis

Fig. 51.10 Champy's miniplate

51.7.5.1 Materials

Plates and screws are made up of pure titanium. The miniplates are 2 cm long, 0.9 mm thick, and 6 mm wide. They had an elastic limit of flexibility between 70 and 80 per square millimeter, and their rupture point lies between 95 and 110 decanewton (daN) per square millimeter (Fig. 51.10).

51.7.5.2 Miniplates (Fig. 51.11)

- The miniplates vary in length from 2 to 9 cm with a thickness of 0.9 mm. They come in different lengths such as 2 holes with gap , 3 holes, 4 holes, 6 holes, and 8 holes to 16 holes with gap or continuous plates.
- The four-hole and six-hole plates are available with intermediate spacing.
- A wide variety of pre-shaped plates like L, X, Y, T, and K, delta shaped, and 3D- and H-shaped plates are also available. 2.1 mm is the minimum diameter of the hole in the plate and has a bevel of 30°.

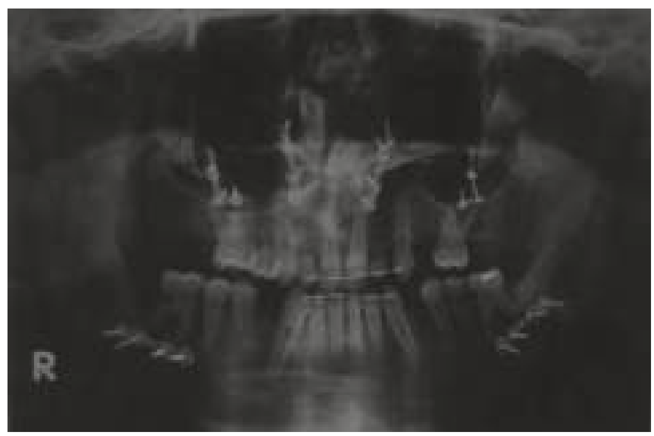

Fig. 51.11 OPG showing fixation with the help of miniplates after Leefort I and bilateral sagittal split osteotomy

51.7.5.3 Screw

- All screws are cortical and self-tapping and have cruciform head.
- Available in lengths of 5, 6, 7, 9, 11, 13, and 15 mm.
- 2 mm is the diameter of the screw with 1.6 core diameter of thread.
- The screw thread is 10/10, so that one turn of the screw corresponds to 1 mm penetration into the bone.
- 2.8 mm is the screw head diameter, and it is designed such that it allows insertion at 30-degree angle with respect to the plate surface.

The drill has the same diameter as the core of the screws—1.6 mm. This ensures firm anchorage of the self-tapping screws.

51.7.5.4 Biomechanical Properties of Screw (Fig. 51.12) [22]

- The external or the outer diameter ranges from 0.8 to 2.0 mm. Core diameter of the screw is its internal diameter. The surgical bone screws act by clamping the bone plate and bone together.

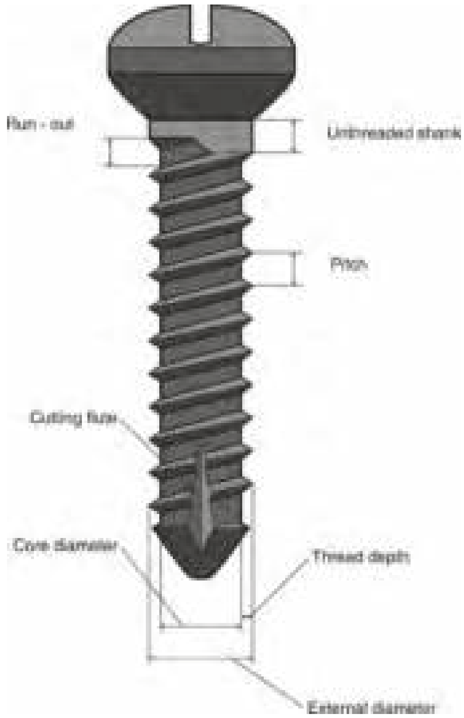

Fig. 51.12 Biomechanical properties of screw

- The pitch of the screw is calculated parallel to the screw axis from a point on one thread to corresponding point on the adjacent thread.
- The difference between core and external diameter is the thread depth.
- The distance between screw runout and screw head is the length of the unthreaded shank.
- The distance between screw runout and plate is the length of the unthreaded shank with plate.

51.7.5.5 Self-Tapping and Drilling Screws [23, 24, 25]

Self-tapping screw: The screw which is inserted into a pre-drilled hole without tapping a screw head is the self-tapping screw.

Self-drilling screw has a drilled-shaped point to cut and does not require predrilling. Self-drilling screws have several advantages over the self-tapping such as it does not require drilling the hole and prevents thermal damage leading to infection, screw loosening, osteomyelitis, and nonunion. It also prevents damage to tooth roots and nerves by the use of drills and also avoids the complications associated with drill bit fracture.

51.7.5.6 Monocortical vs. Bicortical Screws

The monocortical screws are generally used for fixation of mandibular fractures and after sagittal split osteotomy. Chug H-IJ et al. [26] also concluded that monocortical screws provide stable fixation. Also chances of damage to the vital structure like inferior alveolar and lingual nerve are less with monocortical screws. Bicortical screws are usually used at the lower border of the mandible for fixation.

51.7.6 Microplates

The microplate fixation concept was introduced by Luhr in 1988. They are composed of cobalt, vitallium alloy, and molybdenum in the percentage of 68%, 27%, and 5 %, respectively. It has got excellent physical strength and corrosion resistance.

The thickness of plate is 0.5 mm, and the diameter of the screws is 0.8 mm. In all the three dimensions, they can be contoured and maintained an excellent degree of rigidity for osseous segment stabilization. They are used in:

1. Nasoethmoidal fractures
2. Fractures of infraorbital area
3. Fracture of frontal sinus wall
4. Reconstruction of the skull
5. Infant craniofacial surgery

51.7.6.1 Micromesh

Inspite of its reduced thickness (0.3 mm), micromesh is remarkably strong. It is available in sizes of 40 by 60 and 60 by 100 mm. Template made of a soft, malleable tin alloy comes in various sizes. The template is cut to the shape and size required in the individual case, and then it is contoured to the bone surface. The actual titanium micromesh is then cut out with a wire cutter and contoured on the instrument table reduplicating the individual shape of the template.

51.7.7 AO/ASIF System [27]

The association of osteosynthesis/association for the study of internal fixation (AO/ASIF) were founded by a group of 15 Swiss surgeons in 1958. The group was led by Maurice E. Muller; AO/ASIF investigators have documented the biologic basis for the concepts on which rigid fixation techniques are based.

Spiessl applied AO/ASIF concepts of long bone healing and modified AO/ASIF instrumentations for use in mandible in the late 1960s and early 1970s.

Compression can be achieved through static or dynamic means. The two devices that produce static compression are the self-compression plate and lag screw.

1. The self-compression plate designed by Perren for the ASIF has been called the dynamic compression plate (DCP). It generates interfragmentary compression by spherical guiding principle. The DCP principle causes the movement of screw in both vertical and horizontal direction which compresses the fracture segments.
2. Lag screw principle—when the screw is tightened, it compresses the surface when the screw glides through the cortex of one fragment and engages the cortex of the opposite fragment.

The EDCP (eccentric dynamic compression plate) has outer hole which is oblique causing compression on alveolar side and longitudinal inner holes creating basal side interfragmental compression. EDCPs eccentric action eliminates the need for tension band. This plate has most utility for simple fracture of the posterior region where there are no teeth available for splinting.

The reconstruction plate is a load-bearing plate and absorbs the entire functional load. They are designed for use without the tension band. It is large and reinforced version of basal stabilization plate. They can be adapted to local bony contours and are malleable. Depending on the placement of drill hole, it has two-way DC holes that enable compression to be applied in either longitudinal direction.

51.7.7.1 Plates

(I) Linear system (compression plates)
  (a) DCP plates
  (b) EDCP plates
(II) Universal systems (reconstruction plates)

51.7.7.2 Dynamic Compression Plate (DCP)

These are designed to withstand tensile loading force in the mandible. In mandibular angle, body, and symphysis regions, they can be used comfortably. It can be applied intraorally or through an extraoral incision. It is used with a tension band. The dynamic compression plate was developed in 1969.

The DCP has a self-compressing hole design. The holes are oblong, and the portion of each hole distant from the fracture has a sloping form or “shoulder.”

Experimental work showed that the flat undersurface of the DCP interfered with the vascular supply of the underlying cortex onto which it was compressed by the screws. The concept of “footprint” is the area of undersurface of the plate in contact with the underlying bone cortex.

Principles of DCP—The sloping shoulder of the DCP hole has the form of part of an angled cylinder. If a screw is inserted eccentrically, so that its head on final tightening slides down the sloping profile of the hole, the screw/bone unit will be shifted toward the fracture, and the fracture plane will thereby be compressed. Such a screw is often referred to as a load screw.

51.7.7.3 Eccentric Dynamic Compression Plate (EDCP) [27]

It produces a compressive force via arrangement of eccentric and centric (axial) plate holes. EDCP are 8 mm wide and come in four-hole (36 mm long) and six-hole (42 mm long) lengths. The stainless steel plates are 2 mm thick, and the titanium plate is 2.2 mm thick. At the fractures alveolar side, the compression has been provided by the 75° angulation. It is important to place the sloped edge of the angled hole at the mandibular lower border (if the plate is placed upside down, it will tend to distract bone edges at the alveolar border). First central screws are inserted in EDCPs (longitudinal hole eccentrically away from the fracture) than at the lower border; screws are placed in the 75-degree oblique holes eccentrically and in the last rest of the screws inserted in a neutral position. When the plates and tension band splint cannot be used, in those situations EDCP plates are used. The reduction forceps with pressure splinting are useful initially to reduce and compress the fragments when applying the EDCP plate.

51.7.8 Bioresorbable Fixation Systems

Use of titanium plates and screws is time-tested for their use in management of craniofacial fractures. However, it has many drawbacks including infection, hardware palpation and visibility, hypersensitivity to temperature changes, and stress shielding effect. They also interfere with radiographic examination. Sometimes, metal ions leach out into soft tissues. In view of these complications, bioresorbable implants were developed hoping to reduce hardware-associated complications as well as the necessity for hardware removal.

The use of bioresorbable fixation devices must be limited as their mechanical strength is inferior as compared to the titanium hardware. They can be effectively used in low load-bearing areas of maxillofacial skeleton like maxilla, zygoma, and upper regions of face. The bioresorbable system may not be strong enough to provide adequate stability in mandible fractures which are comminuted, as it is a load-bearing bone. It can be used in simple mandibular fractures.

Bioresorbable fixation systems stabilize fracture segments long enough for fracture healing and union to occur then dissolve, thereby reducing complications frequently encountered with metallic hardware such as palpability, visibility, cold sensitivity, and need for removal. Most commonly polylactic acid (PLA) is used in bioresorbable plates.

Complications [28]

1. For allowing the polymer chains to bend without breaking, a heat source is required. Also, the working time is limited to 8–10 s.
2. Screw insertion requires pretapping the screw.
3. Increased operative time.
4. More expensive.
5. PLA decreases stress shielding compared to LD-DC plates.

51.8 Recent Developments

To reduce the stress shielding, reduction in modulus is the answer to correct the disadvantages of internal fixation. To improve the healing of the fracture under the plates, the only solution is to allow micromotion through the fracture site; the design should be made in such a way that it resists torsional, bending, and shear movements.

51.8.1 Three-Dimensional (3D) Plates (Fig. 51.13)

The two miniplates are connected by interconnecting crossbars which are used as 3D plates. Technically, they are not three-dimensional structures, but their closed quadrilateral shape provides stability in all three dimensions.

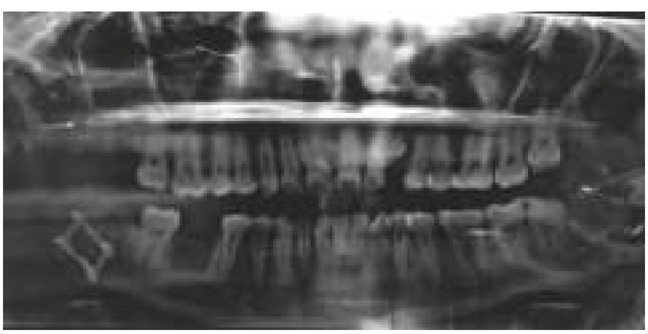

Fig. 51.13 Orthopantomogram showing fixation with three-dimensional plate

51.8.2 Virtual Surgical Planning, Computer-Assisted Design, and 3D Modelling

The management of the facial fracture is very challenging due to its unique three-dimensional contours and nonlinearity of facial skeleton. The recent development in the software technology and 3D modeling has revolutionized the treatment. They can be used as an adjunct to the standard preoperative preparation.

To reduce the operating time in the operation theater, the 3D models can serve as a template on which pre contouring of the fixation plates can be done. Custom-designed titanium implants can be made with the help of 3D printers to get the accurate fit. They can be preferred over the conventional implants and reduce the surgical time. The model design and virtual surgical planning help in constructing the guides which can be used perioperatively, can design the optimal approach preoperatively, and can compare the actual outcome to the virtual design. To reconstruct the multitude of craniomaxillofacial defects of mandible, zygoma, midface, and orbit, these technologies are very helpful. 3D modeling and computer-assisted surgical planning have been very helpful in managing the complications associated with these injuries.

51.8.3 Intraoperative Imaging [29]

Intraoperative imaging is very important in assessing the reduction and fixation of all maxillofacial fractures, and according to its feedback, the surgeons can immediately make corrections of any error that occur during reduction and fixation, which indirectly reduces the complications and avoids potential resurgeries. Computed tomography (CT) is commonly used for the same purpose.

51.9 Conclusion

For the treatment of maxillofacial fractures, many fixation methods have been used with great success. To reestablish the pre-injury esthetics, the normal masticatory function and the proper occlusion in cases of such fractures are the main objectives of the treatment. Maxillomandibular fixation can be done for the conservative management of such fractures which can be carried out with the help of arch bars, wiring, and cap splints and in edentulous patients by gunning splints. The open reduction and internal fixation can be carried out with the help of miniplates, microplates, 3D plates, and reconstruction plates. Different plating systems and wiring techniques make the management of these maxillofacial fractures predictable with high success rate.

Acknowledgment Author wishes to thank Dr. Anshul Rai for providing Figs. 51.6, 51.7, 51.11, and 51.13.

52 Fractures of the Mandible

Anshul Rai

52.1 Definition

A fracture is defined as "A breach in the continuity of bone."

52.2 Introduction

The mandible which is the only mobile bone of the maxillofacial region forms the lower third of the face. Owing to the prominence of the symphysis of the mandible, it is most vulnerable site to be traumatized during the road traffic accidents and, at the same time, most tempting site to be hit during the assault. Thus, the fractures of the mandible are one of the most common in maxillofacial area. It also affects the social life of the patients (Box 52.1).

The word "mandible" derives from the Latin word mandere "to chew" and -bula (instrument) which literally translates to mandibulaie "instrument used for chewing."

The bone is formed in the fetus from a fusion of the left and right mandibular prominences and the point where these sides join, the mandibular symphysis. Like other symphysis in the body, this is a midline articulation where the bones are joined by fibrocartilage, but this articulation fuses together in early childhood.

Box 52.1: General Effect of Mandible Fracture on Social Life [1]

1. Absence from work.
2. Hospital and ICU stay results in separation from family members and friends.
3. Financial loss.
4. Difficulty in feeding.
5. Weight loss (average 5% of total body weight).
6. Increased mental stress.
7. Delayed recovery in medically compromised and mentally challenged patients.

52.3 Surgical Anatomy

The mandible is a horseshoe-shaped only mobile bone of the facial skeleton. It is the strongest bone with thick cortices. Symphysis is the most prominent part of mandible, and the condyles articulate with glenoid fossa of temporal bone. The inferior alveolar neurovascular bundle passes through the bone, and in the case of fracture, it may get traumatized and can lead to hematoma and neurological deficit.

52.3.1 Angle of the Mandible

By definition, there are three types of angle as described below:

1. **Clinical angle:** It is the junction between the alveolar bone and ramus at the origin of internal oblique ridge.
2. **Surgical angle:** It is the junction between body of the mandible and ramus at the origin of the external oblique ridge.
3. **Anatomical angle or (gonion):** It is the junction where the lower border meets the posterior border of ramus.

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_52

Anatomically, mandibular angle is a weaker structure compared to other anatomic subsites.

- The ramus of the mandible is thin as compared to the body. Whenever a thick portion of the bone unites with the thin portion, it constitutes a line of weakness.
- Further the third molars are located in the angle region, and when they are impacted, they occupy lot of space in the bone and undermine it.
- In the case of mesio-angular impaction, the impacted third molar tooth acts as a wedge and predisposes the fracture of angle of mandible, if the direction of force is perpendicular to it.
- The bone grains which are oriented vertically in the ramus change their course at the angle of mandible as they enter the body of mandible. This abrupt change in the course of the bone grains also makes the bone weak. All these factors make the mandible vulnerable for fracture at this site.

52.3.2 Canine Region of the Mandible

In the canine area, also the mandible is weaker as the canine has the longest and the strongest root, and it occupies lot of space in the bone and undermines and weakens it. Thus, the mandible has a tendency to fracture at this site.

52.3.3 Symphysis and Parasymphysis of Mandible

- The symphyseal area is most prominent and most vulnerable to trauma. There is a compression of the outer cortex and expansion of the inner cortex, and the fracture will result when the forces are beyond the limits of the capacity of the bone to withstand them.
- There is a pair of genial tubercles on the lingual cortical plate in the midline, situated supero-inferiorly, which give origin to the genioglossus and geniohyoid muscles, respectively. Whenever there is a bilateral fracture at the parasymphysis area, the tongue tends to lose its anchorage on the bone, and the patient loses control and the tongue tends to fall back. It is especially true for the unconscious patient, where the tongue fall blocks the airway, and it could be fatal if not prevented.

52.4 Classification

The general classification of fractures of bone is described in Table 52.1.

Table 52.1 General classification of fracture of bone

Simple fracture	This type of fracture is not exposed to the external environment as the overlying soft tissue cover is intact
Compound fracture	In such type of fractures, the fracture line is exposed to the external environment. All dentate fractures are compound fracture as they communicate with the oral cavity
Comminuted fracture	Comminuted fractures have multiple fracture lines and more than two bony fragments
Simple comminuted fracture	It is a comminuted fracture not exposed to the external environment
Compound comminuted fracture	This type of fracture is a comminuted one which is exposed to the external environment
Complicated fracture	This fracture involves vital structures like adjacent nerves, vessels, or joint, directly or indirectly
Impacted fracture	The fractured fragments inter-digitate to an extent that there is no appreciable clinical movement. Such a fracture is unusual in the mandible and is commonly seen in the maxilla
Greenstick fracture	It is an incomplete fracture presenting as cortical bending rather than breaking. It is commonly seen in children as their bones are more elastic in nature. This elasticity allows the bone to bend. This type of fracture is commonly seen in long bones and mandibular condyle of children
Pathological fracture	This fracture occurs readily with minimal trauma or sometimes even during normal physiological function as the bone is significantly weak due to existing undermining pathology

52.4.1 Classification of Mandibular Fracture According to Site (Fig. 52.1)

Figure 52.1 highlights the mandibular fracture according to site of fracture with its incidence [2].

52.4.2 Classification of Mandibular Fracture According to the Impact

According to the impact on bone, fracture can be classified as direct fracture and indirect fracture.

During an impact, the force on the cortex results in compression, and the other cortex undergoes tension. If the force of the impact is more than the compressive and tensile strength of the bone, the bone fractures.

In a similar fashion, when there is an impact, the point of application of force gets compressed, and the resultant vector travels along the bone and applies tensor force on the point intersected by this vector. The fracture at the site of impact is called **direct fracture**, and the fracture at the site of intersection with the vector is **indirect fracture**.

For instance, the force applied to the symphysis menti results in a direct fracture at the symphysis. The vector travels to the condylar necks bilaterally and induce indirect fractures

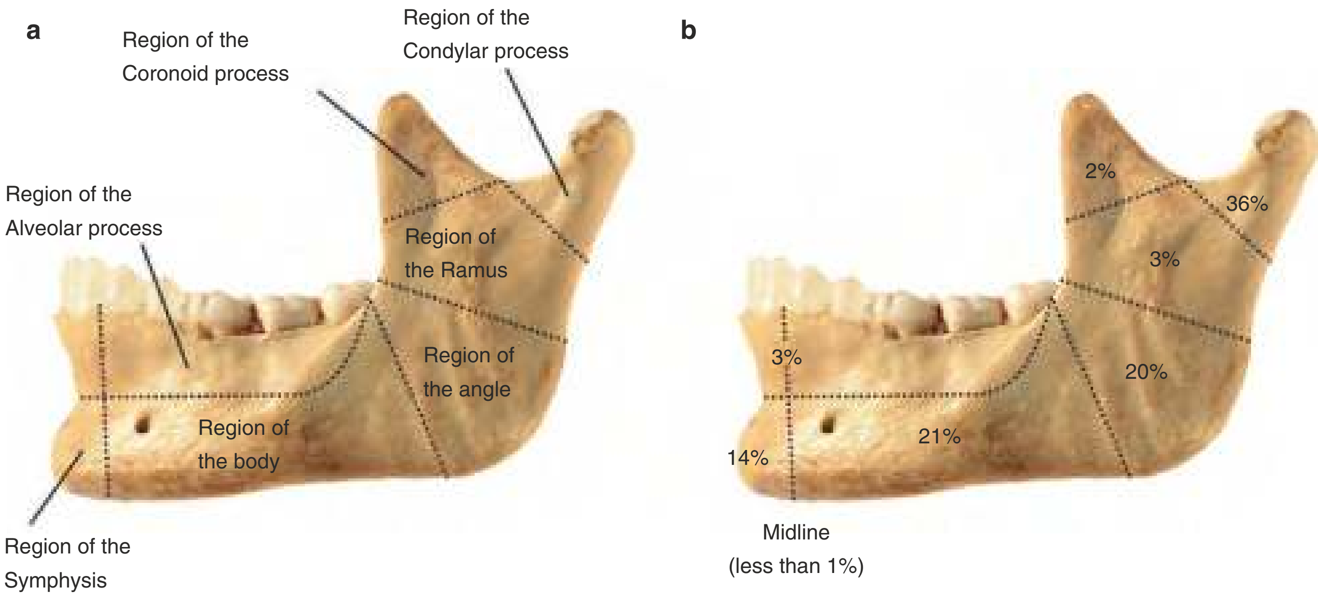

Fig. 52.1 (**a**, **b**) Highlights the mandibular fracture according to site of fracture with its incidence

Fig. 52.2 3D CT showing parasymphysis and bilateral condyle fracture

Table 52.2 Combination of mandibular fractures

Direct fracture	Indirect fracture
Symphysis fracture	Bilateral subcondylar fracture
Parasymphysis fracture	Contralateral subcondylar fracture
Body fracture	Contralateral angle fracture

of subcondylar areas bilaterally, as the condylar necks are weak. This is called a "tripod fracture" (as the fracture is at 3 points) or "parade ground fracture" or "guardsman's fracture." The later terms are used because these fractures are commonly seen among soldiers who stand upright on the parade ground for a long time. When they faint, they fall on their chin resulting in symphysis and bilateral condylar neck fractures.

52.4.3 Combination of Fracture

The most common mandible fracture seen in the developed countries is angle fracture combined with contralateral body or symphysis of the mandible [3]. Table 52.2 and Figs. 52.2, 52.3, and 52.4 highlight various combinations of direct and indirect fractures in the mandible.

52.4.4 Classification of Mandibular Fracture According to Displacement

The fracture fragments are liable to displacement according to unfavorable muscle pull leading to difficulty in the management of these displaced fractures. Table 52.3 highlights various muscles attached to the mandible with their actions.

According to the displacement of fracture fragments due to muscle pull, the fracture can be classified as:

When viewed from superior aspect:

1. Vertically favorable: When the fracture line is passing from buccal cortical plate to the lingual cortical plate with the buccal end lying mesially and the lingual end of the line lying distally. In such situation the distal fragment will be drawn closer to the proximal fragment due to the pull of the medial pterygoid muscle, and the fracture segments will come closer rather than getting separated in buccolingual plane, and thus the fracture is called as vertically favorable (Fig. 52.5a).
2. Vertically unfavorable: In this case, the fracture line passes buccolingually with the buccal end lying mesially. The distal fragment in this case will be easily viewed from superior border. The distal fragment in this case will easily get drifted

Fig. 52.3 Showing right parasymphysis and left condyle fracture

Fig. 52.4 Showing right body and left angle fracture

lingually due to the pull of the medial pterygoid muscle; thus there will be separation of the fragments in the bucco-lingual plane due to the unfavorable muscle pull, and the fracture is said to be vertically unfavorable (Fig. 52.5b).

When viewed from buccal aspect:

1. Horizontally favorable: The fracture line runs supero-inferiorly with its superior end lying posteriorly than its inferior end. In this situation, the muscle pulls from the temporalis, masseter muscle will pull the distal segment superiorly, and the suprahyoid muscles will put the proximal segment inferiorly, thus drawing both the segments closer to each other. This type of fracture is called as horizontally favorable fracture (Fig. 52.6a).
2. Horizontally unfavorable: The fracture line runs supero-inferiorly with its superior end lying anteriorly and the inferior end lying posteriorly; thus, the muscle pull becomes unfavorable and drifts the proximal and distal fracture segments apart. This is described as a horizontally unfavorable fracture (Fig. 52.6b).

Table 52.3 Muscle attachments over the mandible with their actions

Muscle	Action	Attachment
Masseter-medial pterygoid	Elevators of the mandible	Ramus of the mandible
Temporalis	Elevators of the mandible	Coronoid process of mandible
Lateral pterygoid	Depressors of the mandible, lateral movements	Ptreygoid fovea
Suprahyoid muscles (digastricus, geniohyoid, mylohyoid)	Depressors of the mandible	Body and the genial tubercles

52.5 Clinical Features

The clinical features of the fractures are described in Table 52.4 (Figs. 52.7, 52.8, 52.9, 52.10, 52.11, 52.12, 52.13, and 52.14).

52.6 Clinical Examination

52.6.1 Bimanual Palpation

The abnormal mobility at the fracture site can be elicited by the bimanual palpation. The mandible is grasped on either side of the suspected fracture line in such a way that the index finger is on the occlusal surface of the teeth and the thumbs are on the inferior border. The proximal and distal segments are moved in supero-inferior and antero-posterior direction, to elicit abnormal mobility (Fig. 52.15).

52.6.2 Compression Test

When there is a hairline, undisplaced fracture of the mandible especially at the symphysis or angle or in the subcondylar areas and it is not conspicuous clinically and radiologically, a compression of the mandible at the symphysis area and both the sides over the body, using both the palms by the operator, elicits tenderness which may suggest the fracture (Fig. 52.16a, b).

52.7 Radiographic Examination

As a rule, in orthopedics, the X-ray must be taken in two planes perpendicular to each other, i.e., in the anteroposterior and mediolateral. The most common radiographs to detect fracture of the mandible are:

1. Orthopantomogram (OPG) (Fig. 52.17)
2. Posterio-anterior view of the mandible (PA mandible) (Fig. 52.18)
3. Lateral oblique view is taken for body, angle, ramus, and subcondylar fractures.

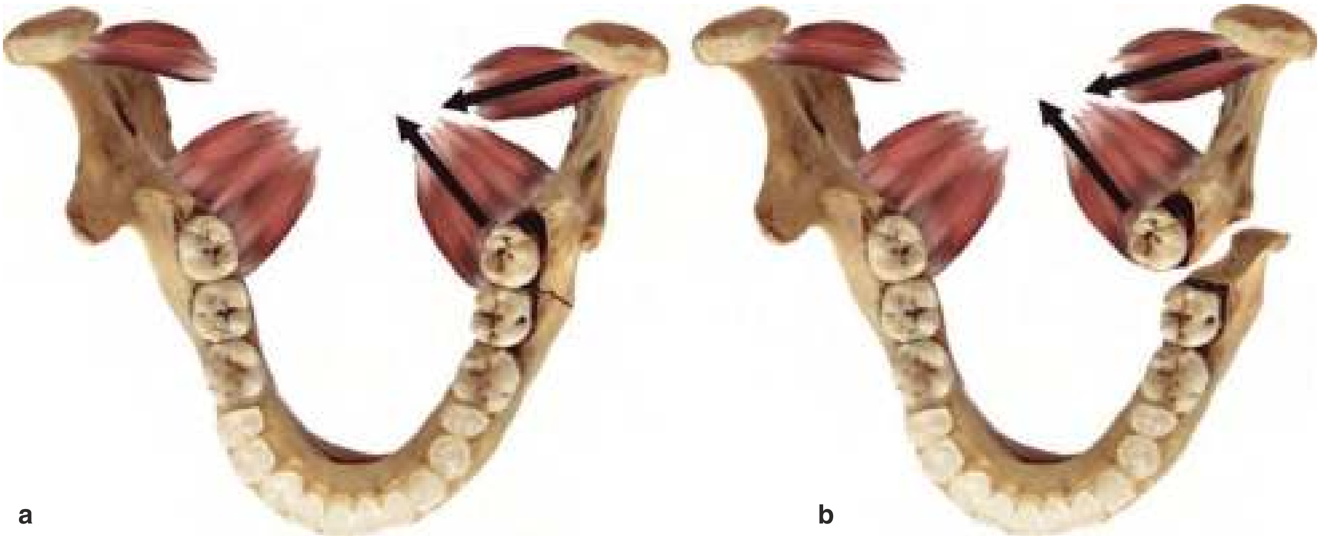

Fig. 52.5 (**a**) Vertically favorable. (**b**) Vertically unfavorable

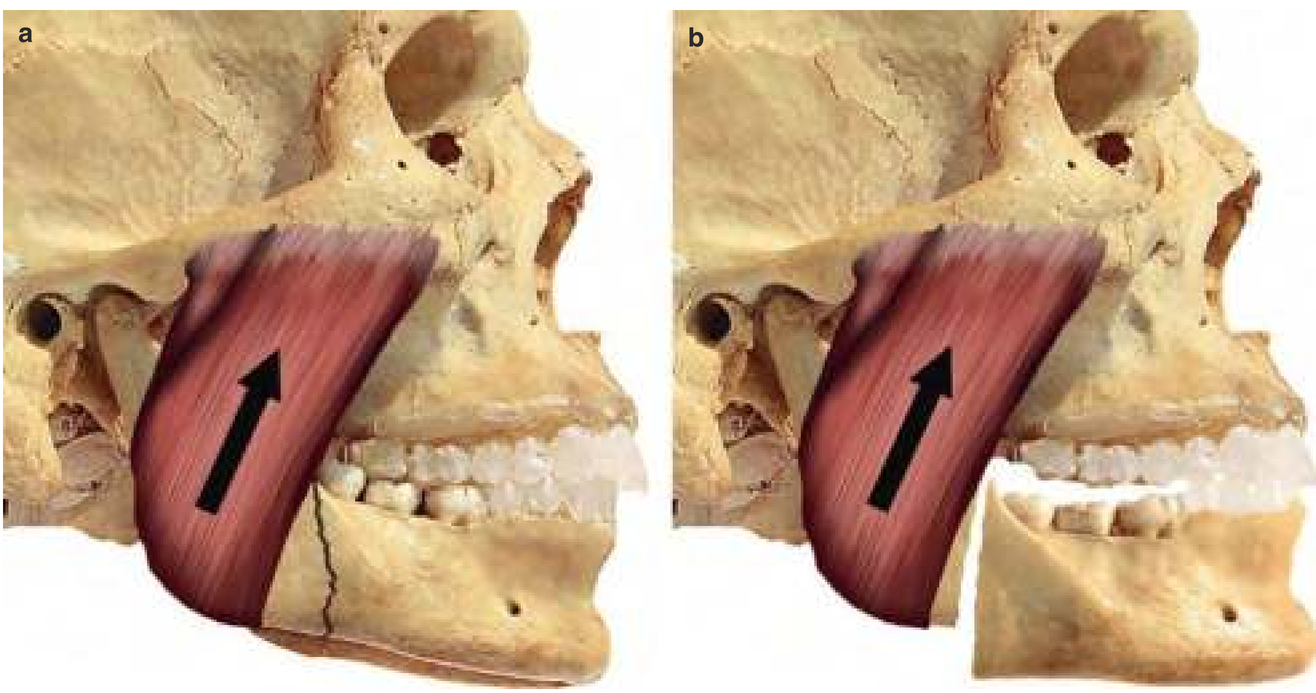

Fig. 52.6 (**a**) Horizontally favorable. (**b**) Horizontally unfavorable

4. Computed tomography (CT) scan (Fig. 52.19)
5. Digital visual tomography (DVT) (Fig. 52.20)
6. Cone beam computed tomography (CBCT) (Fig. 52.21)

– CT, DVT, and CBCT are the most commonly performed radiographs for the accurate diagnosis of mandibular fracture.
– Radiographs should not be advised unnecessary, and they should always be performed after clinical examination and after making provisional clinical diagnosis.
– Surgeons should not depend on the radiologist's report for their diagnosis; radiographs should help in confirming the clinical diagnosis and for the medicolegal record-keeping purpose as much as possible.

Table 52.4 Clinical feature of mandibular fracture

General symptoms	Signs on inspection	Signs on palpation
Pain	Presence of hematoma (Fig. 52.9)	Crepitus over fracture site
Swelling (Fig. 52.7)	Facial asymmetry	Abnormal mobility across fracture site
Difficulty in opening mouth (Fig. 52.8)	Presence of abrasion, contusion, or laceration (Fig. 52.10)	Fracture/mobility/extrusion/intrusion/avulsion of teeth
Tenderness over fracture site	Discoloration of the skin/echymosis (Fig. 52.11)	Tenderness over fracture site
Inability to chew	Trismus due to protective myo-spasm	Intersegmental mobility on bimanual palpation
Inability to swallow	Limited excursive movements of mandible	Positive compression test
Bleeding from the ear/mouth	Visible step deformity in cases with displacement of fractured segments (Fig. 52.12)	
	Malocclusion (Fig. 52.13)	
	Sublingual hematoma (Fig. 52.14) Coleman's sign	
	Tongue fall back in bilateral anterior mandible fracture	

Fig. 52.7 Swelling in angle region after fracture

Fig. 52.8 Difficulty in mouth opening due to displacement and deviation of fracture

52.7.1 Are Postoperative Radiographs Necessary?

The answer is no. The reasons behind this is:

1. More than 100–250 deaths occur worldwide from cancer due to unnecessary radiation from diagnostic radiology as suggested by Royal College of Radiologists [4]
2. If somehow retreatment is required for the patient, it generally depends most commonly on the clinical findings rather than radiographic

However, the postoperative radiographs are required in few cases of:

– Mandibular fracture treated with closed reduction
– In medicolegal cases to prevent judicial complications [5]
– Patients who enrolled in the research activities

Bergh van den et al. [6] also suggested that postoperative radiography is not necessary. The advantages of avoiding postoperative radiographs are:

1. Exposure reduction of patients to ionizing radiation
2. Reduced cost
3. More efficient discharge

52.8 Emergency Management (refer Chap. 48 of this book)

Once the basic Airway, breathing, circulation (ABC) in the emergency management has been secured, the suturing of the extra-/intraoral wounds and initial stabilization and immobilization of the fracture fragments are important. Box 52.2 shows advantages of immobilization of fracture fragments.

Initial stabilization and immobilization is done by:

1. **Bridle wiring (refer Chap. 50 of this book)**

   It is a type of temporary stabilization and reduction of the fracture fragments of the dentate segment with the help of 24- or 26-gauge wires under local anesthesia.

   The wire should be wrapped around two healthy teeth adjacent to the fracture line; if the tooth adjacent to the fracture are mobile, the wire should be wrapped around the second tooth adjacent to the fracture (Fig. 52.22a, b).
2. **Supportive bandage**

   These bandages are commonly used to temporarily stabilize the fracture of the lower jaw. Small crepe bandages can be used for mandible fracture.

   (a) Barrel bandage (Fig. 52.23)
   (b) Four-tailed bandage (Fig. 52.24)

Fig. 52.23 Barrel bandage

Fig. 52.24 Four-tailed bandage

52.9 Goals of Treatment of Mandibular Fracture (Table 52.5)

52.10 Treatment Options for Different Sites

52.10.1 Closed Reduction (Table 52.6)

52.10.2 Clinical Tip

Wiring techniques required use of multiple wires. These wires cause inadvertent finger puncture to the operator's fingers and increases the risk of spread of blood-borne diseases like HIV and hepatitis. To avoid such complication, Rai [7] recommended the use of dynaplast adhesive tape over all fingertips before wearing sterile gloves while doing Maxillomandibular Fixation (MMF) (Fig. 52.25).

52.10.3 Open Reduction (Table 52.7)

52.10.4 Steps in Open Reduction Internal Fixation (ORIF) of Mandible Fracture

1. Incision (extra-/intraoral) (Fig. 52.26a, b).

Table 52.5 Treatment goals for mandibular fracture

1.	Anatomical restitution
2.	Immobilization
3.	Prevention of postoperative complications
4.	Rehabilitation of Functions

Table 52.6 Advantages and disadvantages of closed reduction

Advantages	Disadvantages
1. Day-care procedure, not require hospitalization 2. Cost-effective and safe 3. Avoid damage to the vital structures	1. Restriction of mouth opening for minimum of 4 weeks 2. Patients can take only liquid diet 3. Difficult to maintain oral hygiene 4. Challenging in partially edentulous patients 5. Weight loss 6. Partial trismus for few weeks 7. Contraindicated in asthmatic, in parkinsonism, mentally challenged patients

Table 52.7 Advantages and disadvantages of open reduction

Advantages	Disadvantages
1. Early return to function 2. Exact anatomic reduction under direct visualization 3. No need of MMF in most of the cases 4. Less chances of postoperative complications	1. Requires hospitalization 2. Risk of general anesthesia 3. Extra oral scarring 4. Risk of injuries to the vital structures 5. Expensive to patients when compared to closed reduction

Fig. 52.25 Finger protection before wiring

2. Exposure of the fracture site (Fig. 52.27).
3. Curettage to remove the granulation tissues and irrigation with normal saline.
4. Reduction of the fracture (with the help of bone-holding forceps) (Fig. 52.28a–c). Chin retractor is also helpful in reduction of fracture fragments (Fig. 52.29a, b).
5. Immobilization with MMF.
6. Fixation with plates and screws.
7. Closure of the incised site.
8. Pressure bandage over the surgical site to avoid postoperative hematoma formation in required cases (Fig. 52.30).

According to Dimitroulis [8] MMF is unnecessary in undisplaced angle fracture if there is a skilled assistant present to assist and help manually reduce the fracture fragments for plating. Author also believes that many undisplaced, single fracture of mandible can be fixed without MMF when two skilled surgeons operate the case.

52.10.5 Symphysis and Parasymphysis Fracture (Video 52.1)

Various internal fixation techniques were mentioned in the literature for both symphysis and parasymphysis fractures [9]. They are enumerated in Table 52.8.

Note: Readers has to refer Chap. 51 on plating systems to know the principles of osteosynthesis, tension banding, zone of compression/tension, etc.

Fixation with two miniplates is widely used for the fixation of symphysis and parasymphysis fractures (Fig. 52.31). Some authors preferred use of two lag screws (Fig. 52.32a, b) for the fixation of symphysis fractures, but their uses are less in comparison to two miniplates because they are technique sensitive. Three-dimensional plates require less manipulation and adaptation which indirectly reduce the operating time

Fig. 52.26 (**a**, **b**) Extraoral sub mandibular incision and intraoral vestibular incision

Fig. 52.27 Exposure of the fracture site (left paramedian mandible via vestibular incision)

(Fig. 52.33), but use of it is questionable when fracture fragments are multiple even in isolated symphysis fractures.

Usually, an intraoral approach is preferred for management of symphysis and parasymphysis fractures. However, if an existing laceration or scar is present, it should be utilized for exposure of fractured segments and subsequent management (Fig. 52.34).

52.10.6 Parasymphysis Fracture

1. Mental nerve: The anatomic challenge in ORIF.
2. Plating should be done after the blunt dissection and retraction of the neurovascular bundle.
3. One miniplate above and another below the mental nerve used for fixation of parasymphysis fracture (Fig. 52.35).

52.10.7 Mandibular Angle

The prevalence of angle fractures ranges from 16.5 to 37 % in the literature. Presence of third molar (3M) increases the chance of angle fracture by 3.27 times, and class II-B positions of 3M are the most favorable for angle fracture, while class I-A act as protective factors [10].

52.10.7.1 Impact of Presence or Absence of Impacted Mandibular Third Molar (IM3M) on Angle and Condylar Fracture

– Presence of IM3M generates a weak area in the mandibular angle and predisposes the angle region to fracture after injury; on the other hand, IM3M can decrease the occurrence of condylar fracture which is supposed to be the weakest area of mandible [11].
– Angle fracture is seen most commonly in patients having superficially impacted (vs deeply impacted) third molars (M3s) [12]. The reason behind this is that the mandibular strength is derived from maintenance of cortical and not the medullary bone integrity; this cortical integrity of the external ridge is disrupted by the presence of superficial impacted M3s which produce the point of weakness in the mandible and make it more prone to fractures [13].

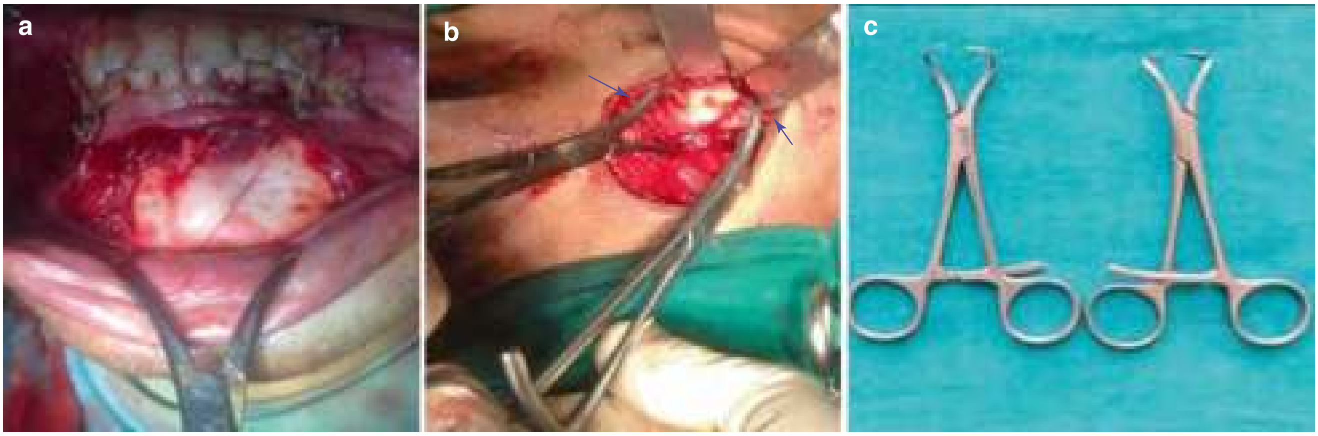

Fig. 52.28 (**a**–**c**) Reduction of the fracture (with the help of bone holding forceps)

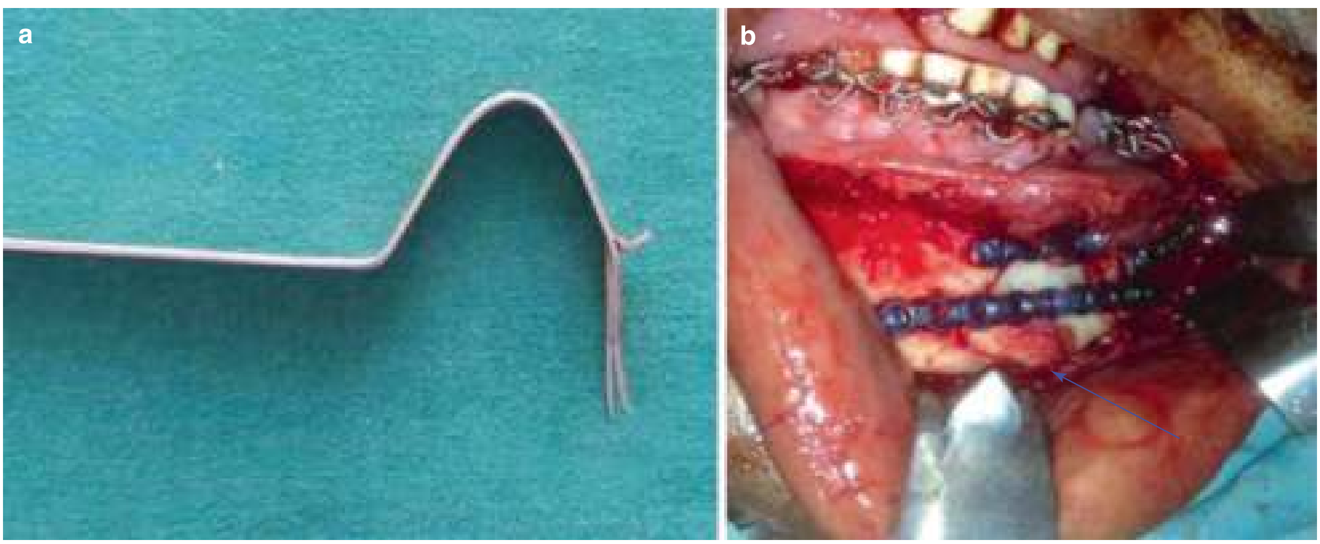

Fig. 52.29 (**a**, **b**) Use of chin retractor in reduction of fracture fragments

52.10.7.2 Open vs. Closed Reduction

Closed reduction is advisable for patients who are medically unfit for surgery (due to any reasons) or those who did not give consent for open reduction internal fixation (ORIF).

52.10.7.3 Approaches for ORIF

1. Intraoral (Fig. 52.36)
2. Extraoral (Fig. 52.26a)
3. Transbuccal (Fig. 52.37)

Intraoral incision is advocated for ORIF with single miniplate, but higher infection rate of 13% was reported in comparison with 2% when extraoral incision was used for plating. Marginal mandibular nerve showed weakness in 8% of cases, and it sometimes has prominent extraoral scarring in patients treated with extraoral approach [14] .

Sugar [15] concluded that the combined use of transbuccal and intraoral approach is safe and effective than the intraoral approach alone for ORIF. Author too prefers the same approach.

52.10.7.4 Advantages of Transbuccal Approach [16]

1. Less operative time
2. Minimal scar formation
3. At the time of plating, direct visualization of the occlusion
4. Low risk of injury to facial nerve

Fig. 52.30 Application of pressure bandage

Fig. 52.31 Fixation bilateral paramedian fracture mandible with 2 miniplates each on either side

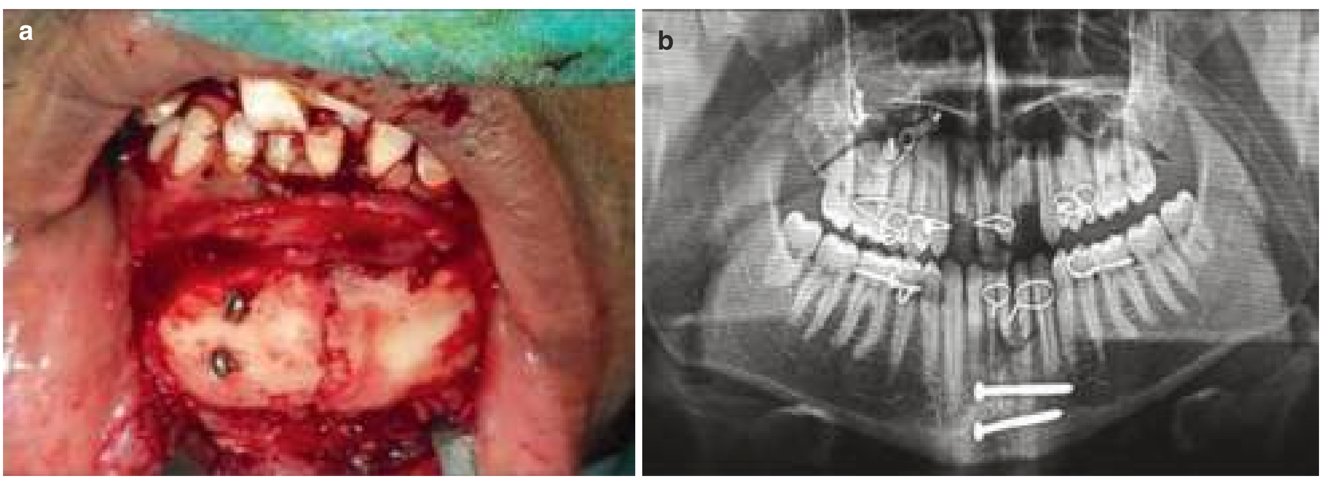

Fig. 52.32 (**a**, **b**) Fixation left para median fracture mandible with lag screws

Position of Trocar Placement [17] (Fig. 52.37)

Gulses et al. described a safe zone to place the trocar in the form of a triangle created by drawing three lines on the face.

Line 1: At the lower border of mandible (mandibular line)
Line 2: Gonial-canthal line which ran from the gonion to the outer canthus of the eye
Line 3: Trago-basal line which ran from tragus to the groove over the body of the mandible at infero-anterior angle of the masseter (at the point of entry of the facial artery over the body of the mandible)

Table 52.8 Various fixation techniques for anterior mandibular fracture

1.	Reconstruction bone plates
2.	Single strong nonreconstruction bone plate
3.	Double miniplates
4.	Two lag screws
5.	Three-dimensional (3D) plate
6.	Segmental arch bar with single large and stronger bone plate

Through a small stab incision, a blunt dissection is performed with dissecting scissors till the mandibular periosteum is torn and the trocar is placed through the dissected channel.

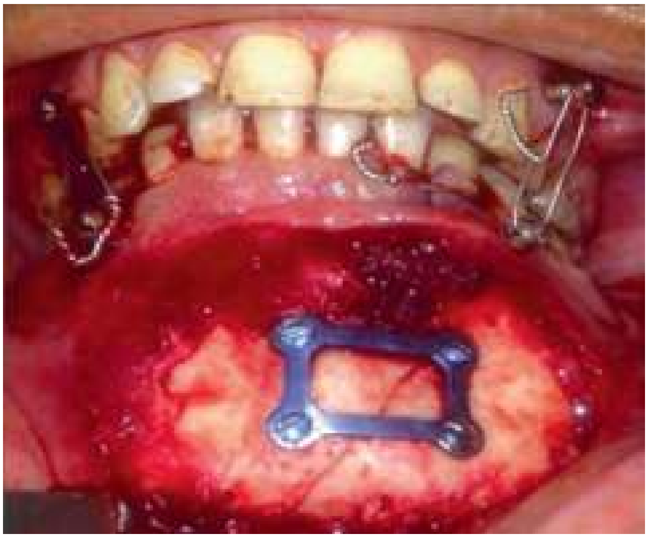

Fig. 52.33 Fixation of anterior mandible with three-dimensional plate

Fig. 52.35 One miniplate above and another below the mental nerve used for fixation of parasymphysis fracture

Fig. 52.34 (**a–c**) Existing laceration has been used as access for fixation of the anterior mandible fracture

Various techniques are mentioned in the literature for internal fixation of angle fracture (Box 52.3) [18]:

52.10.7.5 Single vs. Two Plates vs. 3D Plates

Al Moraissi [19] in a meta-analysis showed that the incidence of wound infection, dehiscence, hardware failure, and overall complications were less in patients treated with one miniplate on external oblique ridge in comparison to two.

Ellis III [20] also advocated use of single miniplate on superior border because:

Box 52.3: Fixation Techniques for Angle Fracture

1. Wire osteosynthesis (obsolete)
2. Single miniplate on the superior border (Fig. 52.38)
3. Single plate on inferior border
4. Two plates, one at superior and another on inferior border (Fig. 52.39a, b)
5. Lag screws
6. Three-dimensional plates (Fig. 52.40)

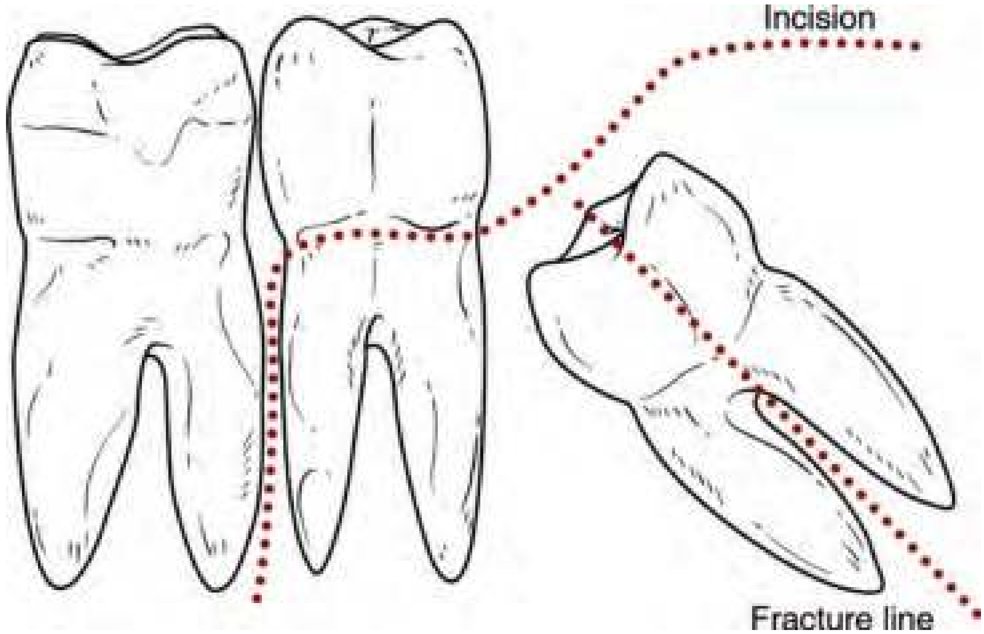

Fig. 52.36 Intraoral incision for exposure

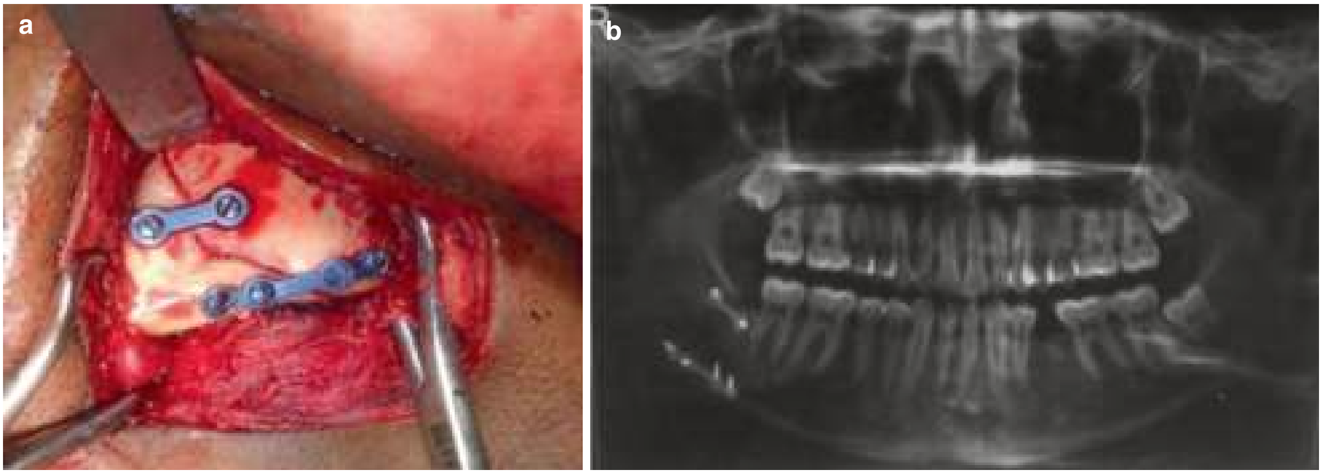
Fig. 52.37 Transbuccal approach used for fixation of angle fractures

Fig. 52.38 Fixation of mandibular angle fracture using single miniplate

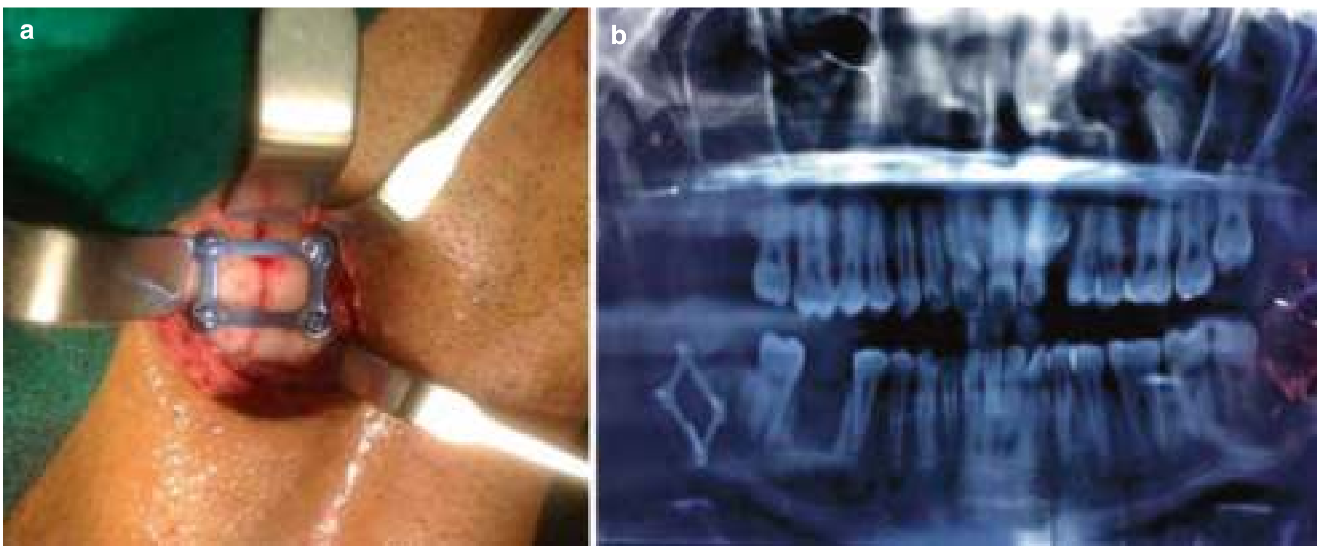
– High rate of sequestrectomy, infection, and subsequent second surgery was more in two-plate technique.
– Fixation with two plates took more time, i.e., average 37 min in comparison to an average of 23.5 min in single miniplate fixation from incision to suturing.
– Second plate fixation at inferior border is more difficult and requires more experience.
– If infection occurs, retrieval of single miniplate can be done under local anesthesia in a clinic, but two plates commonly required general anesthesia which indirectly increases the cost and prolonged the hospital stay.

Rai et al. [21] also conclude better results with two-plate fixation. Second miniplate is supposed to increase stability and protects the fracture site against torsion and bending.



©Association of Oral and Maxillofacial Surgeons of India

Fig. 52.39 Fixation of mandibular angle fracture using two miniplates. (**a**) Clinical picture, (**b**) orthopantamogram



©Association of Oral and Maxillofacial Surgeons of India

Fig. 52.40 Fixation of mandibular angle fracture using 3D plate. (**a**) Clinical picture, (**b**) orthopantamogram

Theoretically second plate establishes a second line of osteosynthesis.

Levy et al. [22]advocated two-plate fixation superior for ORIF of angle fracture. According to them two miniplates provide better stabilization and have reported lowest complication rate in comparison to any other plating technique.

Wusiman et al. [23] demonstrate that three-dimensional (3D) miniplates provide better fixation than standard miniplates. It also provides simultaneous stabilization of tension and compression zones with lower incidence of postoperative complications and good results. According to Zix et al. [24] 1-mm-thick 3D plate is as stable as 2 mm miniplates, and it offers better bending stability and more resistant to out of plane movement or torque.

Ellis III and Ghali [25] used lag screws for treating mandibular angle fractures but reported very high incidence of postoperative infection and bone exposure. Also the fixation of angle with lag screws is technique sensitive and requires expertise.

Kang and Zide used seven-hole angle plate when Champy technique is ineffective and more rigid or semirigid fixation is required [26]. According to them seven-hole angle plate is fixed through transfacial trocar and stabilized intraorally. On the other hand, Champy plate required bending, lacks rigidity, difficulty in screw hole drilling, inaccurate centric placement of screws.

52.10.7.6 Extraction vs. Retention of IM3M in Angle Fracture

The use of postoperative MMF and extraction versus retention of teeth in the line of fracture did not influence any of the outcomes [27]. Increase rate of infection by extraction of a tooth was found in the study by Ellis and Walker in 1994 [28]. However, in another study published in 2002, Ellis [29] reported an increased incidence of infection if teeth were left in the line of fracture. Author advocates extraction of 3Ms at the time of ORIF for better results.

52.10.8 Body Fracture

A single four hole with gap miniplate (Fig. 52.41) below the root apex and the inferior alveolar canal is sufficient for fixation of body fracture of mandible through the intraoral approach most of the times, except when a patient is having extraoral soft tissue injury/scar or having severely comminuted fracture fragments.

Fig. 52.41 Fixation of body fracture with single miniplate

52.10.9 Ramus Fracture

Mandibular ramus (MR) fracture occurs rarely and ranked third least common fracture after alveolar and coronoid fracture [30]. MR fractures are very rare in isolation. It can be horizontal or vertical. Its incidence ranges from 0.9 to 5.5% [31]. Isolated ramus fracture can be managed by closed reduction, but ORIF is the treatment of choice when it is associated with other maxillofacial fractures. To correct the facial height when midface is also fractured, the vertical rami become the only determinant, and re-establishment of these buttresses is very important before repositioning the crushed midfacial bones [32] (Fig. 52.42a–c).

52.10.9.1 Management of Triangular Fragments (TF) at the Lower Border

Heslop et al. [33] advocated repositioning of TF if they are attached to the muscle or periosteum and remove them if they are very small or detached from the periosteum.

According to Blinder et al. [34] to prevent infection and preserve vascularization, TF should be unexposed and unreduced. TF should be sandwiched between the two fracture lines by rigid fixation without exposure, and preserving vascularization may be the treatment of choice

TF of bone at the angle region were more often shown to get infected in comparison to body, symphysis, or parasymphysis because thick, better vascularized, and more cancellous bone presents in these areas as compared to angle region. It's better to remove small fragments in the angle region to avoid postoperative discomfort.

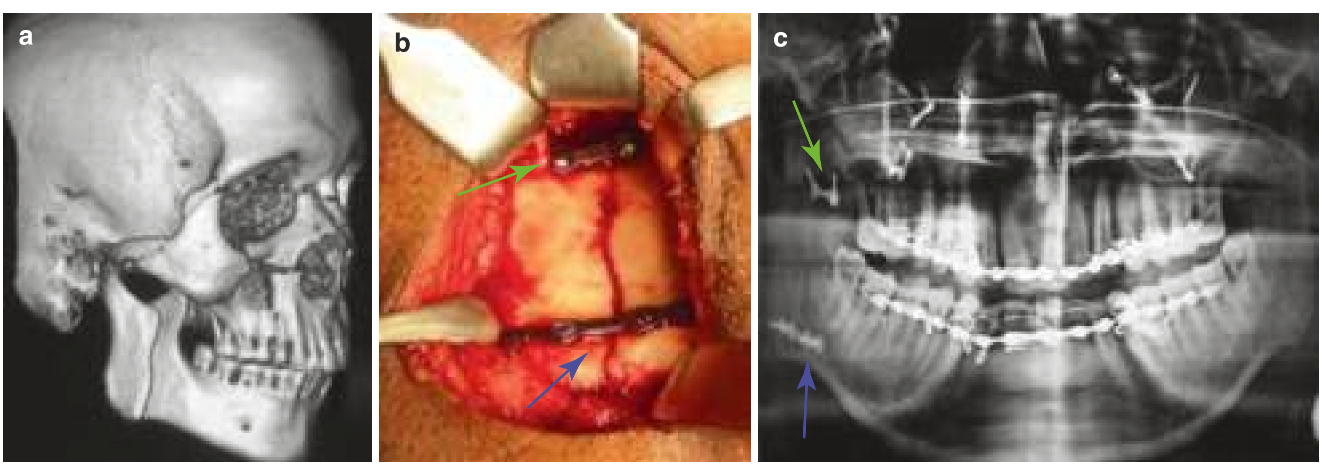


Fig. 52.42 Management of mandibular ramus fracture. (**a**) DVT showing mandibular ramus fracture, (**b**) fixation using two miniplates, (**c**) postoperative orthopantamogram showing fixation of mandibular ramus and midface fractures (blue arrows point to lower border plates and green arrows point to upper border plates)

52.10.10 Coronoid Fracture

It generally occurs in combination with other fracture of the mandible (Fig. 52.43a), and with zygomatic complex fracture (commonly with arch) (Fig. 52.43b), rarely does it occur in isolation. It can be treated by extraoral or intraoral approaches. Later, having low incidence of facial nerve injury and no facial scar. Coronoid fracture ranges from 0.6 to 4.7% of all facial fractures and 1–2.9% of all mandibular fractures [35].

It manifests as [36, 37]:

- Swelling below the zygomatic arch
- Ecchymosis in the retromolar trigone area
- Restricted mouth opening, malocclusion, and facial collapse when occurs in association with other facial fractures

52.10.10.1 Indications for Conservative or Open Reduction of Coronoid Fractures (Table 52.9)

Conservative management in the form of soft diet and mouth opening exercises to avoid bony adhesions to the surrounding structures [38]. If patients are treated with MMF and trismus occurs, it can be managed by removal of the coronoid process [39].

52.10.11 Bilateral Fracture of Mandible

Over half of the mandibular fractures are bilateral; in the case of angle fracture, most of the times, it occurs in combination of contralateral mandibular body and symphysis [40]. ORIF is the treatment of choice most of the times.

Clinical Tip: An MMF screw can be effectively used for reduction of a bilateral mandibular fracture by placing the screw in the symphysis region. A wire is passed through the screw, and the fracture segment can be manipulated for reduction (Fig. 52.44).

Table 52.9 Indications of closed and open reduction for coronoid fractures

Conservative	ORIF
Minimal displacement	Significant fracture displacement and
	Limited mouth opening
	Associated with zygoma, zygomatic arch, mandibular ramus
	Patients who are bad candidates for MMF

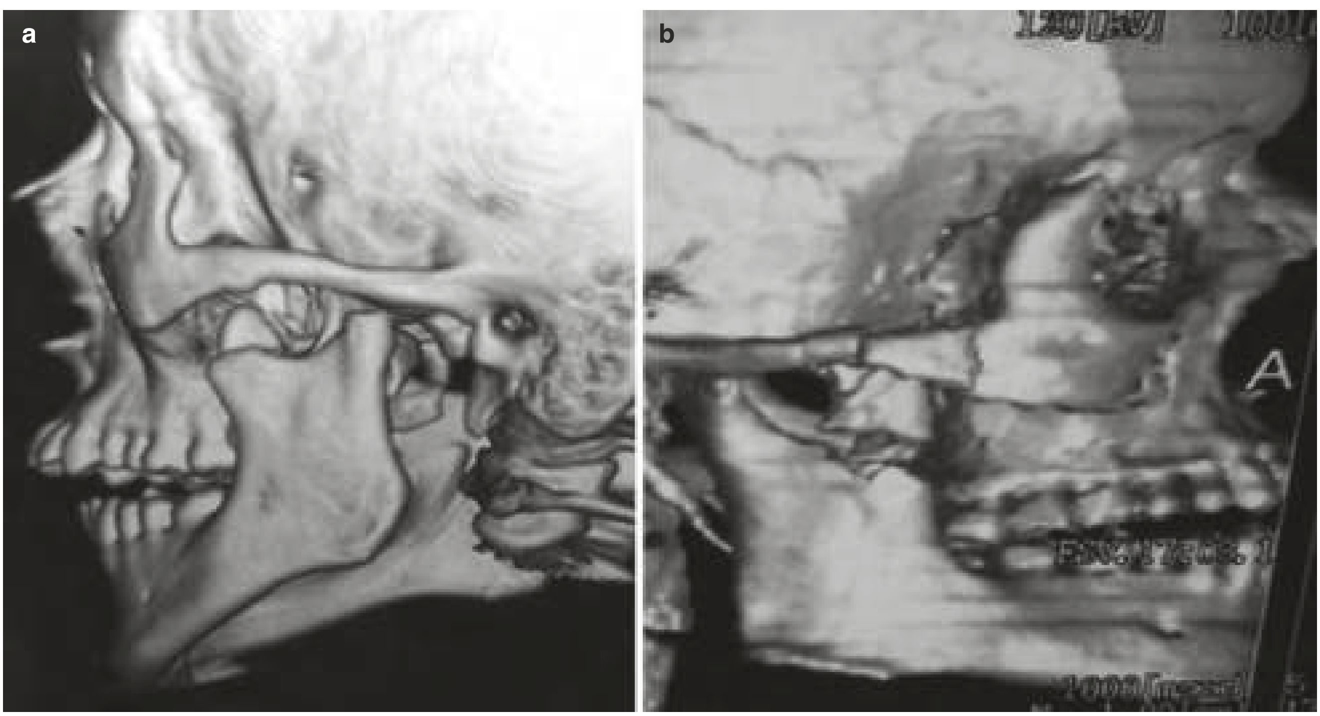

Fig. 52.43 Coronoid fracture (**a**) associated with condylar fracture, (**b**) associated with zygomatic arch

52.10.12 Comminuted Mandible Fractures

Comminution is defined as presence of multiple fracture lines in many small pieces within the same area of mandibular angle, body, ramus, and symphysis [41]. This type of fracture rarely occurs in the condyle region. In a comminuted fracture, bone is "crushed, broken, splintered" into number of pieces, creating multiple small fragments (at least two free segments of bone) (Fig. 52.45a, b).

©Association of Oral and Maxillofacial Surgeons of India

Fig. 52.44 Use of MMF screw in reduction of bilateral parasymphysis fracture

To fix small fragments, multiple options are mentioned in the literature like miniplate, microplate, screws, steel wires, and absorbable sutures. A fragment larger than 1 cm should be conserved, reduced, and fixed [42].

Ellis et al. [43] advocated that more complications are associated with multiple fragment fractures in comparison to fractures having few segments. Therefore, comminuted fractures need load-bearing fixation.

The bone fragments will not provide buttressing to help stabilize the fracture; therefore surgeons operating comminuted mandibular fractures having two or more free bone fragments and/or requiring bone fragment removal should opt for reconstruction plates. Miniplates can be used when comminuted mandibular fractures have only one free bone fragment. Combination of reconstruction and miniplates can be used when multiple small fragments are there in comminuted mandible fracture (Fig. 52.46). Implants used for fixation of comminuted fractures are mentioned in Box 52.4.

Use of reconstruction plates required expertise and it is time-consuming. Sometimes contour is also not favorable

Box 52.4: Implants Used for Fixation of Comminuted Fractures

1. Multiple miniplates
2. Reconstruction plates

Fig. 52.47 Postoperative elastics for correction of minor occlusal discrepancies (Inter maxillary elastics- IME)

which can create slight malocclusion but can be managed by postoperative elastics and selective occlusal adjustments (Fig. 52.47).

Dia et al. [44] used titanium mesh for the treatment of comminuted mandible fracture with successful results. According to them mesh required little soft tissue exposure, had low infection rate, and provides favorable mandibular morphology.

52.11 Inferior Alveolar Nerve (IAN) Injury in Mandible Fracture

According to the literature, the incidence of IAN injury was [45]:

1. 5.4–81.4% before treatment
2. 0.4–91.3% after intervention
3. 0–46.6% after 1 year

The neurosensory testing was done both before and after the treatment of mandibular fracture in which nerve injury is suspected. Two-point discrimination and pinprick testing can be used to assess the level of IAN injury. Preoperative knowledge of the patient's IAN position (based on CT/CBCT) is very important in decision-making regarding fixation position of the fracture fragments with miniplates. Plating should be done above or below the course of IAN. ORIF in the area of IAN takes longer duration to normalization of sensation, and it ranges from 1 week to 12 months. Postoperative CT/CBCT is mandatory if operating surgeon suspected the impingement of screw on the IAN or no relief of sensation after 6 weeks of ORIF for further management. Surgeons should not hesitate to redo the surgery in cases of IAN injury by miniplates and screws.

52.12 Geriatric Mandibular Fracture

With old age, the incidence rate of maxillofacial fracture increases, with mandibular fracture appearing with a greater frequency. As the age advances, the weakening of the mandible occurs due to:

– Loss of teeth
– Reduced vascularity or decreased blood flow in elderly
– Loss of bone mass

The most common mechanisms of injury in geriatric patients are [46]:

1. Fall
2. Assaults
3. Motor vehicle accidents

Fractures of the edentulous mandible pose unique challenges. Old age itself is a risk factor for poor outcomes following trauma. There are associated comorbidities like hypertension, diabetes mellitus, dementia, or stroke which limit the functional capacity of the patient to bear the stress of surgery and postoperative recovery. Also, the atrophic mandible has compromised blood supply with little osteogenic potential resulting in delayed bone healing. Bilateral mandibular fracture (bucket handle fracture) occurs most commonly in elderly (Fig. 52.48).

52.12.1 Management

Controversy exists in the treatment of edentulous mandibular fracture. One school of thought advocated closed reduction, and another school is in favor of open reduction and internal fixation. According to Bradley [47] the major blood supply to the mandible is "sub periosteal Plexus," and reflection of periosteum in ORIF may seriously impair vascular supply to the bone resulting in non-union.

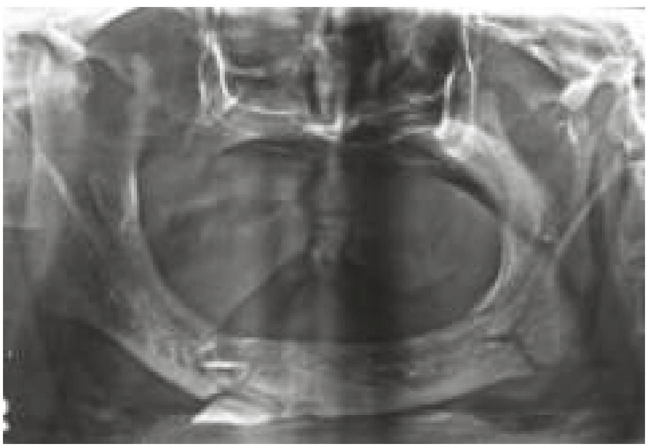

Fig. 52.48 Bilateral mandibular fracture (bucket handle fracture) in edentulous patients

Controversy again exists in the use of bone grafts in edentulous mandible. Are bone grafts necessary? Answer is not always. Reconstruction plates (load-bearing plates) can be used for comminuted fractures and with large defects. Bone morphogenic proteins and tricalcium phosphate can be used as alternative to autogenous grafts in patients whom multiple comorbidities may influence local or systemic outcomes [48].

Few authors advocated extramucosal intraoral plating for the ORIF of the edentulous mandibular fracture. It preserves the blood supply to the mucosa and bone, at the same time provides adequate stability [49, 50].

The techniques of edentulous atrophic mandible fracture management are:

1. Closed reduction (CR)

   This technique is opted when the patient's systemic condition does not allow for an open surgery. CR can be accomplished if the mandibular height is at least 30 mm. It is difficult to achieve CR if the mandibular height is <10 mm. CR can be accomplished using a preexisting denture. If there is no denture, gunning splint can be prepared. The denture/splint is used for immobilization and fixed to the mandible with circum-mandibular wiring (Fig. 52.49a, b).

   Advantages: Periosteal supply to the bone is maintained.

   Disadvantages: Chances of infection and pulmonary issues

2. Open reduction and internal fixation (ORIF)

   This involves use of plates and screws for fixation of fractures. Options for ORIF include use of miniplates or larger reconstruction plates. Miniplates are small and

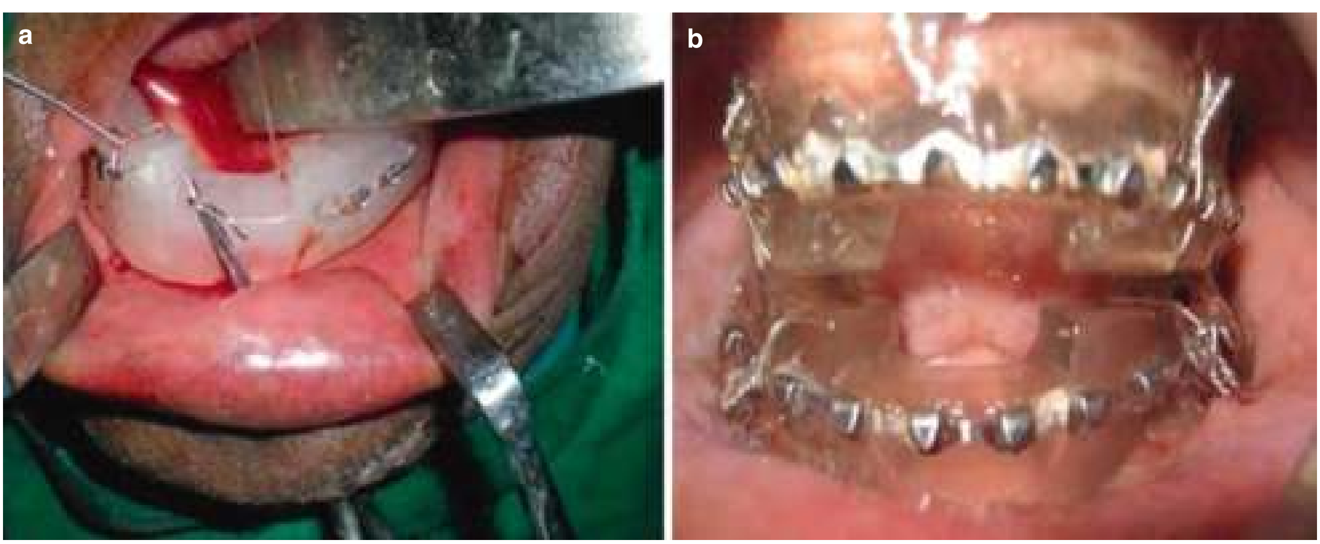

Fig. 52.49 (**a**) Securing gunning splint by circum-mandibular wiring, (**b**) MMF with gunning splint in situ

hence require smaller incision. Screws of miniplates are also small which can easily involve thin fragments. However, in cases of larger fractures, a load-bearing reconstruction plate is preferred.

Advantages: Adequate fixation with no/minimum MMF

Disadvantages: Delayed healing with periosteal blood supply loss

52.13 Pediatric Mandibular Fractures

Among all the maxillofacial fractures, the incidence of pediatric facial fracture is 1–15%. After nasal bone fracture, the second most common fractures in children are mandibular fracture with an incidence of 5–50% [51]. In mandible, the condyle is the commonest site of fracture in pediatric patients followed by symphysis and parasymphysis. The most common mechanisms of injury in children are [52]:

1. Fall from height
2. Bicycle falls
3. Automobile and sports accidents
4. Violence

In children, the developing tooth buds of canine approximate the lower border of mandible. This creates a stress point making the mandible susceptible to fracture in this location. Once the canine erupts, this weak point is reinforced with the bone and is not weaker than any other regions of the mandible. This is the reason probably why parasymphysis fracture is more common in children than adolescents.

With increasing age, the skull-to-face ratio decreases. The larger cranium shields the smaller middle and lower thirds of the face from injuries. This prevents mandibular fracture in small children; however, with increasing age the mandible becomes more prominent resulting in more injuries to this region.

52.13.1 Management

The management of pediatric mandibular fractures is different in comparison to adults due to [53]:

1. Relatively small size of maxillofacial bones
2. Presence of tooth germs
3. Soft bone with good elasticity
4. Instability of deciduous or mixed dentition
5. Rapid repair process
6. Difficulties in cooperation and acceptance

Pediatric mandibular fractures are treated in the following ways:

1. Undisplaced fractures: Managed conservatively with close observation, soft diet, analgesics, and activity prevention
2. Fractures with minor malocclusions: A short period of MMF with the help of bondable buttons and wires for 7–14 days
3. Malocclusion with displacement of segments: Closed reduction using cap splint secured to mandible by circum-mandibular wiring (Fig. 52.50a–c)
4. Malocclusion with severe displacement requiring three-dimensional stabilizations: open reduction and internal fixation

However the absence of teeth due to exfoliation and poor retention of wires on the deciduous teeth crowns makes the ligature wire and traditional use of arch bars difficult or sometimes impossible [54]. In such cases splinting with acrylic splint retained with circum-mandibular wires remains a viable option in treatment of pediatric mandibular fractures.

Cap splints are secured to mandible by circum-mandibular wiring. Kelsey Fry bone awl is used for this purpose. A wide-bore needle can also be used for the same (Fig. 52.51a, b). Intravenous cannula stillete (IVCS) is also mentioned in the literature for performing circum-mandibular wiring. The 16-gauge IVCS was used instead of conventional awl [55].

However, management of pediatric mandibular fracture with ORIF is controversial as the fixation of plates may hamper the growth and development of jaw. Titanium miniplates have been successfully used for ORIF, but the implants are to be removed within 3- to 12-month period [56].

Yerit et al. [57] proposed use of biodegradable plates for ORIF. These plates should be mechanically strong and must undergo resorption within a predictable time frame.

The advantages of biodegradable plates (polyglycolic and poly-L-lactic acid plating system) in comparison to titanium plates are [58]:

1. Does not require second operation for removal, indirectly becoming cost-effective and requiring less hospital visit.
2. Does not cause growth disturbances.
3. Monocortical plates and screws do not cause damage to the tooth buds.

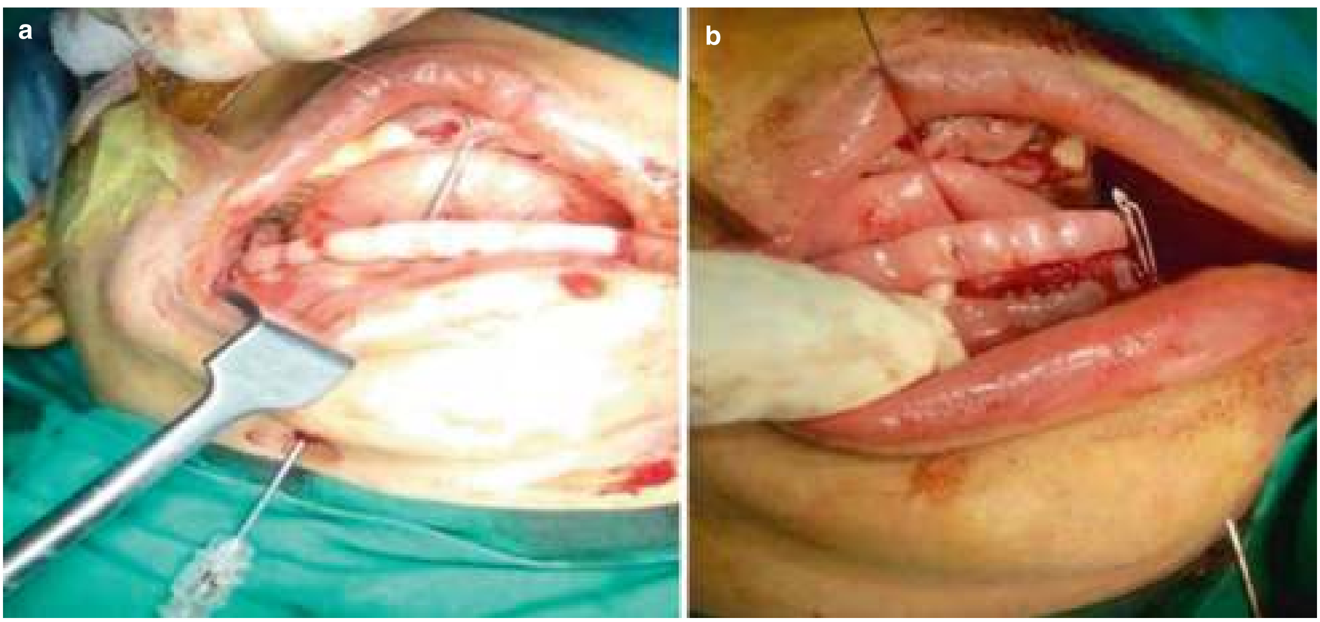

Fig. 52.51 (**a**, **b**) Securing cap splint by circum-mandibular wiring using wide-bore needle

52.14 Use of Bone Grafts in Mandible Fracture Treatment

Anterior iliac crest (cancellous or cortico-cancellous) and fibula (free microvascular reconstruction) are the most commonly used sites from where the bone grafts are used for mandibular reconstruction. All the cases required bone grafting in cases of mandibular fracture treated with ORIF should be kept in MMF of 4 weeks postoperatively.

Bone grafts are indicated in some cases of:

1. Severely comminuted fractures
2. Gunshot wounds
3. In non-union
4. Atrophic mandibular fractures

Rachmiel et al. [59] advocated two-stage reconstruction of mandibular bone defect after trauma by bone grafting followed by alveolar distraction osteogenesis (ADO). This modality helps in correction of intermaxillary vertical relationship and provides sufficient amount of bone for the placement of dental implants and prosthesis.

52.15 Postoperative Care

- Pressure dressing over the site to avoid postoperative hematoma in required cases.
- Elastic traction for correction of minor discrepancies in occlusion (Fig. 52.47).
- Soft and liquid diet.
- Maintenance of oral hygiene by oral rinses.
- Recall visit for review.
- Follow-up appointments and if results are not satisfactory frequent follow-up required.
- If patient is not satisfied, plan for retreatment.

52.16 Complications of Mandible Fracture

Immediate

- Pain
- Swelling

Delayed

- **Infection:** Found to be the most common complication (Fig. 52.52)
- Predisposing factors:
  1. Preoperative oral sepsis
  2. Tooth in the line of fracture
  3. Improper reduction and fixation (Fig. 52.53)
  4. Alcoholic or metabolic disturbances
  5. Prolonged time before treatment
  6. Poor patient compliance
- **Malunion**
  – It indicates that a fracture has healed but in less than an optimal position.
  – It may result when bone is shorter than normal, rotated or twisted in a bad position, or bent.
  – It may cause pain, joint degeneration, posttraumatic arthritis, or catching episodes resulting from instability.
- **Non-union**
  – It is a type of uncommon complication of mandibular fracture, with reported incidence of 2.8–3.9% [60].
  – It is failure of fracture hematoma to become transformed into an osteogenic matrix so that it is converted into non-osteogenic fibrous tissue.
  – Non-union identified by mobility in all planes after interval of minimum 10 weeks.
  – Histologically there is absence of identifiable osteogenic tissue.
  – Radiographically no evidence of progressive decrease in radiolucency at the fracture site and rounding off of the bones' end in the later stages. It can be treated by ORIF by rigid fixation (load-bearing reconstruction plate and sometimes in combination with bone graft) (Fig. 52.54a, b).

52.17 Recent Advances

Kokosis et al. [62] advocated use of virtual surgical planning (VSP) with subsequent computer-aided design and manufacturing in management of acute mandibular trauma patients.

The advantages of the use of custom titanium plate in mandibular trauma are:

1. Avoid need for in situ bending.
2. Serving as a guide and confirming accurate reduction.
3. Customized titanium plates are much stronger than conventional plates.
4. Less palpable.

Computer-assisted surgery (CAS) including computer-aided design and manufacturing, surgical navigation techniques, and rapid prototyping (RP) has been used with lot of success in mandibular reconstruction (refer Chap. 41 of this book). CAS helps in [63]:

1. Preoperative planning
2. Preparation of stereolithographic (STL) models or accurate implantation material
3. Implementation of complex design through intraoperative navigation

Some Important Facts from Review of Literature Regarding Mandible Fracture [64, 65]

1. Injuries caused by assaults were more prone to develop postoperative infection, nerve damage, and malocclusion.
2. 11.8-fold more likely to have poor radiographic outcome in patients with comminuted fracture.
3. Dehiscence, nerve injury, and malocclusion occur more commonly in surgeries taking longer duration.
4. Patients with three or more fractures were 13.8-fold more likely to develop postoperative trismus in comparison to single fracture.
5. Chances of complications are more in patients who took discharge against medical advice.
6. Treatment of isolated mandible fracture can be safely delayed to allow for more improved resource distribution and prioritization of more time-dependent interventions.

52.18 Case Scenarios

Case Scenario 1

A male patient reported with a gunshot injury over right side of face. Patient's Glassgow coma scale (GCS) was 15/15 with stable vital signs, but the patient has difficulty in breathing. On maxillofacial examination, a gunshot wound was present over right side of face at the right mandibular angle region. Deviation of mandible was present on right side with cross bite on right side and open bite on left side. Tenderness was present over right mandibular angle region. On palpation, intersegmental mobility was present over right angle region.

Provisional diagnosis: Right mandibular angle fracture following gunshot

Investigation: Apart from blood investigation, a CT scan was performed, and a final diagnosis of comminuted right mandibular ramus and angle fracture with bullet in situ was made (Fig. 52.57a).

Management: Patient was subjected to emergency surgery under general anesthesia with a treatment plan of bullet retrieval, debridement, and open reduction and internal fixation of fracture. After the anesthesia was induced, patient preparation was done; the fracture site was exposed through an extraoral approach. Thorough debridement was done, and bullet was retrieved in multiple pieces (Fig. 52.57b). The bone segments which were detached were removed, and the fracture segments were fixed using a reconstruction plate following achieving occlusion (Fig. 52.57c). The use of bone graft was eliminated considering the risk of postoperative infection due to scattering of bullet particles. Moreover, the fracture site was a nondentate site; hence bone grafting was not mandatorily indicated for postoperative dental rehabilitation. Figure 52.57d shows postoperative OPG and fixation of fracture with reconstruction plate (refer Chap. 59 on Gun shot injuries).

Case Scenario 2

A female patient reported with the chief complaint of difficulty in chewing following operation to treat mandibular fracture. Patient gave a history of fall from height following which she was operated for ORIF elsewhere. The general condition of patient was good. On maxillofacial examination, mandible was deviated on right side with cross bite on right

Fig. 52.57 Case Scenario 1 (**a**) DVT showing comminuted right mandibular angle and ramus fracture with bullet in situ; (**b**) retrieved bullet; (**c**) bullet retrieval, debridement, and fixation of fracture with reconstruction plate; (**d**) postoperative OPG showing fixation of fracture with reconstruction plate

side and open bite with lingualized occlusion on left side (Fig. 52.58a). Patient provided us with a pretreatment OPG which revealed right subcondylar with left side mandibular comminuted body and angle fracture (Fig. 52.58b). We subjected the patient to another OPG which revealed improper fixation of left mandibular body fracture and no fixation of left angle and right subcondylar fracture (Fig. 52.58c).

Diagnosis: Malunited left mandibular body, left angle fracture, and right subcondylar fracture

Management: Patient was subjected to general anesthesia. Once the anesthesia was induced, patient preparation was done, and fracture site was exposed through extraoral incision for all the fractures. Existing implants were removed which resulted in removal of few small bone fragments. The fractured and carious teeth were extracted and reduction was done by MMF. Occlusion was achieved (Fig. 52.58d), and fixation was performed using two miniplates at subcondylar site and load-bearing reconstruction plate at the body-angle unit. A postoperative OPG was done (Fig. 52.58e). Patient was discharged in stable condition. After 6 months, dental rehabilitation was performed for missing teeth by delivering dental bridge (Fig. 52.58f).

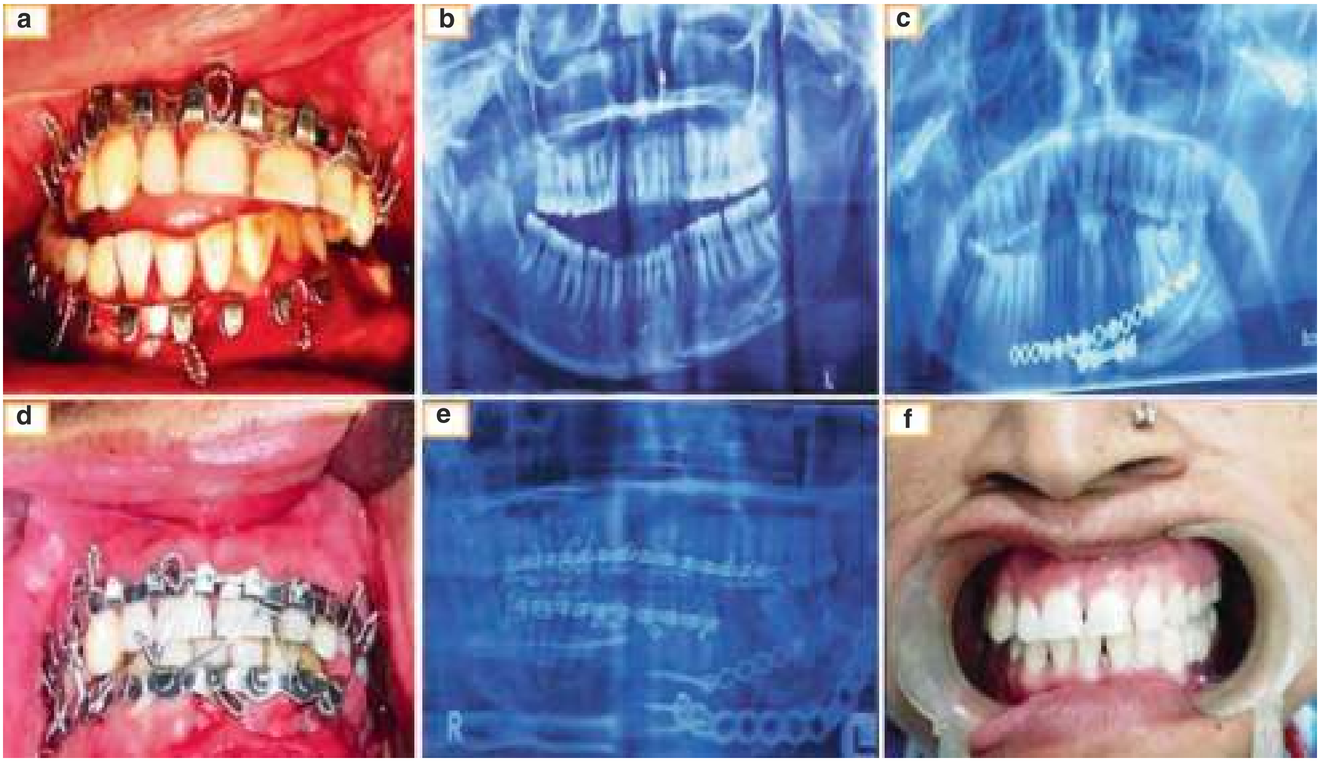

Fig. 52.58 Case scenario 2 (**a**) Deranged occlusion when patient reported to us, (**b**) pretreatment OPG, (**c**) improper fixation of left mandibular body fracture and no fixation of left angle and right subcondylar fracture at other centre, (**d**) intraoperative occlusion achieved, (**e**) postoperative OPG, (**f**) postoperative accurate occlusion

53 Fracture of the Mandibular Condyle

Vikas Dhupar

53.1 Introduction

Maxillofacial surgeons commonly come across a high incidence of condylar fractures in their practice. A French surgeon [1] in the eighteenth century described a high propensity for a narrow portion in the subcondylar region to fracture, which is a common occurrence even today. In spite of a common occurrence, the management has been controversial as there is no established consensus in the treatment of condylar fractures. Traditionally closed reduction has been the treatment of choice for condylar fractures and have been treated by various forms of intermaxillary fixation. With the improvement in radiographic imaging and biomaterials used in the fixation, surgical management has gradually found acceptance as it restores early function.

53.2 Surgical Anatomy

The mandibular condyle forms a part of the temporomandibular joint which is unique (Box 53.1), and it is made of the following structures:

- Condyle of the mandible
- Squamous portion of the temporal bone
- Articular disc (contained within the TMJ)
- Ligaments

Box 53.1. TMJ—Unique Characteristics

- It is a ginglymoarthrodial joint, having both a hinge and a gliding action
- It has an end point closure
- It has a fibrocartilage disc

53.2.1 Condyle

The condyle is one of the two processes of the mandible present on the superior portion of the ramus. The condylar head is ovoid in shape measuring approximately 15–20 mm mediolaterally and 8–10 mm anteroposteriorly in dimension [2]. The mandibular condyle articulates with the glenoid fossa present in the squamous portion of the temporal bone to form the temporomandibular joint (Fig. 53.1). Squamous portion of the temporal bone is as thin as 2 mm as a result; the condylar processes maybe driven into the middle cranial fossa following trauma.

53.2.2 Articular Disc

The squamous portion of the temporal bone and the condyle is separated by a dense fibrous connective tissue called the articular disc. The disc is firmly anchored to the condyle by the medial and lateral collateral ligaments, and it merges with the capsule in the periphery. The joint space is divided into superior and inferior compartments by the disc.

53.2.3 Capsule and Ligaments

The capsule surrounds the TMJ and is reinforced by the medial and lateral ligaments which connect the mandible to the temporal bone. The synovial membrane lines the capsule.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_53) contains supplementary material, which is available to authorized users.

Fig. 53.1 Bony structures of TMJ

This membrane produces synovial fluid which aids in the lubrication and nourishment of the joint. The lateral ligament also known as temporomandibular ligament has a horizontal and an oblique component which stabilizes the joint. The strength of the lateral ligament may be partly responsible for the fracture at the neck of condyle just below the insertion of the ligament [3]. The medial and lateral discal ligaments which are present inside the capsule are also called collateral ligaments. These ligaments connect the disc to the poles of the condyle. In addition to these ligaments, there are two non-capsular ligaments, namely, sphenomandibular and stylomandibular which may have a limited function.

53.2.4 Muscles of Mastication

There are four muscles of mastication, namely, the medial and lateral pterygoid, masseter, and the temporalis. Lateral pterygoid is attached to the pterygoid fovea at the condylar neck and is responsible for the displacement of the condylar fractures. Change in the direction of resultant forces post fracture will alter the function of the mandible during various excursion movements.

53.2.5 Vascularisation

The arterial blood supply to the TMJ is derived from the two terminal branches of the external carotid artery, namely:

- Superficial temporal artery
- Maxillary artery

It may be noted that the condyle receives blood supply from three sources

1. Medullary bone supplied by inferior alveolar artery
2. Overlying periosteum of the condyle
3. Attachment of lateral pterygoid muscle

This may explain the reason for the fractured condyle to remains viable even after stripping of the periosteum during the surgical procedure as the lateral pterygoid muscle remains attached to the fractured fragment [4]. The venous drainage starts in the retrodiscal plexus which drains into the superficial temporal and maxillary veins that join to form the retromandibular vein, which in turn drains into the external jugular vein.

53.2.6 Innervation

It is imperative to understand the innervation of the joint so as to minimize the complications following fracture of the mandible and its management. Both the sensory and motor innervation is encountered while approaching the joint. The sensory nerves are auriculotemporal, masseteric, and posterior deep temporal. Auriculotemporal nerve crosses the condyle medial to it and lies in contact with the condylar neck and capsule [5]. It is encountered in the preauricular incision and may result in postoperative complications.

53.2.7 Facial Nerve

It is the key nerve that transverses the face, and it is liable for the motor function of the muscles of facial expression. This nerve transverses the temporoparietal fascia and finally divides into five terminal branches in the parotid gland (Fig. 53.2). Hence all the extraoral approaches for the condylar fractures are designed keeping the facial nerve in mind. Al-Kayat and Bramley [6] found the nerve was at an average distance of 20 mm with a range of 8–35 mm from the anterior margin of the auditory canal. This is the reason the preauricular incision is given in the skin crease near the tragus or placed endurally. The neck of the condyle can be exposed via the transparotid approach. In this approach the condyle is reached through the space between the temporozygomatic and buccocervical trunks of the nerve. This results in a direct and safe approach to the neck of the condyle. The marginal mandibular nerve is encountered in the submandibular or periangular approach. This branch may further subdivide into two or more branches [7]. As a rule, the submandibular incision is given 2 cm below the lower border of the mandible to prevent paresis of the lower lip.

Fig. 53.3 Function of mandible as class III lever

53.3 Biomechanics of Condylar Fracture

U-shaped mandible supports the condyles on either side. There are two major movements while opening the mouth, rotational, and translational which occur in the inferior and superior compartments, respectively. Mandibular function is characterised as a class III lever with the joint being the fulcrum [8]. The musculature applies the force between the joint and the masticatory load (Fig. 53.3).

53.3.1 Mechanism of Injury

Trauma causing condylar fracture was explained by Lindahl [9]. It is important to understand the pattern as it gives the type of injury sustained (Fig. 53.4).

1. Kinetic energy derived from the momentum created by the subject falling on a static object. This is an axial force which is transmitted to the condyle from the lower border of the mandible. Fracture can occur at the site of injury and at the condyles at a higher level. Occluding teeth cannot reduce the force. May also result in fracture of teeth.
2. Kinetic energy derived from the momentum created by a moving object against a static subject. Generally noted in assaults or sport injuries. More or less horizontal forces will result in a fracture both at the site of impact and at the condyle on the opposite side. Fracture is usually at the base of the condyle.
3. Combination of the above two is seen in a road traffic accident and may result in more severe injuries.

An external force applied generally gets distributed over the entire mandible. However these forces result in the fracture of the subcondylar region which is weak and are subject to tensile stresses. A counter-coup injury is often noted in the condylar region. This prevents displacement of the condyles into the middle cranial fossa especially in bilateral fractures resulting from injuries over the chin.

53.3.2 Effect of Condylar Fracture

The signs and symptoms seen following trauma are due to the functional loss resulting from the disruption of the local anatomy. Following trauma a protective mechanism is triggered. It is generally expected that due to premature contact on the fractured side, excessive forces would be generated during loading of the non-fractured site on mastication. However, it is noted there is a shift of mean force vector towards the non-fractured site which results in protecting the fractured site during biting [10]. This results in neuromuscular adaptation. An increase in the muscle activity on the non-fractured side and a decrease of active force on the opposite

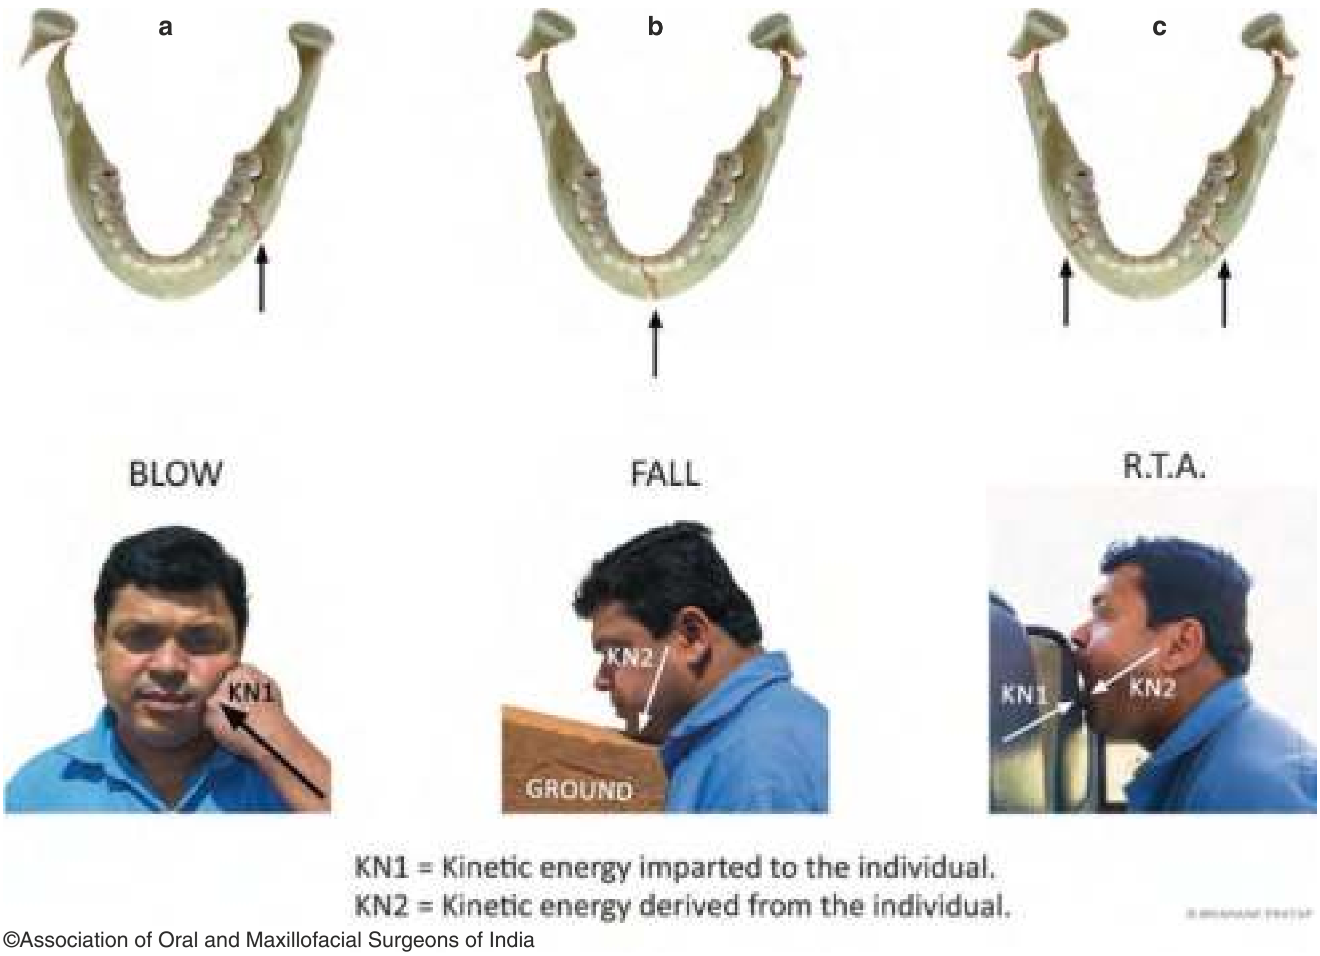

Fig. 53.4 Mechanism of fracture of condyle

side results in this process. Hence most of the masticatory forces are directed towards the non-fractured site and resulting in less neuromuscular adaptation on the fractured site. Refer to the article by Ellis et al. [8] for a comprehensive understanding of the biological considerations of fractures of mandibular condyle.

53.3.3 Adaptation to Fracture

Following condylar fracture of the mandible, patients adapt to the injury by compensation mechanism which is divided as follows:

- Skeletal
- Neuromuscular
- Dental

Intervention by the surgeons either by open or closed reduction minimizes the dental compensation. It is noted that there is a decreased masseter activity on the fractured site transferring load to a non-fractured site. This results in neuromuscular adaptation which may also be a protective phenomenon [8]. In case of an open reduction, there is minimum amount of neuromuscular adaptation. Usually a closed reduction results in an articulation which is inferior and anterior to the articular eminence which may limit the transitional movement. This can be avoided by open reduction and fixation. Minimum complications have been reported in the studies evaluating closed reduction in treatment of condylar fractures as pain and mouth opening were the only criteria which were evaluated. A statistically significant reduction in the incidence of malocclusion and lateral deviation on opening, along with an improved protrusive and laterotrusive movements, were noted in patients treated with surgical therapy vis-á-vis closed therapy in a recent meta-analysis report [10]. Compared to closed reduction where skeletal and neuromuscular adaptation is seen, in open reduction only neuromuscular adaption will take place following treatment.

53.4 Classification of Condylar Process Fractures

Condylar fractures can be described as a fracture line above the mandibular foramen that runs from the posterior border of the ramus to sigmoid notch or the condylar head (Fig. 53.5). Literature mentions numerous classifications of condylar fractures. Most classifications described the fracture based on the anatomical site, displacement, and fracture level, inclined towards close reduction. With the advancement of imaging modalities and better understanding of open reduction procedures, classifications which are relevant are discussed.

Various terms describing the condylar fractures have appeared in the English literature (Fig. 53.6):

- No displacement—Fracture maintains anatomic position
- Deviation—Fragments are in primary contact
- Displacement—There is no contact of the fracture fragments
- Dislocation—Extra articulation of the joints

In 1927 **Wassumund** [11] differentiated between the head and neck fractures of the condyle. Early classification only described anatomical position but had no relevance in treatment as it did not document the angulation of displacement or dislocation. Condylar fractures were classified as:

- Base fracture
- Neck fracture
- Head fracture (diacapitular)

Fig. 53.5 Area of condylar fracture

MacLennan [12] was the first to differentiate between simple bending, displacement, and dislocation fractures of the condylar process.

Class I: no deviation (bending)
Class II: deviation (bending) at the fracture level
Class III: displacement (condylar head remains within fossa)
Class IV: dislocation (condylar head outside of fossa)

Spiessl and Schroll [13]. A classification well accepted in the European literature, which differentiated between fractures of the base and neck of the condyle, it also noted the range of angulation with deviation, displacement, or dislocation (Fig. 53.7).

- Type I: condylar neck fracture with no associated deviation/displacement
- Type II: low condylar neck fracture with deviation/displacement
- Type III: high condylar neck fracture with deviation/displacement
  - IIIa: ventral
  - IIIb: medial
  - IIIc: lateral
  - IIId: dorsal
- Type IV: low condylar neck fracture with dislocation
- Type V: high condylar neck fracture with dislocation
- Type VI: intracapsular fracture of the condylar head

There are numerous modifications of Spiessl and Scholl classifications and were given over a period of time as a result subtypes has evolved especially in type V and VI fractures. Modifications included Rasse [14], Neff et al. [15], Hlawitschka and Eckelt [16], and Loukota et al. [17].

- Type A: There is a continuous bony contact within the glenoid fossa, with a component of the remaining condylar head and the fracture supported with no loss of ramal height (Fig. 53.8a).
- Type B: Loss of support within the articulating fossa and with the loss of mandibular ramal height (Fig. 53.8b).
- Type C: The highest portion of the fracture is below the level of the lateral ligament, as a result there in a loss of ramal height (Fig. 53.8c).

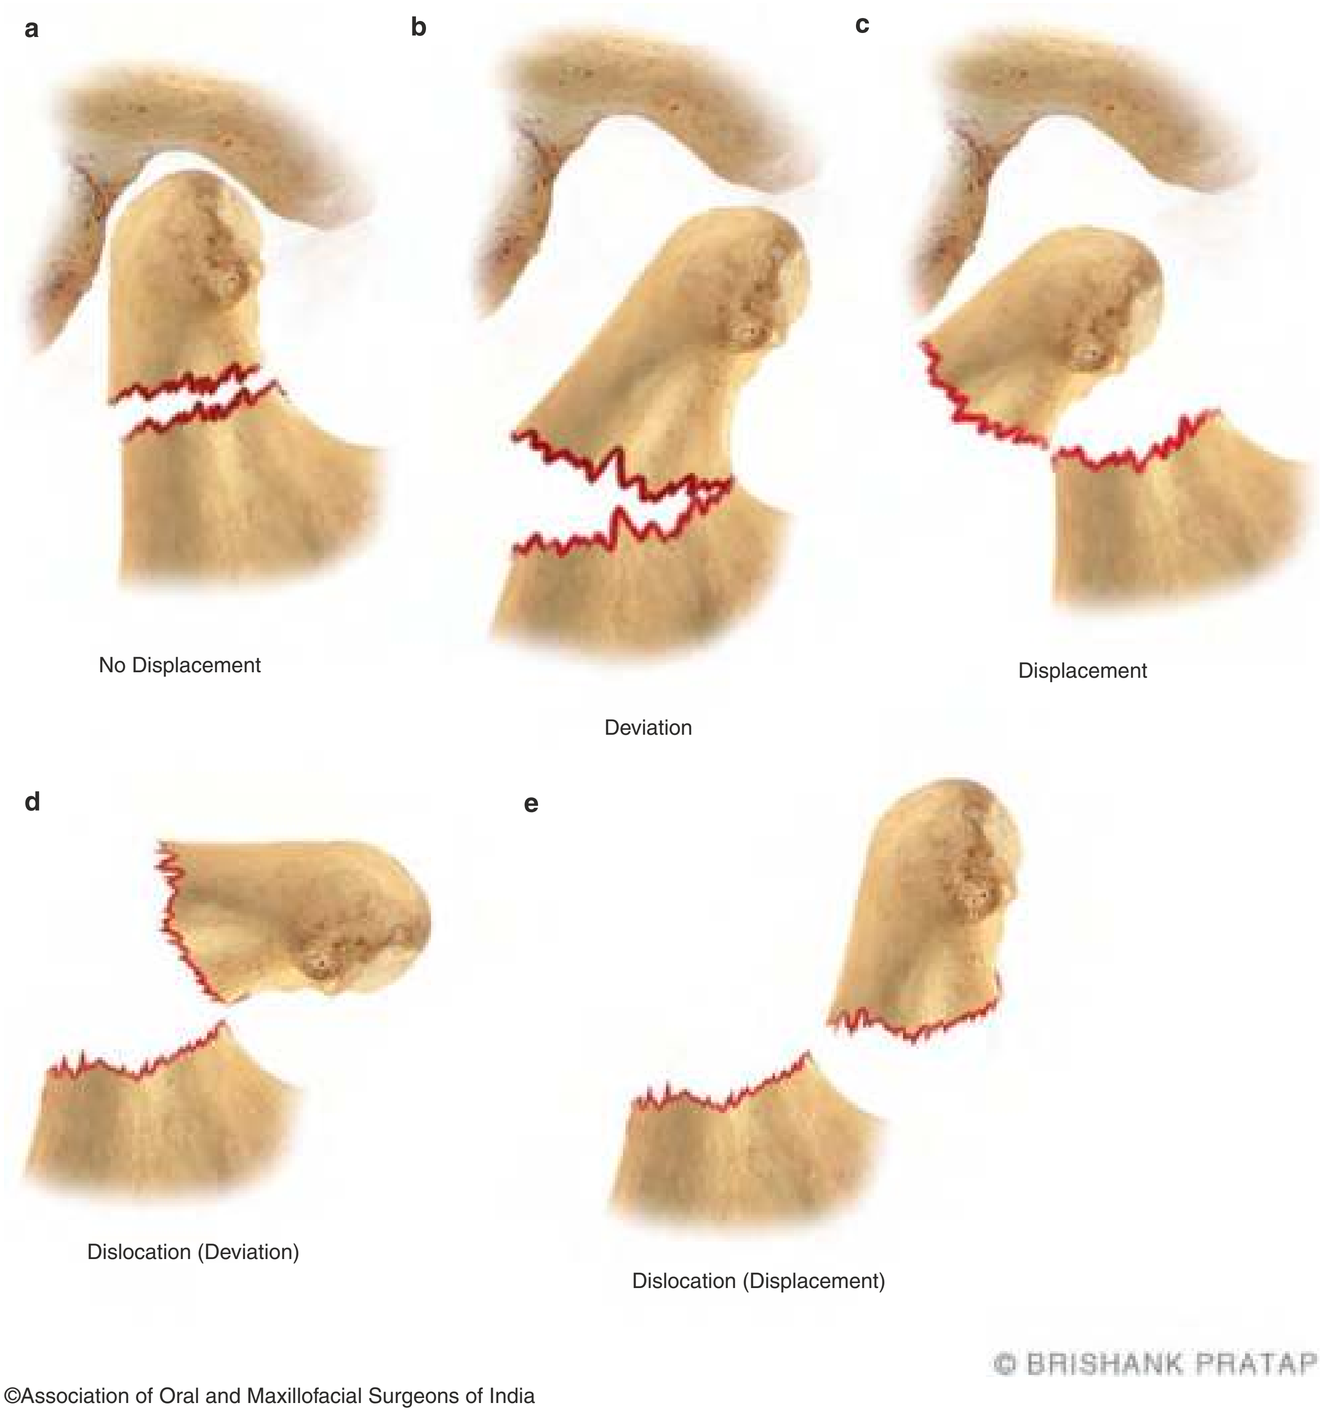

Fig. 53.6 (**a**) No displacement. (**b**) Deviation. (**c**) Displacement. (**d**) Dislocation (deviation). (**e**) Dislocation (displacement)

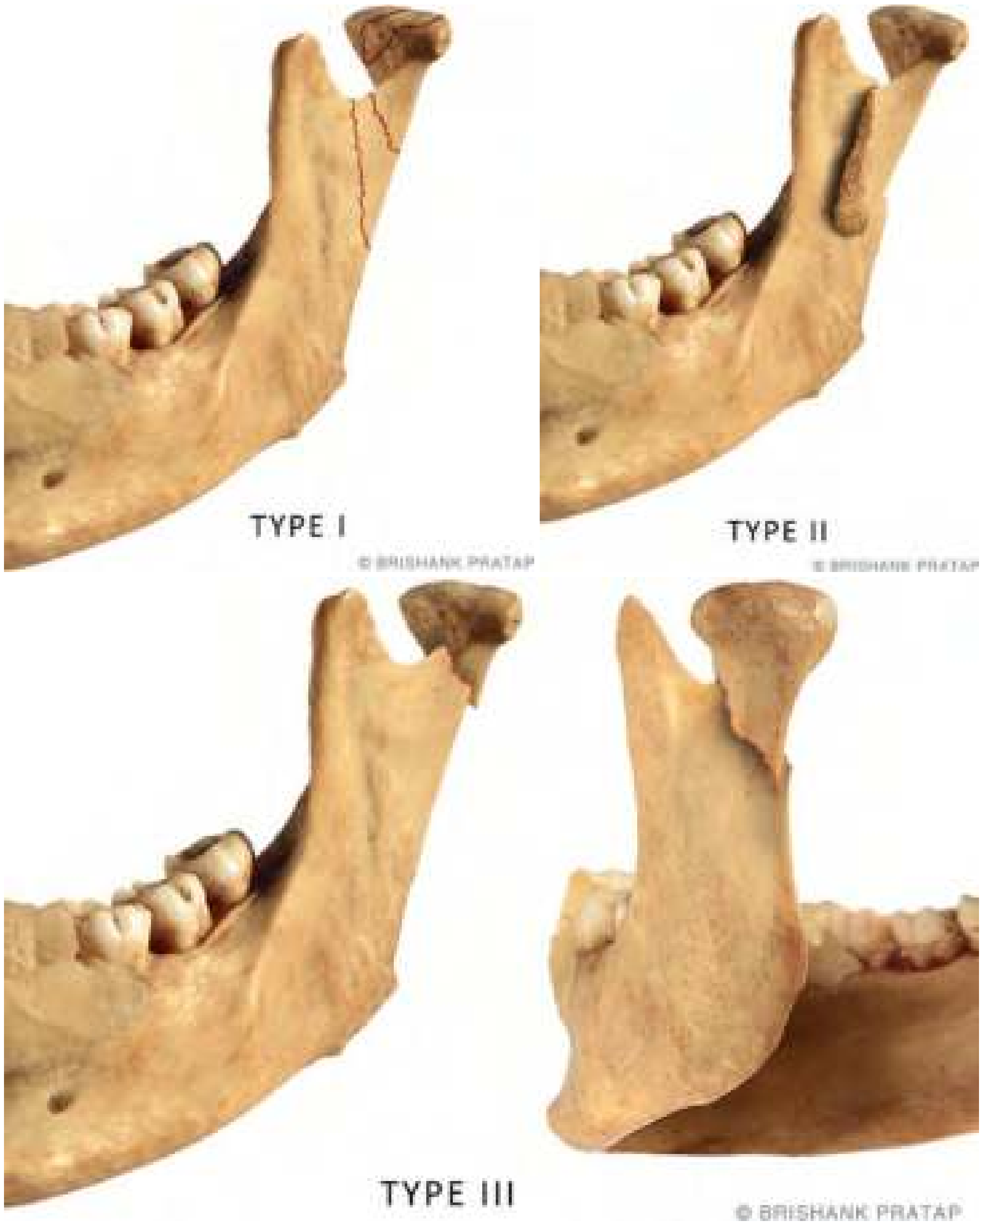

Fig. 53.7 Types I–VI: Spiessl and Schroll classification

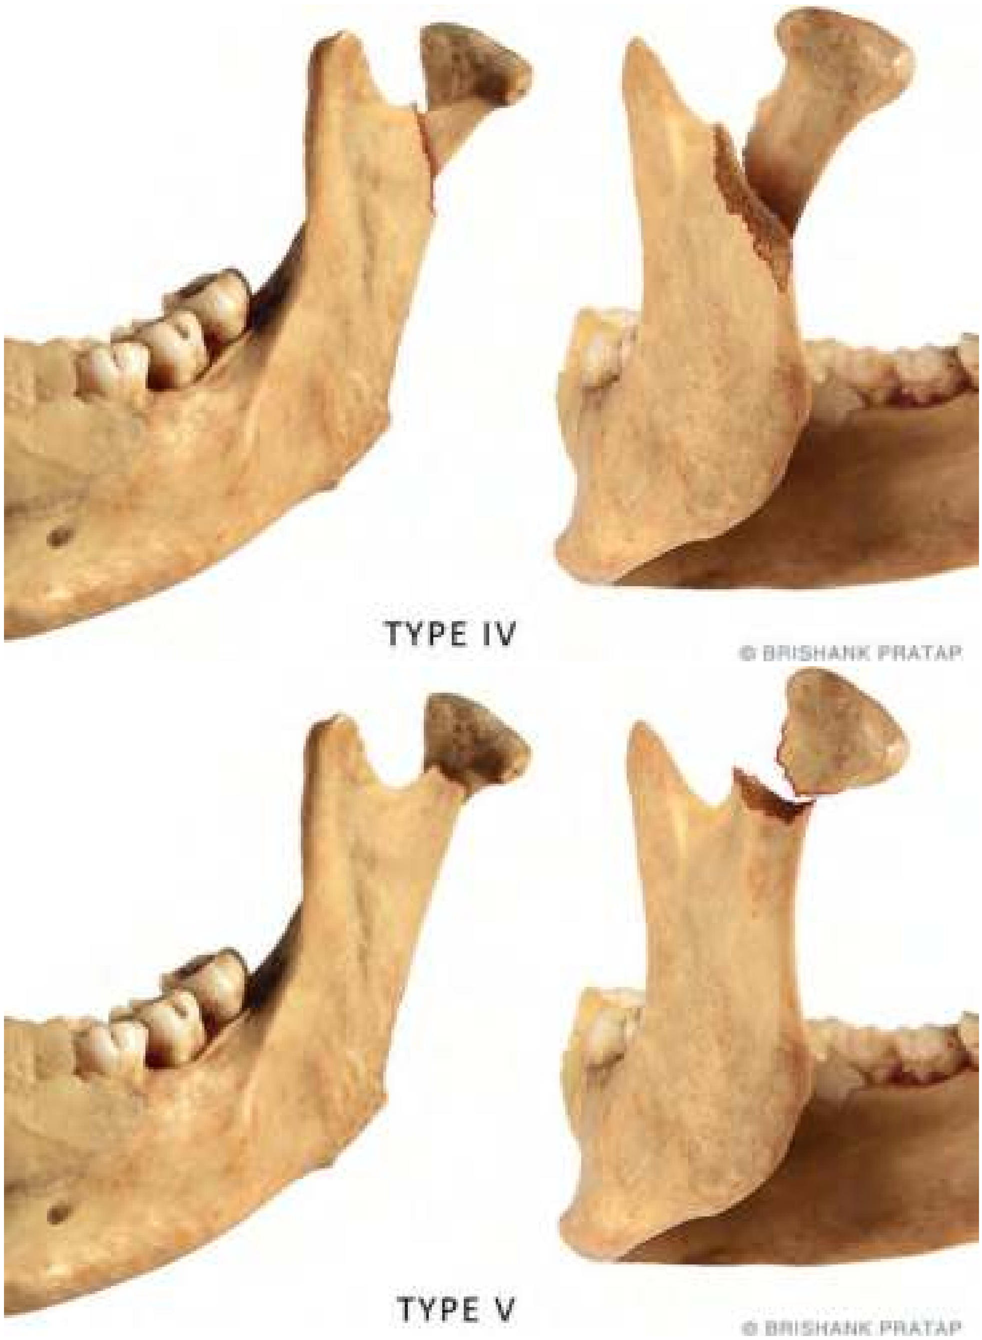

Fig. 53.7 (continued)

Fig. 53.7 (continued)

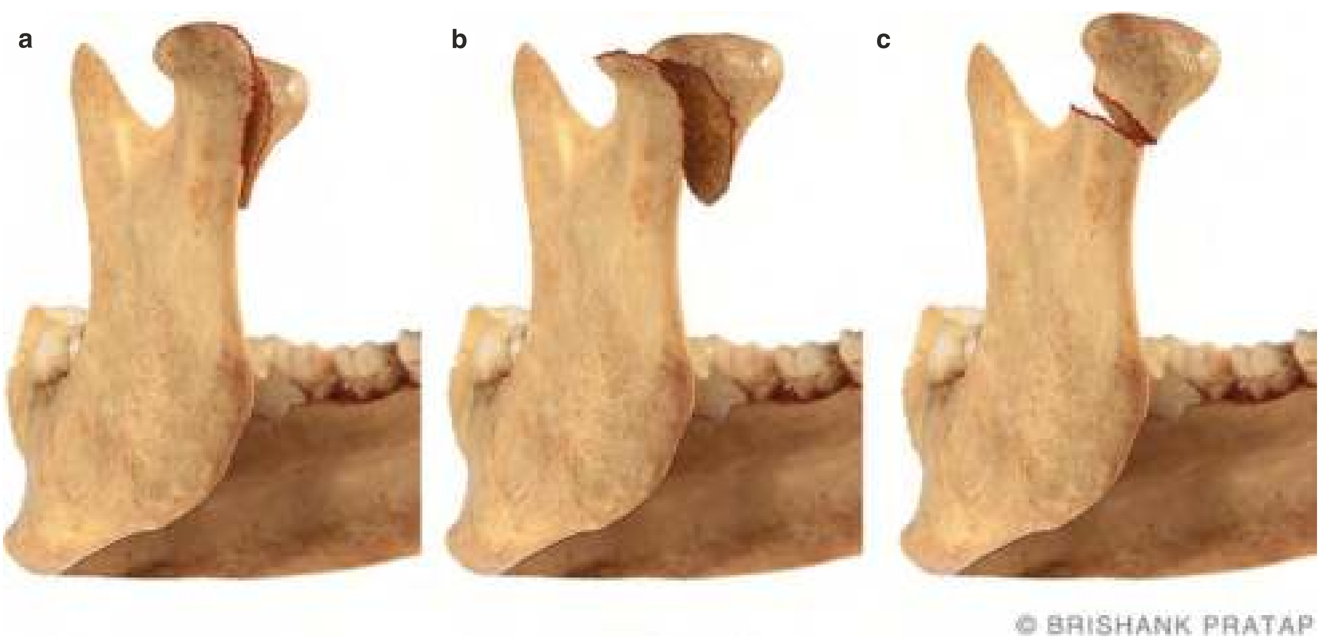

Fig. 53.8 Modified classification Type A, B, C

Lindahl [9] gave the most comprehensive classification. Although descriptive, it is a complicated classification [9].

1. Fracture level
   (a) Condylar head
   (b) Condylar neck
   (c) Subcondylar/condylar base
2. Deviation and displacement
   (a) Bending/deviation with medial overlapping segments
   (b) Bending/deviation with lateral overlapping segments
   (c) Bending/displacement without overlapping
   (d) Nondisplaced fracture without deviation
3. Relation between condylar head and fossa
   (a) No dislocation
   (b) Slight dislocation
   (c) Moderate dislocation
   (d) Severe and/or complete dislocation
4. Condylar head fracture
   (a) Horizontal
   (b) Vertical
   (c) Compression fracture

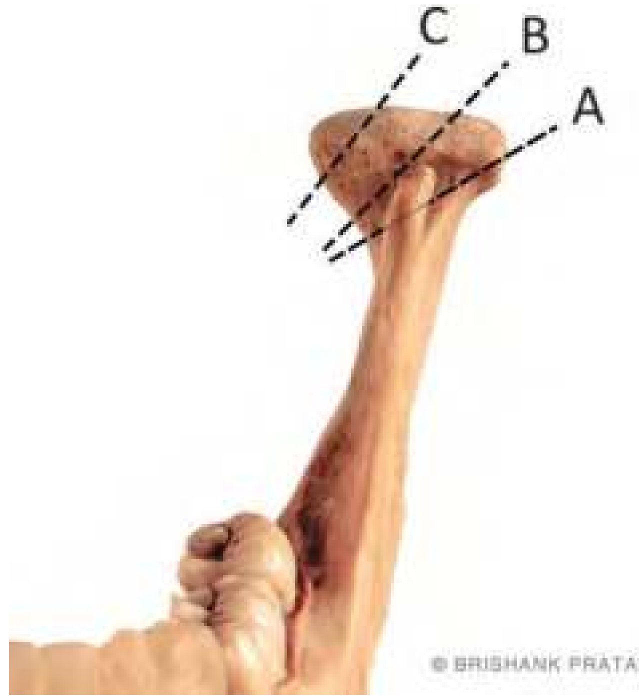

Fig. 53.9 Classification of diacapitular fractures (Type M not shown in figure)

Lindahl's Definition

- **Subcondylar fracture:** The fracture line starts at the sigmoid notch and extends to the posterior border of the mandible.
- **Condylar neck fracture:** It is located at the condylar process which is below the level of the condylar head.
- **Condylar head fracture:** The majority of the fracture components or the whole fracture is contained within the TMJ capsule.

A most common classification of diacapitular fractures was given by He et al. [18]. The types of fractures that can be recognized are (Fig. 53.9):

- Type A—Lateral third portion of the condylar head has the fracture line, and there is reduction of the ramus height.
- Type B—Central third portion of the condylar head has the fracture line, and there is no reduction of the ramus height.
- Type C—Medial third portion of the condylar head has the fracture line, and there is no reduction of the ramus height.
- Type M—It is a fracture which is comminuted with multiple fragments, usually more than three, of the condylar head.

Loukota et al. [19] proposed a system of classification for condylar processes fractures of the mandible. This classification was adopted by SOR group which is based on a line A drawn perpendicular from the lowest portion of the sigmoid notch to the posterior border of the mandible. This helps in identifying the anatomy of the mandibular ramus even in cases following severe trauma. A clarification is also given on the condylar head fracture, and it clearly defined the term minimal displacement.

Diacapitular fracture: Starting in the articular surface the fracture line may extend outside the TMJ capsule (Fig. 53.10a).

Condylar neck: Major portion of the fracture line which starts above the line A remains above it (Fig. 53.10b).

Condylar base: Major portion of the fracture line remains below the line A, and it extends behind the mandibular foramen (Fig. 53.10c).

Minimal displacement: Less than 10^0 displacement or 2 mm overlap of the bone edges or both.

AO Foundation in 2010 expanded on Ellis [20] classification with the determination of "high-neck" and "low-neck" fractures in the online AO Surgery Reference, which pro-

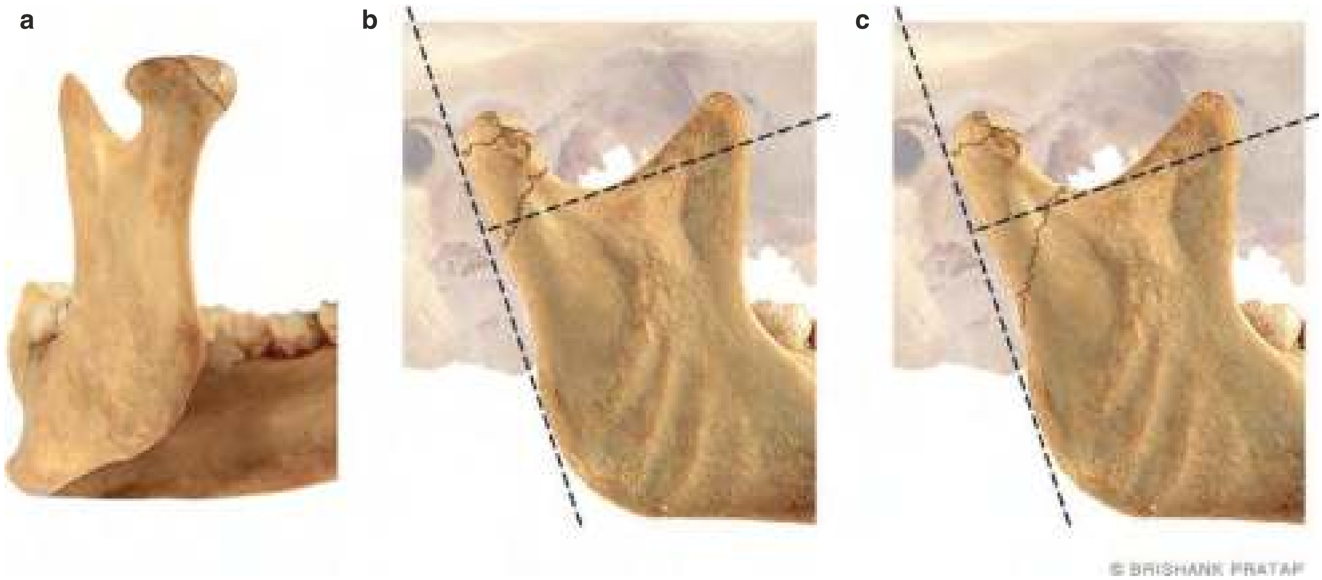

Fig. 53.10 (**a**) Dicapitular fracture. (**b**) Condylar neck. (**c**) Condylar base

vided a great detail to the location of "high and low" fractures as explained by Loukota:

- **Line 1** runs parallels the posterior border of the mandible line .
- **Line 2** as called the sigmoid notch line runs perpendicular to line 1 at the deepest portion the sigmoid notch.
- **Line 3** is perpendicular to the first line and is below the lateral pole of condylar head.
- A line is also drawn half way between the line 2 and line 3 which differentiates between high- and low-neck fractures (Fig. 53.11).

Neff et al. [21] published the Comprehensive AOCMF Classification System: Condylar Process Fractures. It is a system that highlights fracture location, identification, displacement, comminution, and dislocation. Location of the condylar fracture is clearly identified:

- *Condylar head*: the condylar head reference line runs perpendicular to the posterior ramus below the lateral pole of the condylar head.
- *Condylar neck*: the sigmoid notch line running through the deepest point of the sigmoid notch perpendicular to the ramus line extending superiorly to the condylar head.
- *Base of the condylar process*: the sigmoid notch line running through the deepest point of the sigmoid notch perpendicular to the ramus line extending inferiorly.

In the early days classification systems for the condylar fractures were entirely focused in locating the fracture. This was followed by systems which added the relation of the condyle with the adjacent structure. Loukota [19] gave a

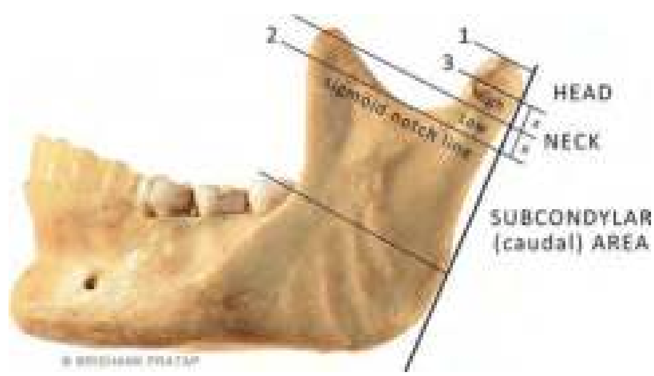

Fig. 53.11 AO foundation classification

classification which accurately locates the fracture with reference to treatment which is a simple classification to follow.

The aim of classifying the condylar fractures of the mandible is to locate the type and nature of the fracture which in turn will give a clear understanding of the nature of injury. This in turn will help the surgeon make a decision on the modality of treatment which may be open or closed.

53.5 Incidence and Pattern

In the facial skeletal, one of the most common bones to fracture is the mandible. Analysis of the fracture of different anatomical sites of the mandible revealed that there was a 10–40% incidence of condylar fractures [22–24]. Ellis et al. [25] published a study that showed condyle fractures represented 29.3% of all mandibular fractures. Zachariades et al. [26] stated that 72% of the condylar fractures were associated with other mandibular fractures. Isolated condylar fractures were rare, and occurrence of malocclusion was more dependent on the site of fracture. Incidence of fractures of condylar base were 57%, neck 31%, and head 12% as reported by Maclennan [27]. Incidence of condylar head was the least with the majority fractures at the condylar base. Frequency of unilateral fractures is higher than the bilateral fractures.

The highest incidence of mandibular fractures in males was 20–30 years and females 30–40 years [25] with the male-to-female ratio 3:1 [26]. Condylar fracture can result from direct or indirect trauma. The degree, direction, magnitude, and point of application of force determine the severity of displacement [27]. Personal violence [28] followed by fall [29–31] is the most common aetiology of condylar fractures.

53.6 Clinical Features

The patient may show mild to severe signs and symptoms following a condylar fracture. These are entirely dependent on the amount of displacement of the fractured fragments. Condylar fractures infrequently occurred in isolation and are generally associated with fractures of other sites of the facial bones. Surgeons may overlook subtle clinical features.

Signs and symptoms:

- Pain and swelling over the preauricular region
- Ecchymosis over the mastoid region
- CSF otorrhea
- Hollowness over the condylar region
- Restricted incisal opening
- Locked mandible

53.6.1 Condylar Fractures: Unilateral

- Premature occlusion on the ipsilateral side (Fig. 53.12a).
- Open bite due to the loss of vertical height on the contralateral side.
- Affected side deviates on opening and is common because of the interruption of the action of the lateral pterygoid muscle.
- Limited laterotrusive movements away from the fractured side but may be maintained towards the fracture.

53.6.2 Condylar Fractures: Bilateral

- Bilateral loss of vertical height results in anterior open bite with posterior gagging (Fig. 53.12b).
- Restricted mouth opening
- May be associated with other fractures

53.6.3 Radiographic Assessment

Condylar fractures can be evaluated by a number of conventional views. A set of two radiographs are usually taken perpendicular to each other for optimum evaluation. However the assessment has become more descriptive with availability of specialized radiographs. Various views which can be taken to evaluate the condylar fracture are as follows (Fig. 53.13):

- Towne's view
- AP mandible coronal position
- Panorex
- CT scan
- MRI

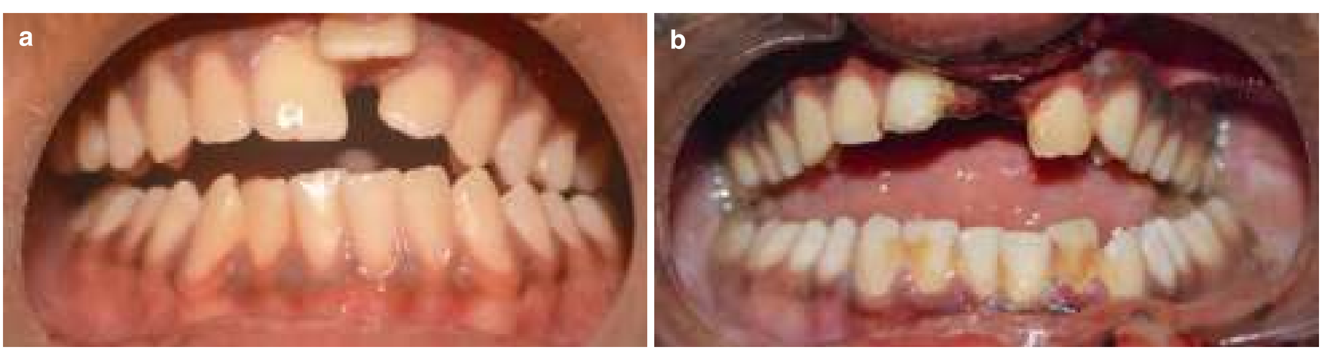

Fig. 53.12 Occlusion post condylar fracture. (**a**) Unilateral condylar fracture of the left. (**b**) Bilateral condylar fracture

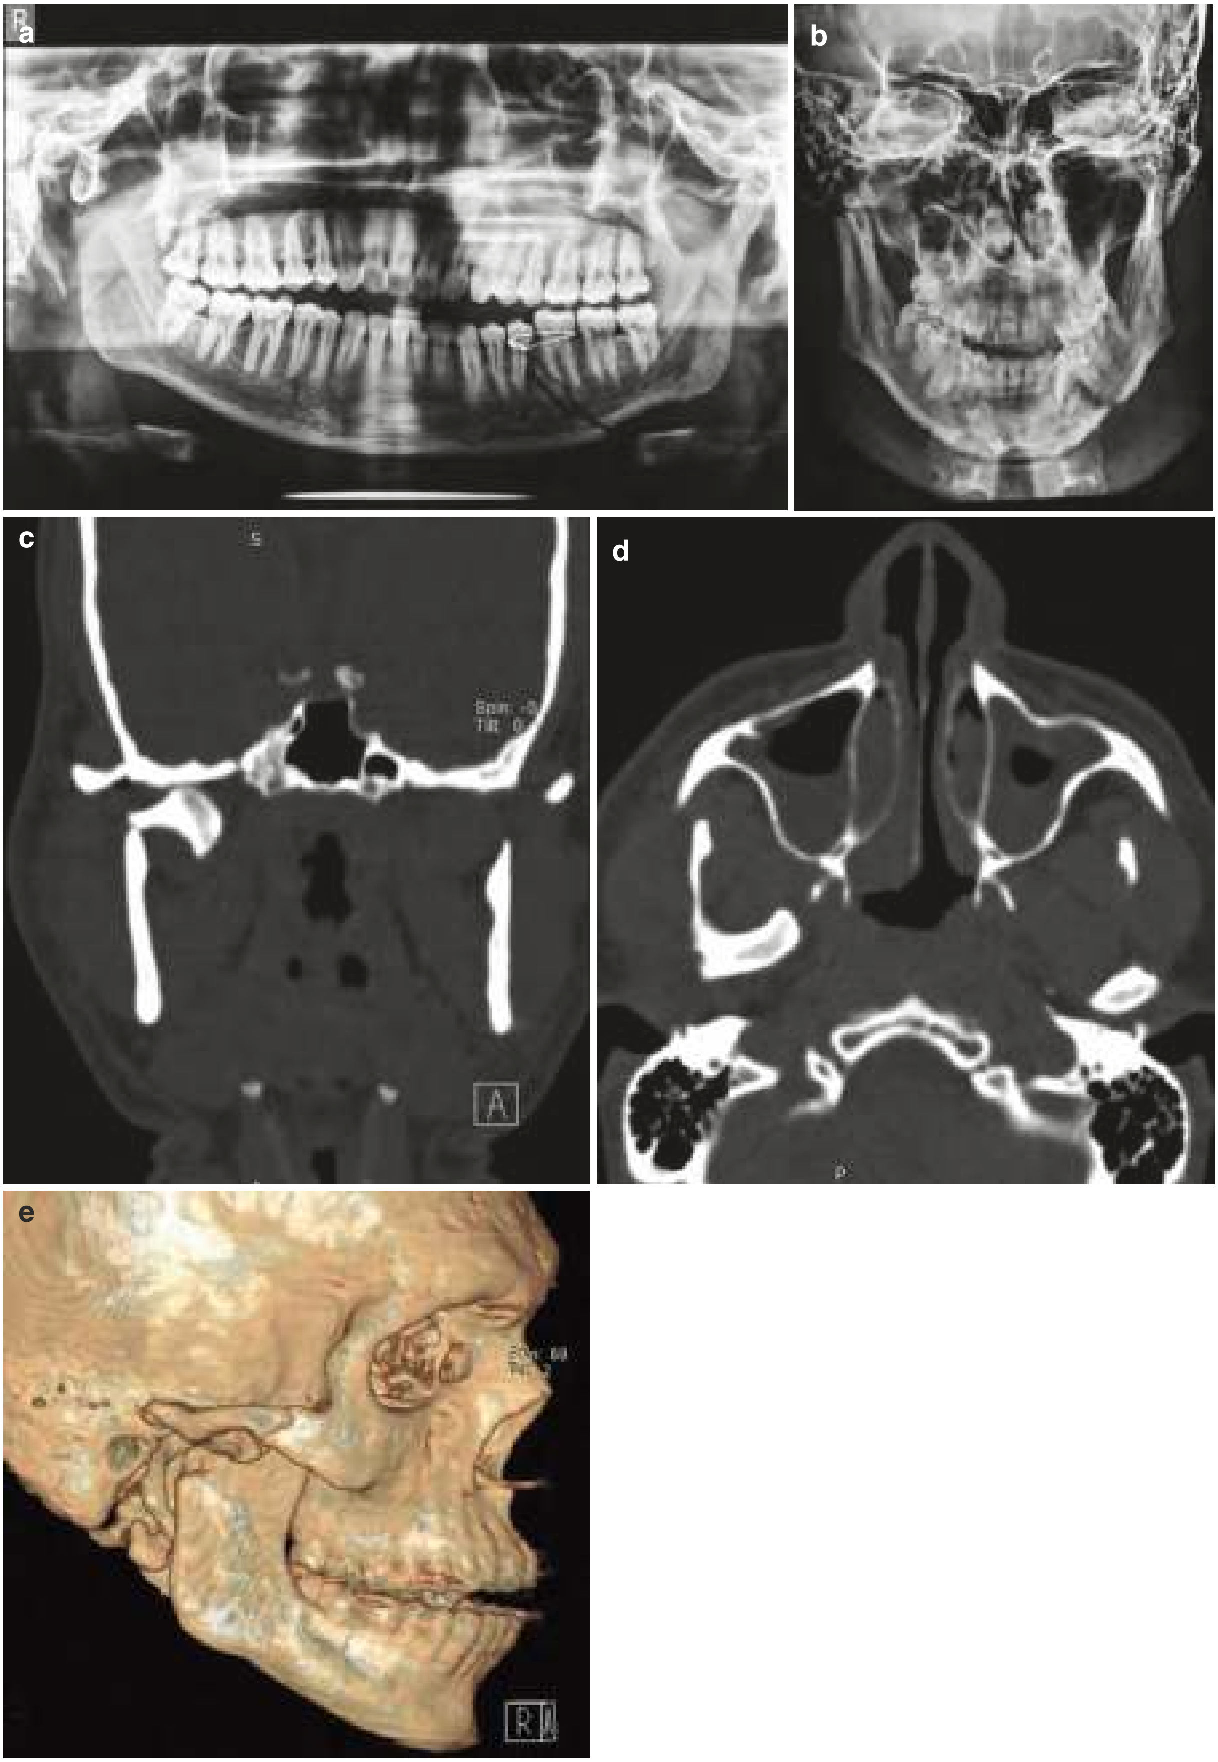

Fig. 53.13 A case of unilateral fracture of the right side of condyle with a left body of mandible. (**a**) OPG. (**b**) PA mandible. (**c**) Coronal view. (**d**) Axial view. (**e**) 3D view of the CT scan

However it may be noted that with conventional radiography, very limited information is available. CT scans in the three plains, namely, coronal, axial, and sagittal, with volumetric studies can reveal the true picture of the fracture both for the terms of evaluation and treatment planning. MRI are essential to evaluate the disc injuries specially in dislocation and intracapsular condylar fractures; however MRI are not taken as a routine practise

53.7 Management

Historically there has been no clear agreement among the surgeons on the line of management of the fractures of the condyle. The goals of treatment which were enumerated by Walker [32] (Box 53.2) are well accepted.

Box 53.2. Treatment Goals [32]

- No pain and minimum interincisal distance of 40 mm on opening the mouth.
- On excursions movements are good.
- Restore pre-injury occlusion.
- Good stable temporomandibular joints.
- Good symmetry of face and jaw.
- Good facial and jaw symmetry

Box 53.3. Indications for Open Reduction
Zide and Kent's [33]

Absolute

- Condyle displaced into middle cranial fossa
- Not possible to obtain adequate occlusion by closed reduction
- Lateral capsular displacement of condyle
- Presence of foreign body

Relative

- Bilateral condylar fracture in an edentulous patient without splint
- Comminuted midface fracture, prognathic or retrognathic jaws having associated bilateral condylar fractures
- Generalized periodontal conditions
- Jaws—totally or partially edentulous
- Unilateral condylar fractures with lack of base

Box 53.4. American Association of Oral and Maxillofacial Surgeons [34]

- Evidence of fracture—clinical
- Evidence of fracture—radiographic
- Malocclusion associated with fractures
- Mandibular dysfunction
- Abnormal maxillo-mandibular relationship
- Foreign body invasion
- Lacerations and/or haemorrhage in external auditory canal
- Cases having hemotympanum, CSF otorrhea, effusion, or hemartorisis

Literature has indicated that closed reduction has been the treatment of choice. This may be due to the complexities involved with open reduction. Surgical approach is technically demanding and associated with complications in inexperienced hands. As a result, some centres have exclusively treated condylar fractures by closed reduction. However as opposed to closed reduction, a few centres follow a protocol for management where open reduction is treatment of choice. Patients managed by surgical treatment have a superior outcome in term of post-treatment malocclusion, protrusion, laterotrusion, and lateral deviation during mouth opening. However, there was a higher infection rate as compared to non-surgical treatment. However, there is no statistical difference in post-treatment pain and maximum mouth opening in the two modalities of management [10]. Management can be divided as non-operative and operative (Box 53.6).

53.7.1 Non-operative

Some patients can be managed by observations provided they have a minimal nondisplaced fracture, dentate with a stable occlusion and having minimum pain. An important factor is that the patient must be complaint. At the onset of the treatment, patient must be explained about the possibility of additional treatment in the form of closed reduction which may be required.

Protocol followed is as follows:

1. Diet: There is no restriction on the diet; generally a patient would be restricted to a soft diet in order to avoid pain.
2. Rehabilitation: Patient is instructed to perform exercises of the jaw such that all the excursion movements are carried out. Goals of rehabilitation are mentioned in the (Box 53.8).

Box 53.5. Indication for Open and Closed Reduction
Fonseca [35] adapted from references [36–43]

Absolute
- Condyle displaced into middle cranial fossa
- Presence of foreign body
- Extracapsular displacement of condyle laterally
- Malocclusion not amenable to closed reduction (e.g., functional reduction of ramus height)

Strong evidence for open reduction
- Bilaterally fractured condyles
- Condyle displacement grossly >45° (severely displaced)
- Anatomic reduction of ramus height ≥ 2 mm
- Condylar fractures with an unstable base (associated midface fractures)
- Unstable occlusion generally seen in periodontal disease, less than three teeth per quadrant
- Condylar fractures for which adequate physiotherapy is impossible

Mixed evidence for open reduction
- Moderate condylar displacement, 10–45°

When to treat with closed reduction
- Nondisplaced or incomplete fractures
- Isolated intracapsular fractures
- Condylar fractures in children (except for absolute indications)
- Reproducible occlusion without dropback or with dropback that returns to midline on release of posterior force
- Medical illness or injury that inhibits ability to receive extended general anaesthesia

Box 53.6. Management of Condylar Fractures

Non-operative:
- Observation, physiotherapy, etc.

Operative:
- Closed procedures:
- MMF (arch bars or screws—elastic or wire)
- Open reduction and internal fixation (ORIF)
  - Approach is determined by:
    - (i) Surgeon preference
    - (ii) Fracture location
    - (iii) Type of fixation

Box 53.7. Factors Taken into Consideration for Treatment
- Location of the fracture
- Amount of vertical reduction in height of the ramus
- Degree of angulation
- Relation of condylar head to the glenoid fossa
- Fragmentation pattern (simple versus complex)
- Association with other mandibular injuries
- Dental occlusion/status of dentition
- Association with other facial bone injuries
- Association with systemic injuries
- Association with the condition of the patient (comorbidity factors)
- Foreign body in temporomandibular joint (TMJ)

Box 53.8. Closed Reduction

Advantages
- Relatively safe procedure
- No injuries to vital structures
- Hospitalization may not be required

Disadvantage
- Long period of intermaxillary fixation
- Growth disturbances can occur in children
- Success depends on patients cooperation
- Long-term follow
- Contraindicated in medically compromised
- Challenge in partially or totally edentulous patients

3. Follow-up: Recall visit is scheduled after 1 week. At this visit progress is recorded. Next visit is scheduled after 2 weeks if the patient is compliant. In case the progress is not satisfactory frequent follow-up would be required or a change in treatment plan.

53.7.2 Closed Reduction

Closed reduction is a misnomer. It is never possible to achieve anatomic reduction as seen in management of other fractures. Closed reduction relies on the functional adaptation where a stable occlusion is achieved. Advantage of this technique is that it is minimally invasive and may not require hospitalization. It is entirely possible to carry out the procedure under local anaesthesia. However adaptation is never complete in adults as opposed to children. It may be possible to treat all types of condylar process fractures by this technique, but the surgeon must exercise his judgement based on the case and patient requirements. Closed reduction may involve the following:

1. Maxillomandibular fixation (MMF): Some surgeons prefer period of MMF which may range over 2–6 weeks. MMF can be obtained by using arch bars, Ivy loops, IMF screws or any other method a surgeon is comfortable; however method used will depend on the use of elastics or wires, and MMF may entirely be based on the level of fracture. The reader is advised to refer Chap. 50 of this book for details on various wiring and IMF techniques The lower the fracture, the longer the period of immobilization. In children immobilization may range from 7 to 10 days as there are high chances of developing ankylosis. This is followed by functional treatment.
2. Functional treatment: At times only, functional treatment may be followed. This treatment relies on guiding elastics and active movements. Elastics are given to achieve repeatable occlusion. Initially heavy elastics are placed and then slowly shifted to light elastics. During the meals elastics are removed. After an initial period of 2–4 weeks, elastics are placed only during the night. Minimum elastics must be used as the aim is to permit maximum mobility of the jaw. Functional treatment can be supported by myofunctional orthodontic treatment employing activator therapy. Myofunctional therapy should be started as soon as the mouth opening enables taking dental impressions.

53.7.3 Open Reduction and Fixation

This modality is technically challenging due to the complexities in terms of anatomy, approach, and fixation. It has been observed that by achieving anatomical reduction irrespective of the type of fixation used, it will result in restoring back the skeletal architecture. This in turn would require only neuromuscular adaptation for full recovery of the patient. According to the reports, this may be the reason for open management to be superior to the closed [36].

Surgical approaches to the condylar fracture are entirely dependent on the following factors (Fig. 53.14):

1. Location of the injury
2. Type of osteosynthesis

Incisions used to approach the fractures are divided as

1. Intraoral
2. Retromandibular
3. Submandibular/ periangular
4. Preauricular/ retroauricular

Box 53.9. Open Reduction and Fixation

Advantages
- Anatomic reduction of fractures
- Short or no intermaxillary fixation
- Early function

Disadvantage
- Complications such as scar and injuries to neurovascular structures
- Infections
- Hospitalization required
- High cost of treatment
- Steep learning curve for surgeon

53.7.3.1 Submandibular/Periangular (Fig. 53.15a, b) (Video 53.1)

This is an approach most maxillofacial surgeons are familiar with in their practise popularly known as Risdon approach. It exposes the base along with the neck of the condyle. Incision can either be parallel to the lower border or placed in a skin crease for maximum cosmetic results. For the condylar, fracture's incision is extended backward and upward to give a maximum exposure hence also referred to as periangular incision. The marginal mandibular nerve is protected by marking the incision 2–3 cm below the lower border of the mandible. Incision transverses through the skin, subcutaneous fat, and platysma. A superior platysmal dissection will expose the marginal mandibular nerve; however this may not be necessary. After dissection of the platysma, superficial layer of deep cervical fascia is transected; this may expose the facial artery and vein. These may be required to be ligated and reflected superiorly. This will protect the marginal mandibular nerve. Then pterygomasseteric sling is divided and periosteum reflected to expose the lower border of the mandible. This gives an adequate exposure for osteosynthesis.

A modification of the submandibular/periangular approach known as the high submandibular approach or the high cervical transmassetric anteroparotid approach provides good aesthetics and reduces the chances of damage to the facial nerve [44]. A curved incision measuring three to five cm in length is placed about 1 cm from the angle of mandible [45]. This is followed by layered dissection. An avascular pouch is created superiorly, and the pterygomasseteric sling is identified. Stripping the masseter muscles of its attachments will lead to the exposure of the fracture [46] (Video 53.2).

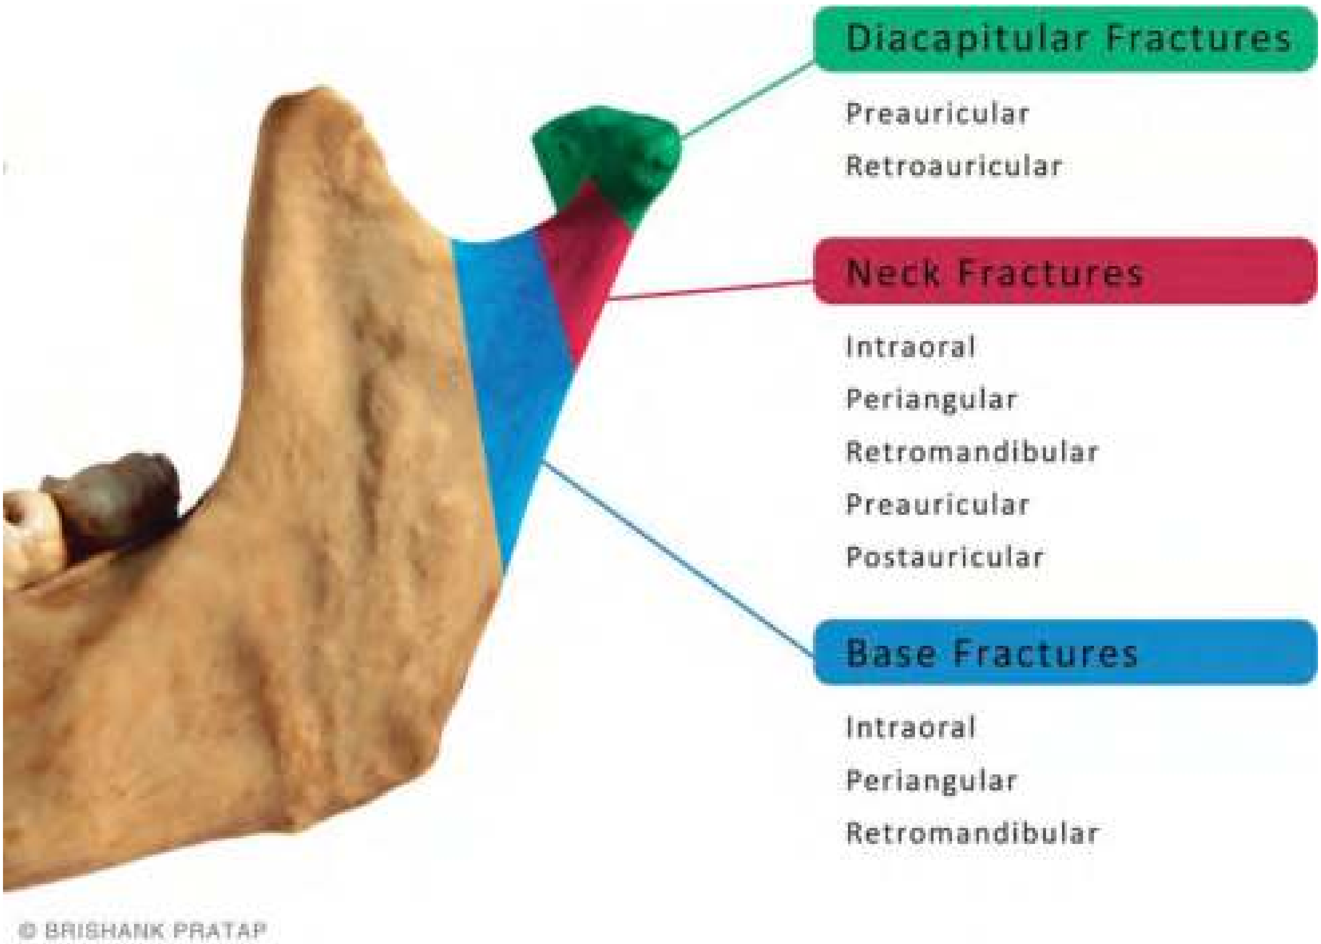

Fig. 53.14 Various incisions possible for condylar fractures based on location

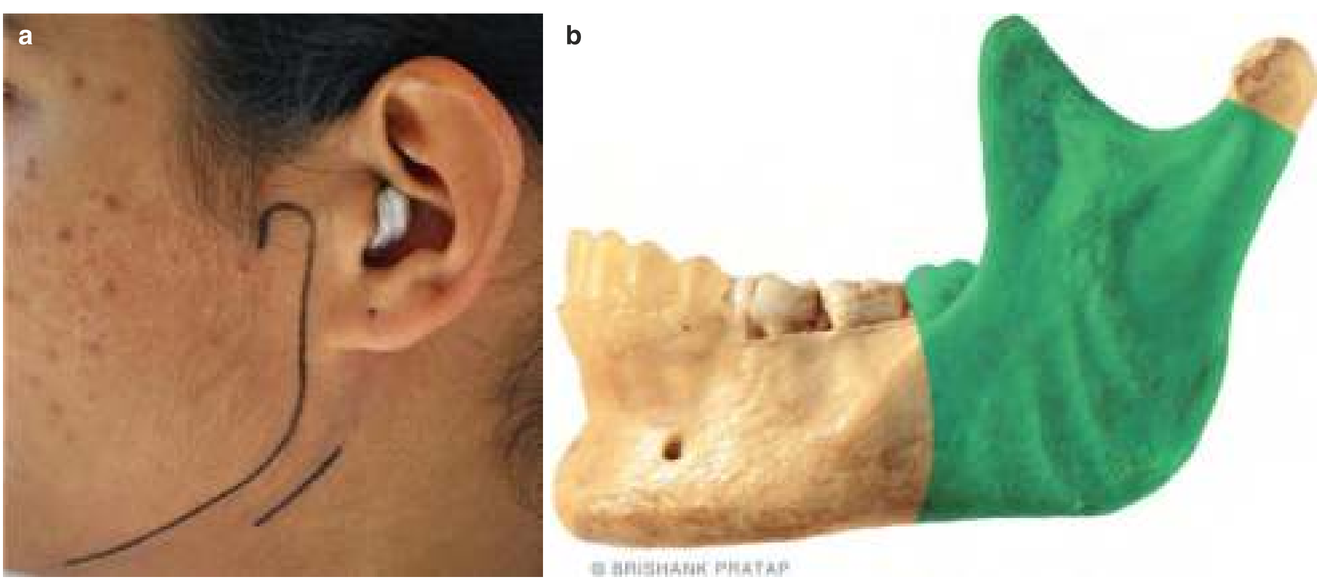

Fig. 53.15 (**a**) Incision for submandibular/periangular approach. (**b**) Area exposed marked green in the mandible

53.7.3.2 Retromandibular (Fig. 53.16a, b) (Video 53.3)

Entire posterior border can be exposed via the retromandibular approach [47]; hence this approach is useful in treating fracture of the condylar neck and the base. The anatomic structures encountered in this approach are the main trunk of the facial nerve and retromandibular vein. It has two main variations transparotid and retroparotid. In both the variation marking of the incision is 5–10 mm below the lobule of the ear, parallel to the posterior border usually 3–4 cm long.

Transparotid Approach

In this approach incision is extends from the skin to the subcutaneous tissue, and it is undermined to reach the parotid capsule which is divided horizontally between the path of the buccal and zygomatic branches of the facial nerve. Dissection is carried out parallel to the direction of the facial nerve branches, and it is not important to locate the branches. Pterygomasseteric sling is sectioned, and periosteal flap elevated to expose the posterior border of the mandible.

Retroparotid Approach

In this approach parotid gland is lifted rather than transected to approach the posterior border of the mandible. Incision in this approach is placed more posterior as compared to transparotid approach as a result exposure is also restricted. After the parotid fascia is identified, dissection is carried out behind the gland. The gland is lifted to expose the posterior border; from here the dissection carried out is the same as the transparotid approach.

The wound is closed in layers to avoid dead space. Also, the parotid fascia should be sutured tightly to prevent sialocele or parotid fistula. Drains can also be placed.

53.7.3.3 Preauricular Approach (Fig. 53.17a, b) (Video 53.4)

This incision is most commonly used by the surgeons in the TM joint surgeries. Diacapitular fractures are approached via this approach [48]. Branches of facial nerve are involved in this approach along with the superficial temporal artery and vein. Incision is placed along the crease of the skin following the tragus and helix of the ear which can be extended in the temple region. This extension on the temple minimizes traction and prevents weakness of facial nerve. Incision is carried from the skin to the subcutaneous tissue till the white glistening temporal fascia is reached. Root of the zygoma is palpated, and an oblique incision is given parallel to the frontal branch of facial nerve. Superficial temporal fascia is incised, and a periosteal elevator is inserted below the fascia to strip the periosteum of the zygomatic arch. This will expose the capsule of the temporomandibular joint. Capsule is incised in an open method to expose the head of the condyle. The neck is exposed by doing a subperiosteal dissection. Closure is done in layers first being the capsule followed by temporalis fascia, subcutaneous tissue, and the skin. The main disadvantage of this approach is an unaesthetic scar. This can be overcome by placing the incision endurally. The scar hides behind the tragus, but it can cause perichondritis.

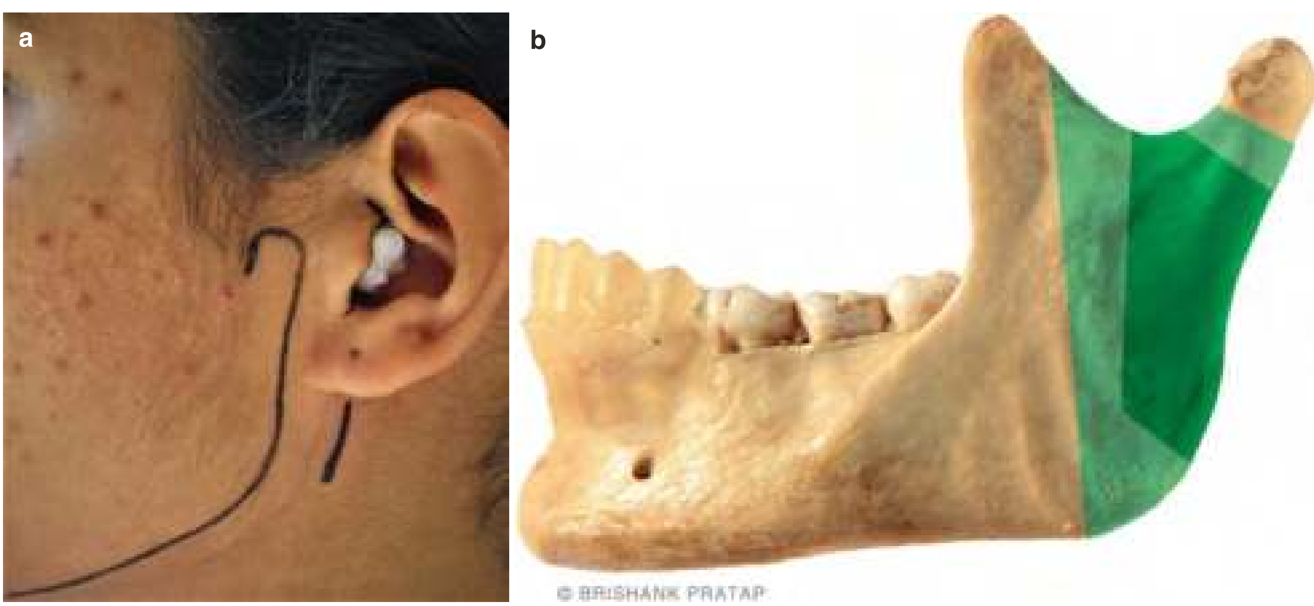

Fig. 53.16 (**a**) Incision for retromandibular approach. (**b**) Area exposed marked in mandible (dark green, retro parotid exposure; light green, transparotid exposure)

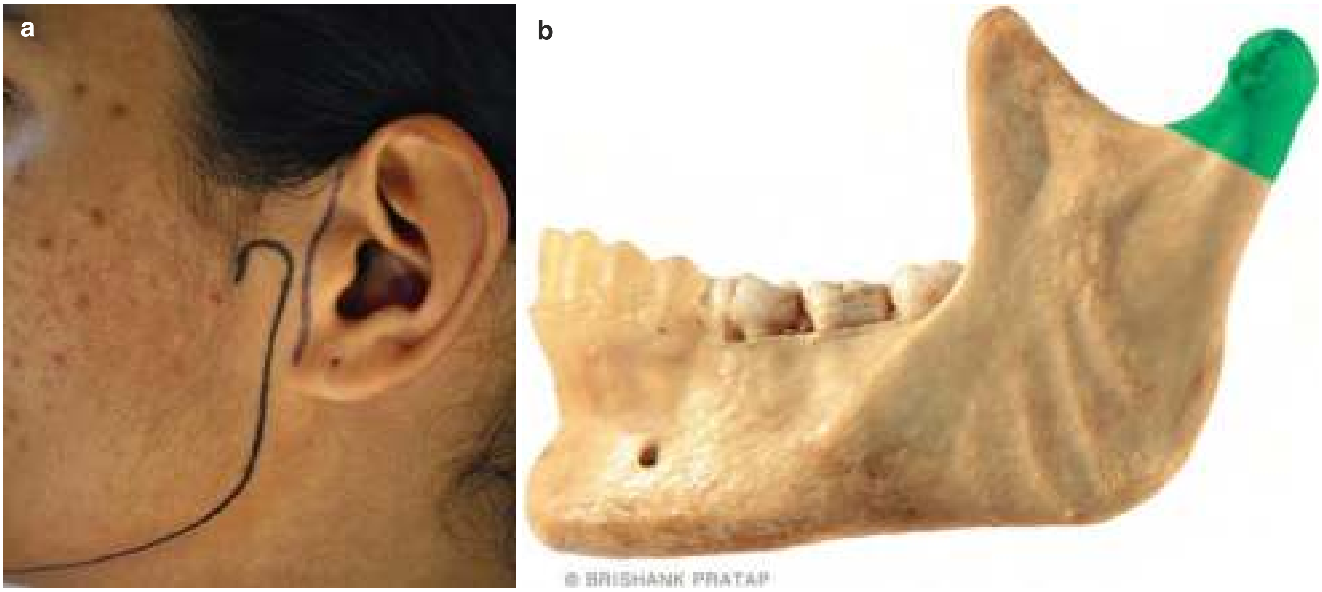

Fig. 53.17 (**a**) Preauricular approach incision. (**b**) Area exposed marked in the mandible

53.7.3.4 Retroauricular Approach

This is an approach which will provide best cosmetic results. However major disadvantage is that it can result in stenosis of the external auditory canal. Also, the closure takes a longer time. Incision runs parallel to postauricular flexure approximately 3 mm behind it. Skin followed by postauricular muscles and fascia overlying mastoid are incised. External auditory canal is identified and completely transected at bony cartilaginous junction. Temporalis fascia is identified, and from here dissection followed is similar to preauricular approach to expose the condylar head. Closure is done in layers with a special attention given to the external auditory canal.

53.7.4 Reduction

After the adequate exposure of the fractured fragments reduction is achieved under direct vision. If the distal fragment is placed laterally, reduction tends to be easy. However, in most of the cases, the fragments tend to be displaced medially resulting from the pull of lateral pterygoid muscle. A medially displaced fragment must be lateralized before an attempt is made to reduce the fracture. For easy manipulation, a plate with a single screw is fixed on the distal fragment. This will help in easy lateralization of the distal fragment and prevent the fragment from slipping back as the lower end of the plate acts as a rest on the proximal segment. Before an attempt is made to reduce the fracture, manual traction is applied to the mandible so that the vertical height of the posterior mandible is restored. This can be achieved as follows (Fig. 53.18a–d):

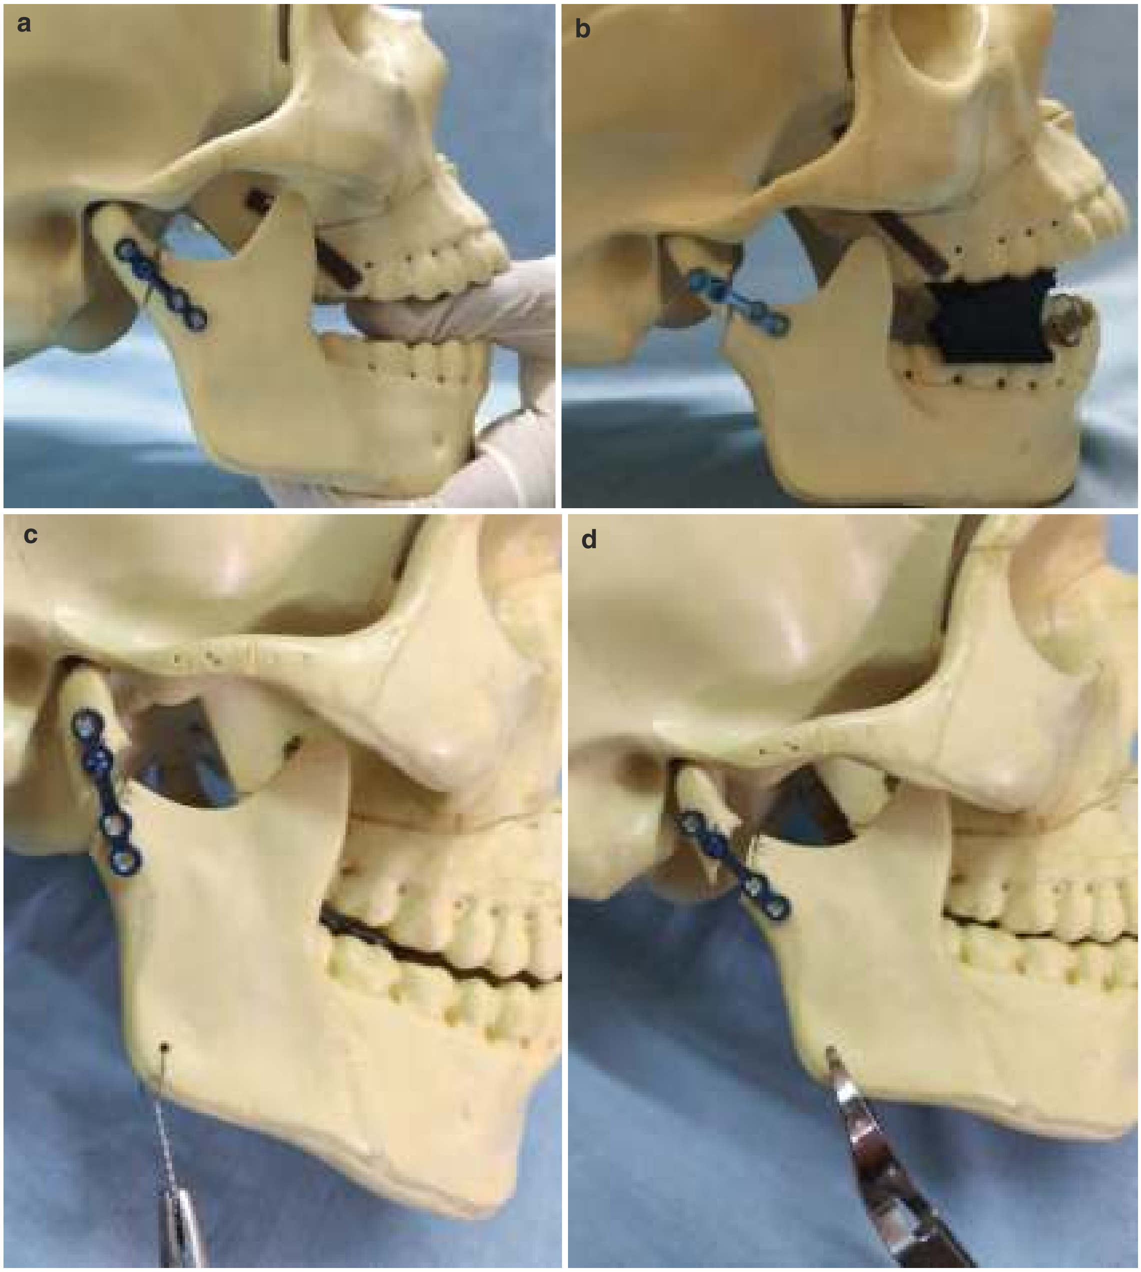
1. Manual digital traction: Thumb is placed on the lower teeth and fingers support the lower border. Mandible is pulled in inferior and anterior direction.
2. Bite block: A bite block is placed on the same side of the condylar fracture in the molar region. This will result in inferior distraction of the mandible with rotation.
3. Transosseous wire: A transosseous wire can be passed along the posteroinferior border of the mandible. A traction is applied on this wire in an inferior and anterior direction.

Once the fracture is reduced with the help of a clamp in the lowermost hole of the plate, pressure is applied to keep the fractured end in place. Figure 53.19a–d shows the reduction and fixation of a medially displaced condyle fracture.

In a case where two plates are planned for fixation, the smaller plate along the anterior border of the condyle is fixed first with a screw. Once the anterior plate is fixed on the distal segment, similar steps are followed as mentioned earlier for single plate for reduction and fixation.

Sequencing the case of multiple fractures is as follows:

1. Fractures with contralateral condylar fractures—Fractures in the tooth bearing anterior segment are fixed before the condyle is fixed.



©Association of Oral and Maxillofacial Surgeons of India

Fig. 53.18 (**a**) Manual digital reduction. (**b**) Traction using bite block. (**c**) Transosseous wiring. (**d**) Towel clip

2. Bilateral condylar fracture with anterior mandible—In these cases there can be flaying of the mandible resulting in increase of transverse dimension of mandible. Anterior fractures are reduced and fixed taking into consideration into the lingual reduction. Anterior fractures are fixed before the posterior.
3. Panfacial trauma—Principal remains the same, mandible is fixed as mentioned above before the midface fractures are reduced and fixed. This may change depending on the sequence followed for fixation of panfacial fractures

53.7.5 Fixation Techniques (Fig. 53.20a–d), (Case 1: Fig. 53.21a–b), (Case 2: Fig. 53.22), (Case 3: Fig. 53.23a–e), (Case 4: Fig 53.24a–d)

The most significant advances that have taken place in the management of fracture of condylar process include the osteosynthesis material and the technique. Fixation with titanium plates and screws has given optimal results when adequate bone, proper site selection with proper techniques

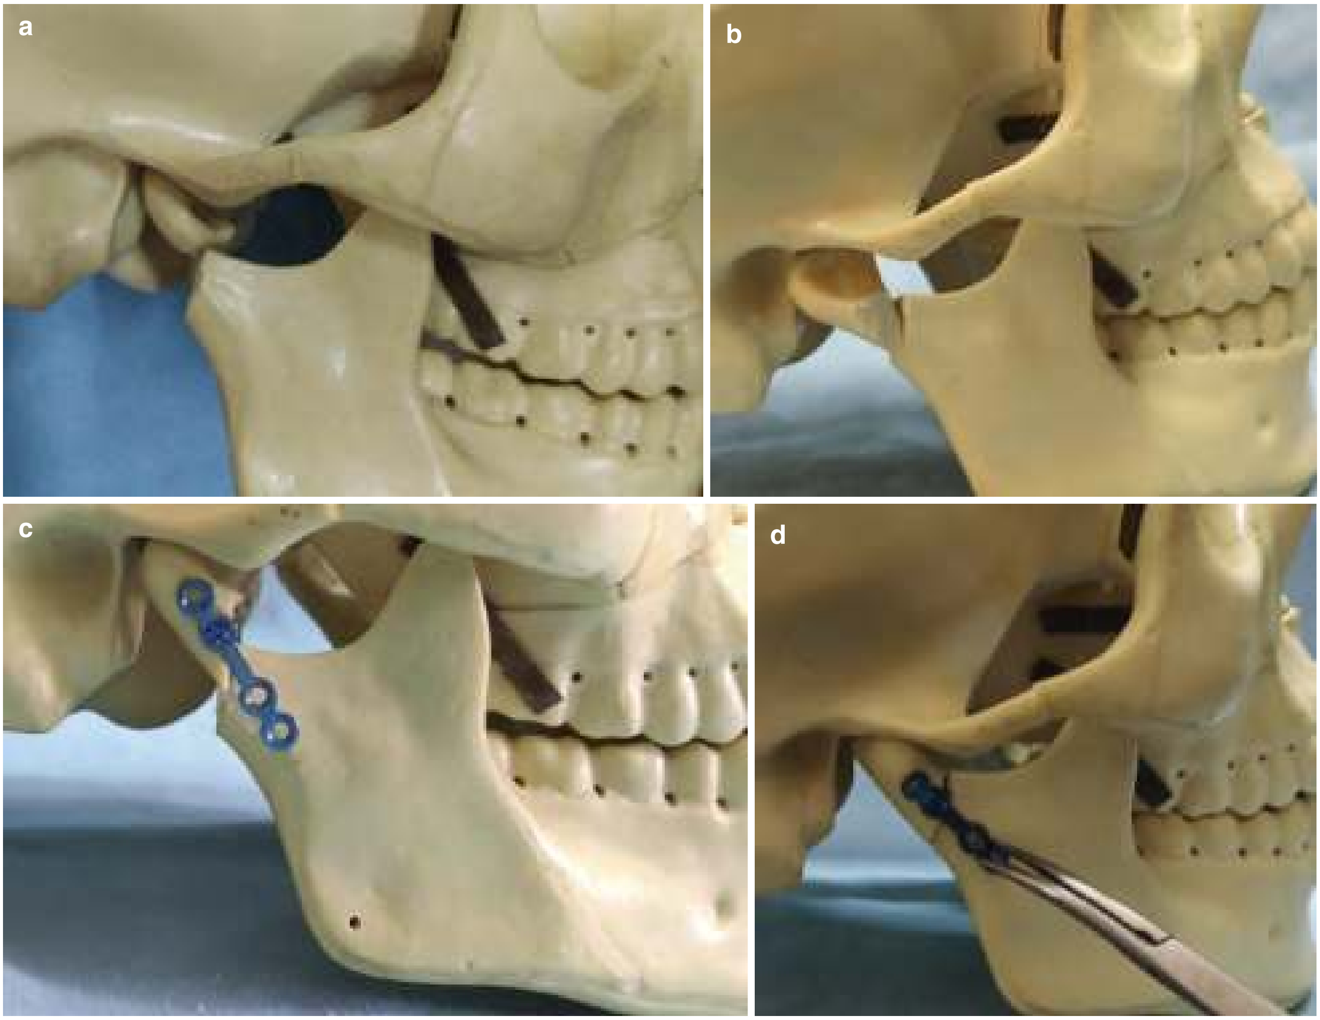


Fig. 53.19 (**a**) Medially displaced condylar fracture. (**b**) Fracture lateralized. (**c**) Distal segment secured with a plate. (**d**) Fracture reduced

followed [49]. At the time of surgery fixation, technique is selected based on the following parameters:

1. Fracture morphology
2. Amount of bone available
3. Surgeon preference

Fixation can be in the form of one plate, two plates, hybrid plates, lag screws, or restorable plates. Studies have shown that use of two plates is superior to one plate [40, 50]. Two plates must be used for lower level fractures to overcome tension and stress in the neck region by placing plates along the anterior and posterior border in a triangular fashion (Fig. 53.20a–d). In cases where there is limited bone, available fixation can be done with heavier single plate. Single plate is fixed along the long axis of the condyle. There are many types of hybrid plates available. These are designed to incorporate the principle of two plates in a single plate. However, this makes the plates bulky as a result it may be at times difficult to fix them especially when there is limited bone available. Irrespective of the type of plate used, there should be at least two screws on either side of fracture.

Fixation of condylar head is a challenge because of the limited space available and the fractures are intracapsular. In addition, there could be multiple small fragments and associated injury to the disc and the capsule which may be required to be repaired. Several osteosynthesis techniques are available for fixation like the mini plates, stainless steel wire, standard lag screws, resorbable screws, resorbable pins, and cannulated lag screws (Fig. 53.25). Reduction and fixation of the condylar head is technically challenging as the small fragments can easily necrose if stripping of the muscle is done. Use of two lag screws would be idle as it will prevent the reduced fragments from displacement during function, but times it may not be possible to fix two screws due to limited space Table 53.1 [51].

Intraoral endosocpic approach for treatment of condylar fractures is given in detail in Chap. 54 of this book.

5. Close supervision by the surgeon

53.8 Condylar Fractures in Children

The most common fracture seen in the maxillofacial region in children is fracture of the condylar process [53]. Condyle is unique in children as there is a very thin cortical bone surrounding a highly vascular cancellous bone. This can result in a comminuted type of fracture also called mushrooming. Condylar fractures can result in definitive deformities, both in terms of function as well as

Case 4: Fig. 53.24 (**a**, **b**) Pre operative PA view and OPG showing fracture left condyle. (**c**, **d**) Post operative PA view and OPG showing the fixed Delta plate via Periangular approach

a facial asymmetry in cases of inappropriate treatment. Intracapsular fractures can result in retardation of growth [54, 55] or in excessive growth on the fractured site [56]. Remodelling of the condyle is inversely proportional to age [9, 25, 26]. Children have a better adaptation than the adults. Adaption in children is skeletal, neuromuscular, as well as function. In adults only functional adaptation is seen. For this reason, literature has supported conservative management of fracture of the condylar process. It is paramount to rehabilitate the patient with the restoration of minimum mouth opening, lateral excursion movement with stable occlusion. However, a long-term follow-up showed 50–53% of patients had complaints even though minor in nature irrespective of the type of treatment carried out [57]. Early mobilization is recommended in children below 15 years. Patients are encouraged to be on soft diet to avoid pain. In cases where an open bite is present, guiding elastics will help in restoring the occlusion. There is no concrete evidence of prolonged period of maxillomandibular fixation.

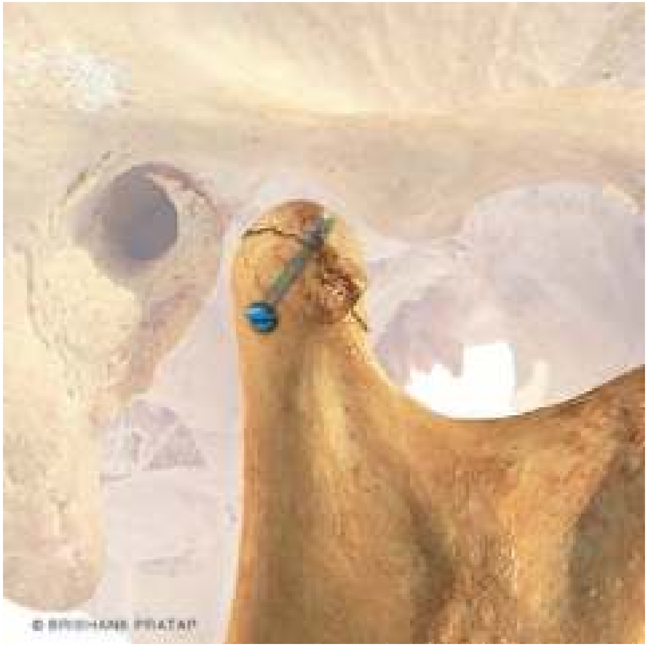

Fig. 53.25 Fixation of the condylar head fracture with lag screw

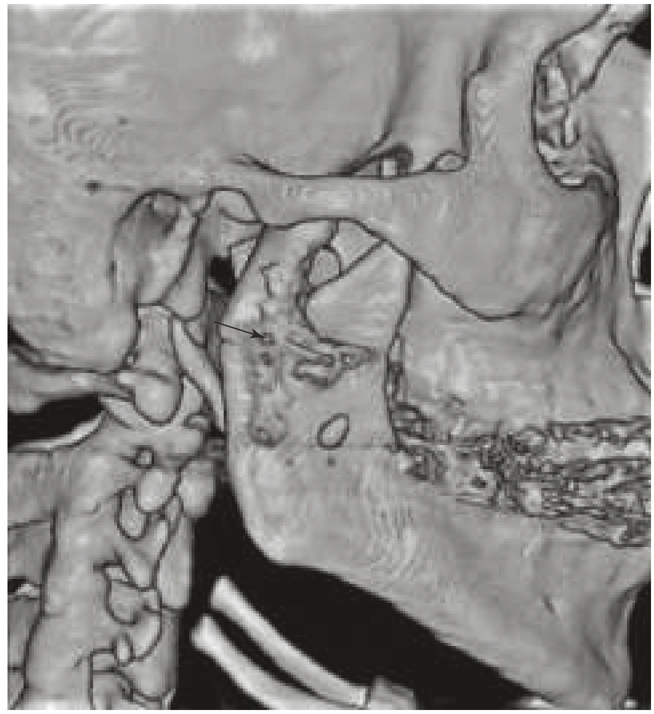


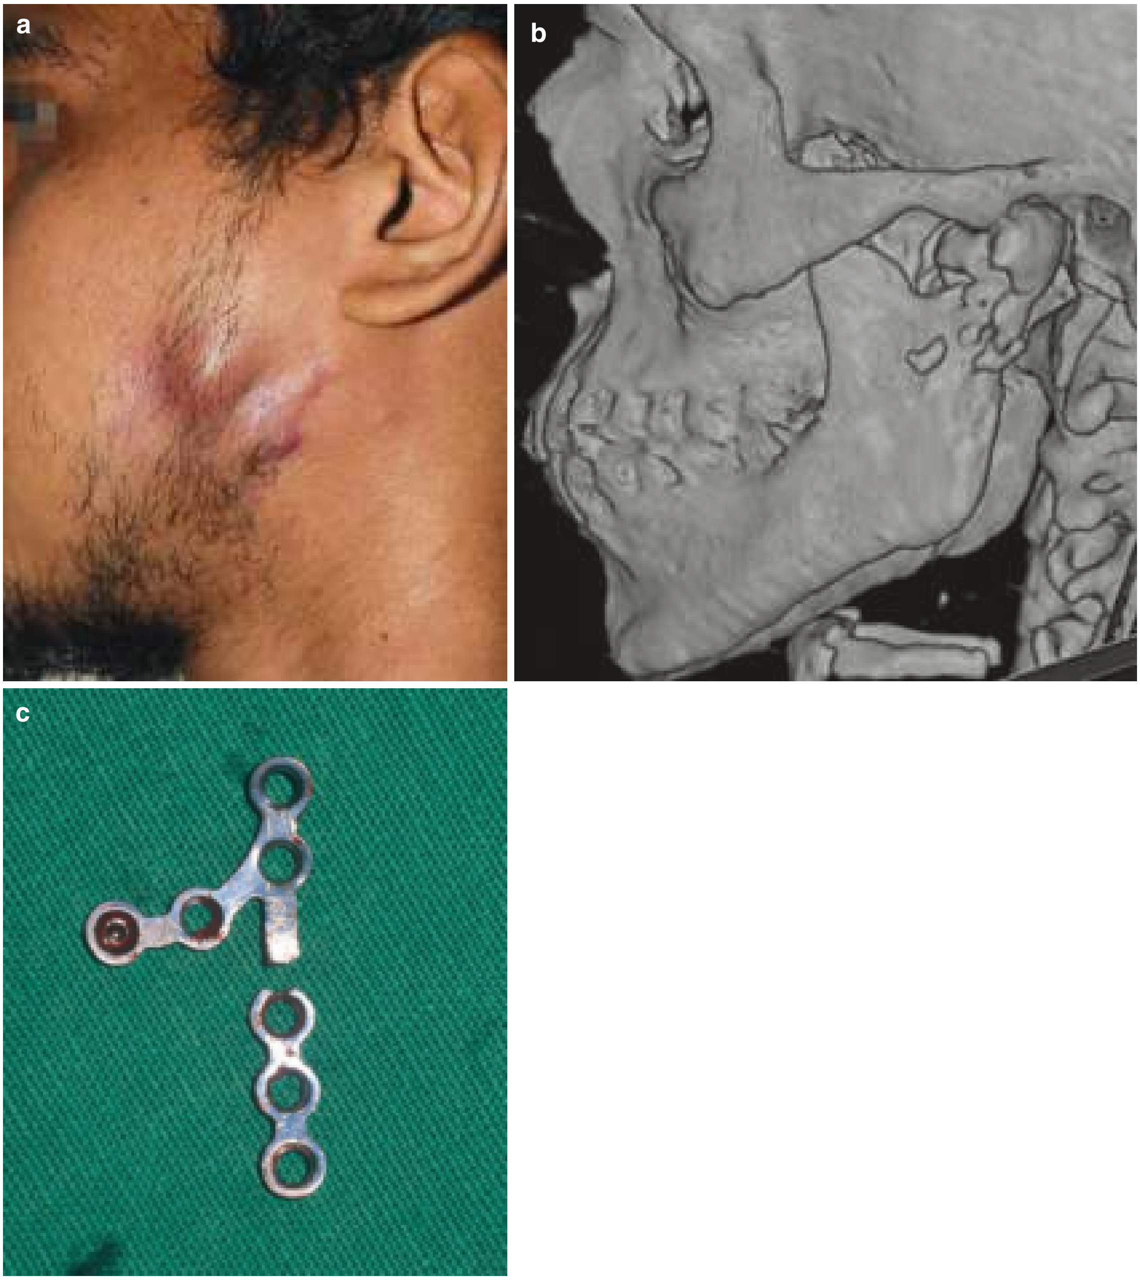
Case 5: Fig. 53.26 Shows improperly reduced fracture condyle which has been fixed in a dislocated position of the condyle-arrow points towards the plate fixed in wrong position

Table 53.1 Comparison of different fixation methods used for fractures of the mandibular condyle

Type of plate used for fixation	Advantage	Disadvantage
Single plate	• Easy to adapt and fix as placed along the long axis of the condyle.	• Does not neutralize the forces acting on the fracture ends. • Relatively heavier plate needed.
Two plates	• Neutralizes the tension and stress along the fracture. • Easy to triangulate. • Aids in reduction of fracture. • Suitable with multiple fractured fragments.	• May be difficult to fix two plates in a narrow neck of the condyle.
Lambda plate	• Single plate neutralizes the tension and stress as two lower limb follow the anterior and posterior border of the condyle. • Suitable in narrow neck of the condyle.	• Wider exposure is needed. • Junction of two lower and upper limb area of weakness prone for fracture. • Difficult to adapt as the stock plates may not be suited for all types of fractures.
Delta plate	• Single 3D plate neutralizes the tension and stress as two vertical struts follow the anterior and posterior border of the condyle. • Plates don't have an area of weakness.	• Wider exposure is needed. • Difficult to adapt. • At times upper horizontal strut may be wider than the bone available.

53.9 Complications of Condylar Fractures (Case 5: Fig. 53.26) (Case 6: Fig. 53.27a–c)

1. Malocclusion—Quite common with closed reduction if improperly treated. Also seen in patients with prolonged hospitalization [58].
2. Mandibular hypomobility—Prolonged immobilization and delayed physiotherapy, more common in children [59].
3. Ankylosis—seen more commonly in children due to meniscal disruption and lack of physiotherapy. This may be seen in comminuted fractures or disruption of articular disc.
4. Asymmetry—In children due to growth disturbances may result in facial asymmetry, occlusal cants, and reduced ramal height [60]. In adults asymmetry is due to deviation on opening of the mouth.
5. Dysfunctional degeneration—All injured joints can turn arthritic. Factors affecting these are age, long period of immobilization, capsular, or meniscal injury [61].
6. Condylar resorption—Occurs if the condyle becomes devoid of blood supply, but it is extremely rare.
7. Hardware failure—Such as fracture of plates can occur.
8. Infection—Postoperative infection.
9. Chronic pain seen in closed reduction.
10. Neurosensory disturbances—Seen following trauma or inappropriate surgical incisions.



Case 6: Fig. 53.27 (**a**) Chronic infection left side condyle region following reduction and fixation, (**b**) CT scan showed osteomyelitis like changes at left condyle (**c**) the fractured infected plate removed

Box 53.11. Recent Advances [49]

- Improvements in imaging (CT scan/MRI) have resulted in better visualization of fracture site and understanding of soft tissue injuries along with the fracture.
- Surgical approaches better understood, and their application is based on the site of condylar fracture.
- Importance of anatomic reduction which leads to early full range of function.
- Improvement in open or assisted internal fixation techniques.
- Ability to approach and manage intracapsular fractures.
- Need to manage soft tissue injury as and when need.
- There is an improvements and wide choice of fixation materials including resorbable materials.
- Early and effective postoperative rehabilitation.

53.10 Conclusion

There have been numerous controversies in management of condylar fractures. They have ranged from which classification to use, surgical approach, type of fixation, and outcome of the treatment. But till date even with all the advances available to us, we still cannot agree on the two schools of thought for management of condylar fracture that is closed or open. Danda et al. [38] concluded in their study that there was no difference in treatment outcome in both the groups. This can be debated as it is not possible to compare the two modalities of treatment in absolute terms. Although it is pointed out that there are better results in function with open reduction and fixation, there are inherent complications that are only seen in cases treated by open reduction [62] such as nerve injuries and scars.

In an alternative interpretation of evidence, Leon A Assael [63] opined that both open and closed reduction have a critical role in management of condylar fractures. Treatment outcome such as full pain free range of movement and good aesthetics is seen in both the groups. Malocclusion, functional deficit, and internal derangement are seen irrespective of line of treatment. Over the years, complications noted in open reduction have reduced with the better understanding and improvement of technique, but it can be burden on the patient. These complications can only be weighed against the functional advantage patient gets in open reduction and fixation. Treatment of a condylar fracture will entirely be dependent on multiple factors.

To conclude it can be safely stated that management of condylar fractures should be patient centric not entirely based on absolute indications mentioned by various authors. Generally, in children and dentulous adult patients, closed reduction is the choice of treatment, whereas open reduction and fixation would be the choice of treatment for the patients with multiple fractures of mandible, panfacial trauma, partially or totally edentulous jaws, and underlying medical conditions preventing maxillomandibular fixation. Finally, function should be considered as an important parameter while formulating a treatment plan along with the resources available and skill of the surgeon.

Intraoral Endoscopic Approach for Treatment of Condylar Fractures of the Mandible

54

Frank Wilde

54.1 Introduction

The literature is replete with techniques regarding the open reduction and fixation of the condylar fractures of the mandible. The extraoral approach is preferred by the majority of surgeons in comparison to the intraoral approach. Nevertheless, open reduction and internal fixation by an extraoral approach has the evident risk to cause transient or even permanent facial nerve injury [1–4], leads inevitably to a facial scar [1, 5], and can course salivary fistulas, sialoceles [1, 6], Frey syndrome, or disturbance of the great auricular nerve [1]. In contrast, an intraoral approach is minimizing these abovementioned risks and facial scars can be avoided in general [7, 8].

Silverman in 1925 was the first person to mention about the intraoral approach to condylar fractures [9]. However, at that time, the surgeons were facing several difficulties treating those fractures due to a lack of adequate instruments. Fritzemeier and Bechthold developed the 90-degree angular screwdriver, and it served as a milestone in the intraoral management of condylar neck fractures. In their study, there were 32 fractures of which 2 cases showed early failures. Other cases during follow-up showed minor deviation from axis, but there were no evident problems in the temporomandibular joint function [10].

Based thereupon, several authors were reporting about the use of an intraoral approach treating condylar fractures surgically. Forty-eight cases of displaced and shortened mandibular condyle fractures were treated by an intraoral approach and studied by Mokros and Erle in 1996. In 2/3 of the treated fractures, the reduction was successful, and no significant complications were noted in the intraoperative or postoperative period.

TMJ function was good in 90% of the patients, 43% were free of symptoms, and 47% had minor dysfunction. The authors came to the result that proper reduction of the bone fragments is most important for therapeutic success [11].

Schön et al. [8] compared in a study an intraoral endoscopy-assisted approach with an extraoral approach for the treatment of condylar fractures. A reduced risk of facial nerve damage and no visible scars were the major conclusion of the study, and they also opined that intraoral endoscopic approach is a reliable technique for treating condylar fractures [8]. Veras et al. [12] were looking in their study on 25 patients with condylar fractures which were treated surgically by an intraoral approach. The mean mouth opening postoperatively was 4.8 cm. Patients postoperatively did not have clicking of the joint, facial nerve weakness, or pain of the muscles or the joint. They opined that intraoral reduction allowed the anatomic ramus height to be restored and that the functional results were acceptable [12].

Other authors like Jensen et al. [13] or Schneider et al. [14] were not so enthusiastic about the outcome of surgical-treated condylar fractures employing an intraoral approach [13, 14]. Jensen et al. in 2006 stressed on the fact that intraoral approach for the condylar fractures is very technically demanding and there is a chance of getting postoperative complications [13]. Schneider et al. [14] compared in a retrospective study 21 fractures which were treated with an intraoral approach with 24 fractures which were reduced by an extraoral perimandibular approach. In their study, the cases treated by intraoral approach showed suboptimal radiologic findings, and the patients' subjective feelings pointed to less favorable clinical results. They put forward the suggestion that fractures which do not require extensive manipulation and fractures which can be reduced exactly under a limited view only should be approached intraorally. For all other fractures, they recommend extraoral approaches [14].

54.2 Surgical Technique

From the authors' experience, fractures of the condylar base and the low and medial part of the condylar process can be addressed typically by the following described technique. Treating high condylar neck fractures is demanding and requires experience in using such an approach. Fractures of the condylar head or the transition zone between the neck and head cannot be reached with this approach, and extraoral incisions are still required when this kind of fractures is getting treated surgically.

For the below-described technique, a team of three surgeons (one leading surgeon and two assistant surgeons) are highly recommended.

54.2.1 Special Surgical Instruments and Devices

To facilitate open reduction and internal fixation of condylar fractures via an intraoral approach with predictable results, special equipment is mandatory.

The most important instruments are a 90° angled screwdriver and drill (Fig. 54.1a). The screwdriver should have necessarily a sliding screw-holder which facilitates to hold the screw and plate together (Fig. 54.1b), because positioning a plate with one hand and fixing the screw with the other hand is not appropriate and will lead to unsuccessful procedures. Self-retaining screwdriver-bits or even self-tapping screws should be avoided as well. The authors recommend a straight 90° angled screwdriver with the aforementioned sliding screw-holder and centric-positioned screwdriver-bits. Screwdrivers with eccentric-positioned screwdriver-bits show a lower height indeed. However, they will lead to tilting of the screwdriver during the activation of the device, which results in an inadequate transfer of the force and a frequent loosening of the screws from the bit.

Besides the 90° angled screwdriver and drill, extra-long instruments in the form of raspatories and reposition hooks have to be recommended insistently (Fig. 54.2). They simplify the manipulation and reduction of the fractured condyle with a good direct view into the operation site. Using standard configurated instruments results in less vision due to obstructing the view by the operator's hands.

An appropriate light-intensive headlight is necessary for proper illumination of the operation site (Fig. 54.3).

A 4 mm caliber 30° angled endoscope has to be recommended as well. In combination with a special retractor in which the endoscope can be inserted, a good visualization, especially of the posterior border of the ramus, can be achieved (Fig. 54.4).

In addition, a special retractor with a fiber-optic light guide which can be positioned buccally to the posterior border of the ramus enables good illumination of the surgical site (Fig. 54.5). Nevertheless, having an appropriate headlight, this instrument seems to be dispensable.

It can be further useful to fix the patient during surgery in a Mayfield head clamp as it is commonly used by the neurosurgeons. This allows traction with the retractors without any movement of the head.

Besides the described instruments, there are several special instruments and devices available on the market to facilitate open reduction and internal fixation using an intraoral approach. However, from the authors' experience, the aforementioned instruments and devices are the most helpful in treating condylar fractures by an intraoral approach.

Fig. 54.5 Retractor with a fiber-optic light guide (Karl Storz, Tuttlingen, Germany)

54.2.2 Surgical Access

By extending the standard vestibular incision in a superior direction along the ascending ramus, the ramus and the condyle region can be exposed intraorally (Fig. 54.6). The approach is following Obwegeser's principles of avoiding visible scars by extending his approach to the mandibular ramus for sagittal split osteotomy. During the incision of the oral mucosa, the anatomical course of the buccal nerve has to be taken into account. The dissection of the mucoperiosteal flap starts from the mandibular corpus in the region of the first molar to mandibular angle and far up to the condyle until the facture line can be explored. To get an appropriate

Fig. 54.6 Intraoral approach to the condyle region by extending the standard vestibular incision in a superior direction up the ascending ramus

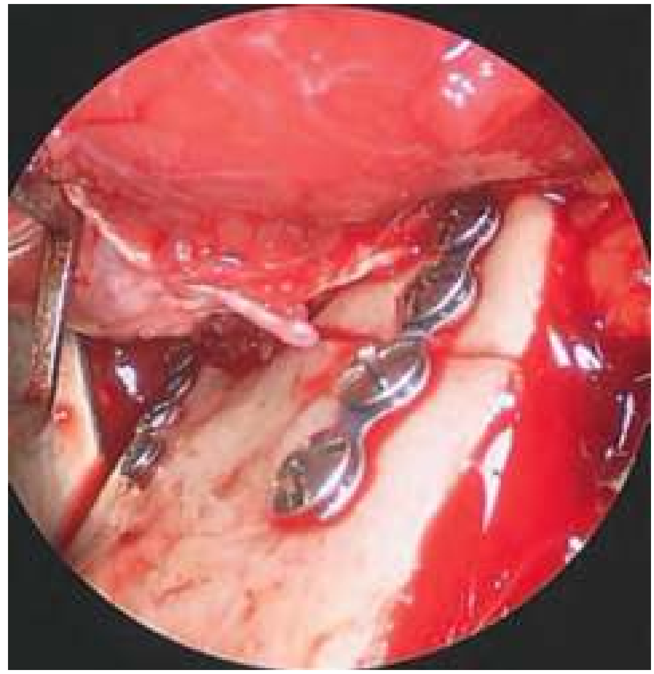

Fig. 54.7 After temporary osteotomy and re-fixation of the coronoid process to get better access for repositioning of medial displaced condyle

visualization of the condylar neck region, the mucosa including the fibers of the temporal muscle had to striped from the coronoid process up to or even higher than the mandibular notch. During dissecting the posterior border of the mandibular ramus, the retromandibular vein has to be taken under consideration. Coagulation in this region has to be done carefully, due to the anatomical proximity to the facial nerve which is running laterally in the parotid gland. This is the region where the facial nerve may be damaged during the procedure. In addition to coagulation, vigorous traction can damage the facial nerve in this location as well.

54.2.3 Surgical Procedure

After dissection to get sufficient access to the condylar neck region, the displaced condyle has to be identified. The best instrument for this is the extra-long raspatorium depicted in Fig. 54.2. During this procedure, the ramus has to be distracted. This can be performed by pulling the mandible caudally by hand. Another option is to fix one mini-screw in the mandibular angle to twist a wire around, which is diverted out of the skin in the mandibular angle region by a stab incision. However, this leads to a small extraoral scar.

For this maneuver, a full relaxation of the patient by the anesthesiologist is recommended. Due to the very low risk for facial nerve damage employing this approach, this can be done without increasing this risk.

For medial displaced condyles in high condylar neck fractures, it is sometimes helpful to perform a temporary osteotomy of the coronoid process to get better access for repositioning. A later re-fixation of the osteomized coronoid process by a miniplate is in theory not needed but recommended by the authors (Fig. 54.7).

Once the dislocated fragment is identified, it has to be repositioned anatomically. MMF cannot be recommended in all cases. In some cases, it can be helpful to get a stable reduction during osteosynthesis; however, in most cases, MMF is not very helpful. This decision has to be made individually case by case.

In most cases, the reposition of the proximal fragment is not stable from the beginning (Fig. 54.8). Therefore, the authors recommend to drill the first screw hole in the condyle fragment close to the fracture line in the region of the sigmoid notch. A four- or five-hole 1.0 mm up to 1.2-mm-thick miniplate is fixed in this hole with a 5- to 6-mm-long screw with a diameter of 2.0 mm. The screw should not be tightened completely. Then the reduction of condyle fragment

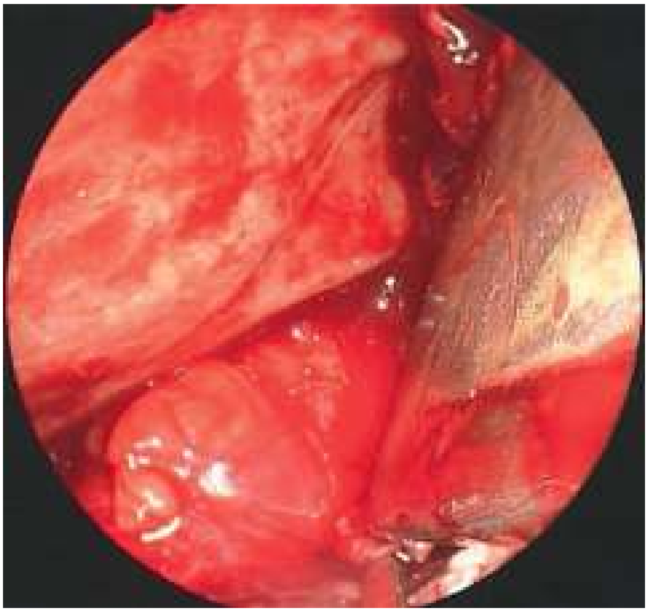

Fig. 54.8 Endoscopic view after repositioning of a condylar neck fracture

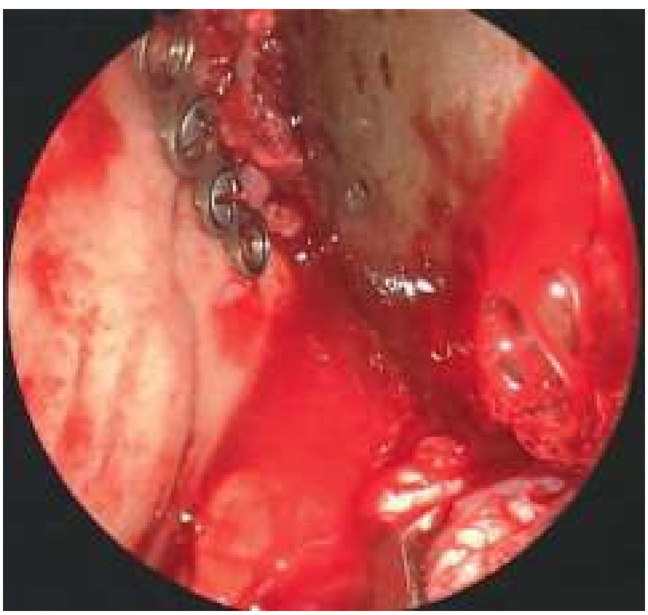

Fig. 54.9 Endoscopic view after fixation of a four-hole miniplate close to the sigmoid notch with two screws adjacent to the fracture line

can be achieved by pulling on the miniplate with one of the extra-long reposition hooks. By visual control of the repositioned fragment, the miniplate should now be fixed in the ramus part of the fracture close to the sigmoid notch by eccentric drilling of the screw hole for fracture line compression during screw insertion. After fixing the second screw, the first screw has to be tightened completely (Fig. 54.9).

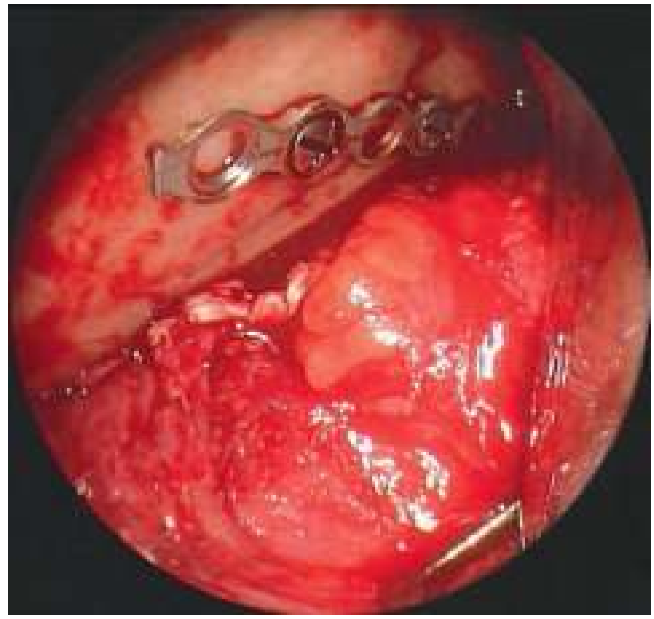

Fig. 54.10 Endoscopic view after fixation of a five-hole miniplate at posterior border with two screws adjacent to the fracture line

Once this is facilitated, often a small gap and flaring can be identified at the posterior border of the condylar neck. To close this gap, a second four- to five-hole miniplate has to be fixed at the posterior border of the condylar neck. Here also the hole has to be drilled in the condyle fragment close to the fracture line. First, the plate has to be fixed in this hole and should be aligned along the posterior border of the condylar neck respectively the ramus. Again, the screw should not be tightened completely at this stage. After exact anatomical reposition of the condyle, the next screw is now drilled for compression osteosynthesis in the ramus part of the ramus close the fracture line and immediately fixed with the fourth screw (Fig. 54.10). The third screw is then tightened completely to stabilize the fracture. After attaining control of the anatomical correct reposition with the endoscope or in low condylar neck fractures even with a simple dental mirror, the other screw holes in both plates are drilled and fixed, starting with the plate at the posterior border and ending with plate close to the sigmoid notch. Figure 54.11 shows the final endoscopic view with the two plates fixed. Figure 54.12 is illustrating the recommended sequencing of plate and screw positioning to facilitate open reduction and internal fixation via an intraoral approach using two miniplates.

In addition, the authors recommend intraoperative imaging with a 3D C-arm device at the end of the procedure when available (Fig. 54.13). This allows the intraoperative radiologic control and documentation of the reduced fracture and of the position of the plates in a multiplanar view and enables an immediate intraoperative correction when the result of the

Fig. 54.12 Recommended sequencing of plate and screw positioning to facilitate open reduction and internal fixation via an intraoral approach using two miniplates

procedure is not satisfactory. This reduces the risk for revision surgeries considerably [15, 16].

When the result is satisfactory, the intraoral mucosa has to be closed in the standard way like every intraoral incision. Even when the fracture is reduced and stabilized with success, the authors still recommend a light MMF with elastics strained over two or four MMF screws or arch bars for approximately 1 week for slight immobilization and guidance into the proper occlusion. In case of a postoperative insufficient occlusion, a prolonged functional treatment as in nonsurgical treated condylar fractures with elastics or an orthodontic device like an activator or bionator has to be recommended.

54.2.4 Osteosynthesis Material

As mentioned before, the author is recommending the usage of two miniplates. The plate at the posterior border is responsible for the stability primarily, whereas the plate in the region of the sigmoid notch prevents flaring of the distal fragment during function additionally.

For osteosynthesis, 1.0-mm up to 1.2-mm-thick miniplates can be recommended (Fig. 54.14). It can be favorable to use 1.2-mm-thick miniplates at the posterior border due to stability reasons. The screws should be usually 5–6 mm long with a diameter of 2.0 mm. Locking screws are not necessary and should never be used for the screw holes which are adjacent to the facture line. These holes should be drilled eccentric to achieve compression at the facture line. In modern osteosynthesis systems, locking and non-locking screws can be used with the same plates. Using such a system, it may be advantageous to use locking screws for the fracture-distant screw holes. Nevertheless, as mentioned before, locking screws are not needed in this technique.

Besides standard miniplates, there is the option for the use of so-called 3D plates or special designed condylar neck plates (Fig. 54.15). However, from the authors' experience, plating with two miniplates enables the aforementioned successive repositioning and fixation of the facture most easily and leads to sufficient stability.

There are new developments of anatomically preformed 3D condylar neck plates with integrated reposition wings for the posterior border and the sigmoid notch (Fig. 54.16). Whether these kinds of plates are beneficial or not has to be investigated in the future.

(**b**) Displaced right condylar neck fracture. (**c**) Condylar neck fracture after repositioning and fixation employing an intraoral approach

54.3 Complications

There is no much difference in complications by treating condylar factures via an intraoral approach in comparison to all other treatment options. Postoperative infection is the most common complication followed by malocclusion. Dysfunctional degeneration of the injured joint can lead to joint clicking, pain, reduced mouth opening, and mandibular deviation during opening and closing. Even severe arthritis or condylar resorption can occur up to the total destruction or loss of the joint. Hardware failure in form of plate fractures or loosening of screws can be seen occasionally as well.

In addition to the avoidance of any visible extraoral scar, the biggest advantage in comparison to all extraoral approaches for surgical treatment of condylar fractures is the very low complication rate concerning facial nerve injuries, salivary fistulas, sialoceles, Frey syndrome, or disturbance of the great auricular nerve.

54.4 Conclusion

The described intraoral approach for the treatment of condylar fractures is favorable for fractures of the condylar base and the condylar process. The biggest benefit and advantage in comparison to all extraoral approaches is the very low complication rate concerning facial nerve injuries and the avoidance of extraoral scars. A disadvantage is the need for special equipment to facilitate this technically demanding procedure with regular success (Table 54.1).

Table 54.1 Advantages and disadvantages of an intraoral approach for the treatment of condylar fractures

Advantages
• No visible scars
• Very low risk for facial nerve damaging
• Very low risk for salivary fistulas, sialoceles or Frey syndrome
• No risk for disturbance of the great auricular nerve
Disadvantages
• Need for special equipment
• Technically demanding
• Not suitable for condylar head fractures

54.5 Case Scenario

History: A 24-year-old female with history of a bicycle accident.

Clinical features: Malocclusion with lateral open bite left. Limited and painful mouth opening. Mobile mandible paramedian region left. Chin hematoma.

Diagnosis: Medial displaced condylar process fracture right and slightly displaced paramedian fracture left (Fig. 54.17a–b).

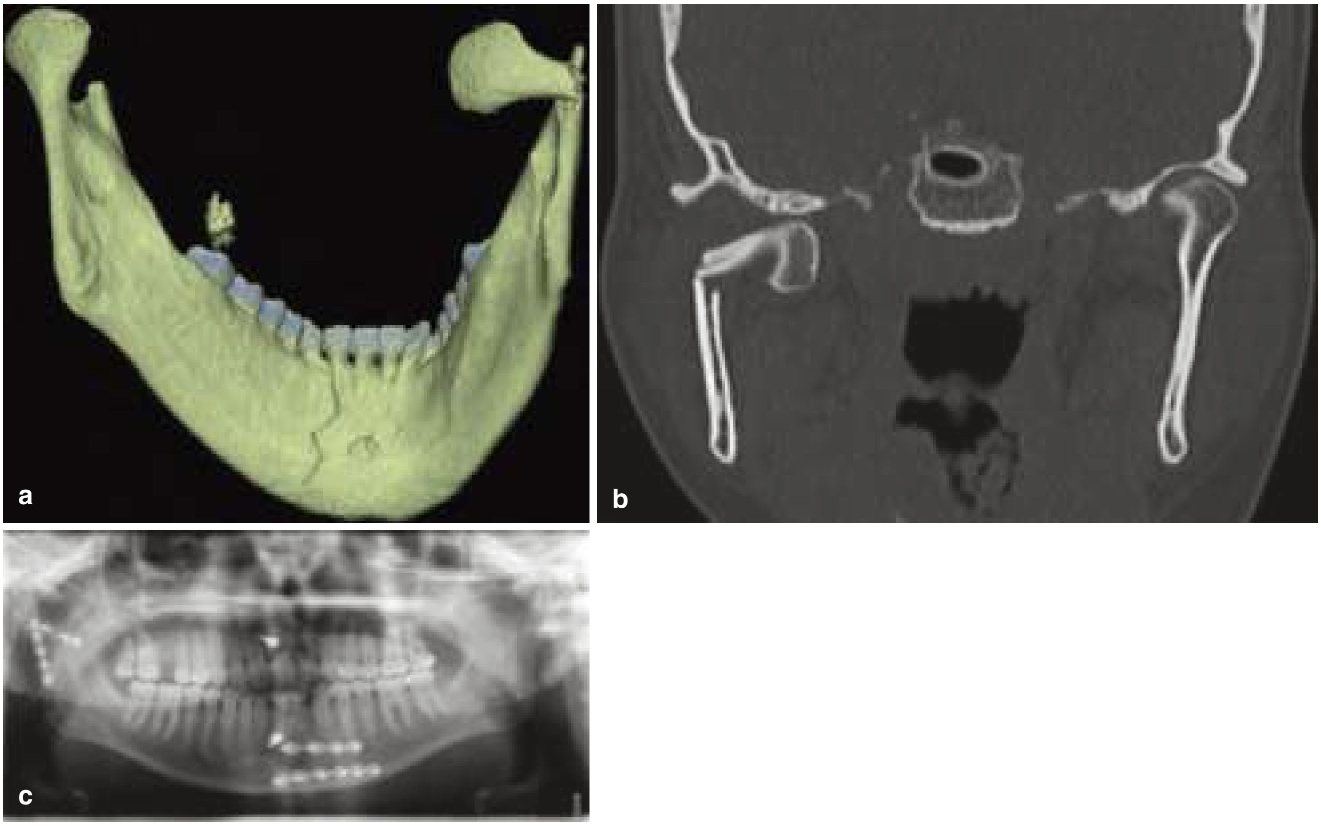

Fig. 54.17 (**a**) 3D reconstruction of the preoperative CT scan showing the medial displaced condylar process fracture right and slightly displaced paramedian fracture left. (**b**) Coronal view of the preoperative CT scan showing the medial out of the fossa displaced condylar process fracture right. (**c**) Postoperative panoramic X-ray showing well-sufficient reduced and with miniplates stabilized fractures paramedian left and at the condylar process right

Surgical plan: Open reduction and internal fixation of both fractures employing an intraoral approach. The paramedian fracture should be fixed first with two miniplates. A gap of the lingual cortex should be prevented by compression of the mandible in the posterior region and overbending the plates. The condylar neck fracture should be fixed second with two miniplates as well.

Postoperative findings: Sufficient reduced and stabilized fractures at the condylar process right and paramedian left (Fig. 54.17c). Proper occlusion and regular mouth opening 4 weeks after surgery without any deviation during function.

55 Maxillary Fractures

Oommen Aju Jacob and Akhilesh Prathap

55.1 Introduction

Complex midface trauma has challenged the diagnostic and operative skills of surgeons through the decades. Robert Marciani in his fifty year review article dated 1993, vividly described the challenges faced by early surgeons regarding the clinical and radiological diagnosis of mid face fractures and the compromised surgical results that may ensue [1].

Table 55.1 Milestones of maxillary fractures

Date	Author	Key finding
1822	Charles Fredrick Reiche	First treatise on maxillary fractures
1823	Carl van Graefe	Use of a head frame to treat a maxillary fracture
1901	René Le Fort	Paper on midfacial fracture patterns
1943	Crawford	Used a Halo frame which was secured directly to the skull using pins

55.1.1 History (Table 55.1)

In an area so anatomically complicated as the midface, the lines of fracture produced in the middle third are classified based upon the experimental studies of René Le Fort in 1901 [2]. The earliest known writings of maxillofacial fractures were recorded in the Edwin Smith papyrus in 1650 BC. Hippocrates who is often portrayed as the "Father of Medicine" described a myriad of facial injuries around 400 BC and his insight provided the basis for bandages and single jaw interdental wiring as methods of fixation and stabilization of facial fractures. Over the subsequent centuries, there appeared many techniques which in essence were variations of what Hippocrates had described. In the nineteenth century, Charles Fredrick Reiche provided the first detailed treatise on maxillary fractures [3]. It was also in the same century that Garretson and Blair advocated mandibular-maxillary fixation with the aid of splints to primarily treat maxillary fractures.

In 1901, a French surgeon René Le Fort published his classic paper on midfacial fracture patterns. He inflicted blunt facial trauma on cadavers, then subsequently removed the soft tissue and examined fracture patterns of the facial skeleton. This study has ever since been the basis for the description of maxillary fractures.

55.1.2 Surgical Anatomy/Osteology

The middle third of the facial skeleton is made up of the following bones (Fig. 55.1)

1. Two maxillae
2. Two zygomatic bones
3. Two zygomatic processes of the temporal bones
4. Two palatine bones
5. Two nasal bones
6. Two lacrimal bones
7. The vomer
8. The ethmoid and its attached conchae
9. Two inferior conchae
10. The pterygoid plates of the sphenoid

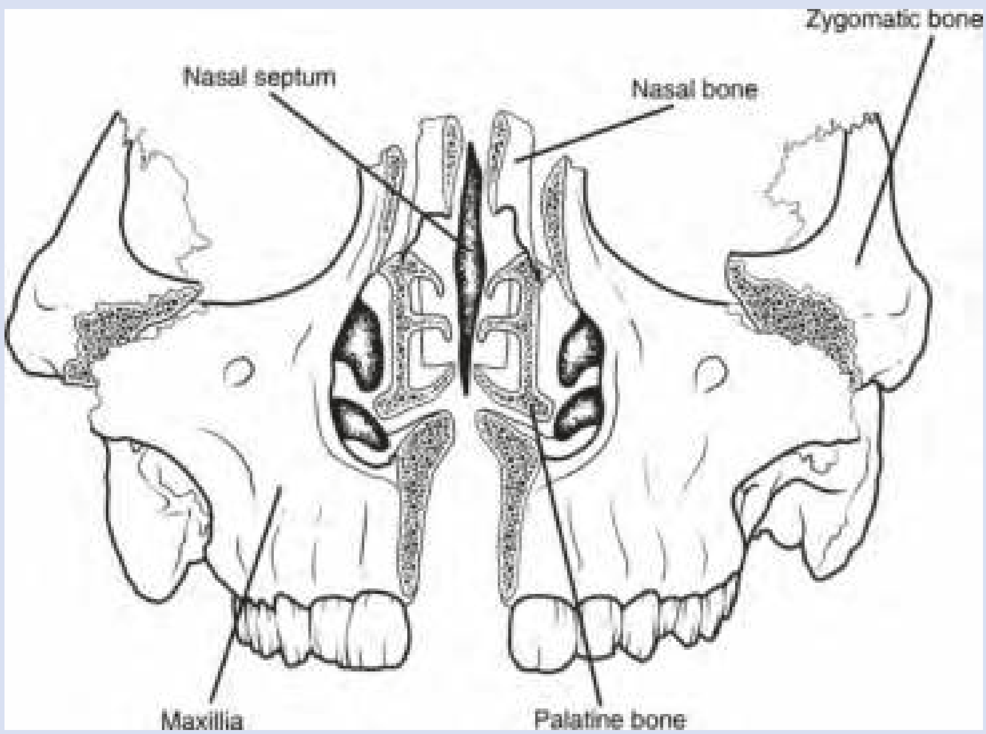

Fig. 55.1 Bones of the midface

The middle third of the face is made up of a number of bones which rarely fractures in isolation. The complex nature of the midface is such that it will withstand the forces of mastication from below and provide protection in certain areas for vital structures. The middle third of the facial skeleton consists of a series of bone struts (buttresses) passing upwards from the upper teeth to the bones of the skull [4] (Fig. 55.2).

The relative fragility of the midface skeleton makes it act as a cushion for trauma directed towards the cranium from an anterior or anterolateral direction. The facial skeleton can be designated by this famous figure, where the skull is similar to a helmet, the midface is similar to a matchbox (crumble zone) and the mandible is similar to a hockey stick (Fig. 55.3). The most common causes of facial fractures in the adult population are assaults and motor vehicle accidents [5].

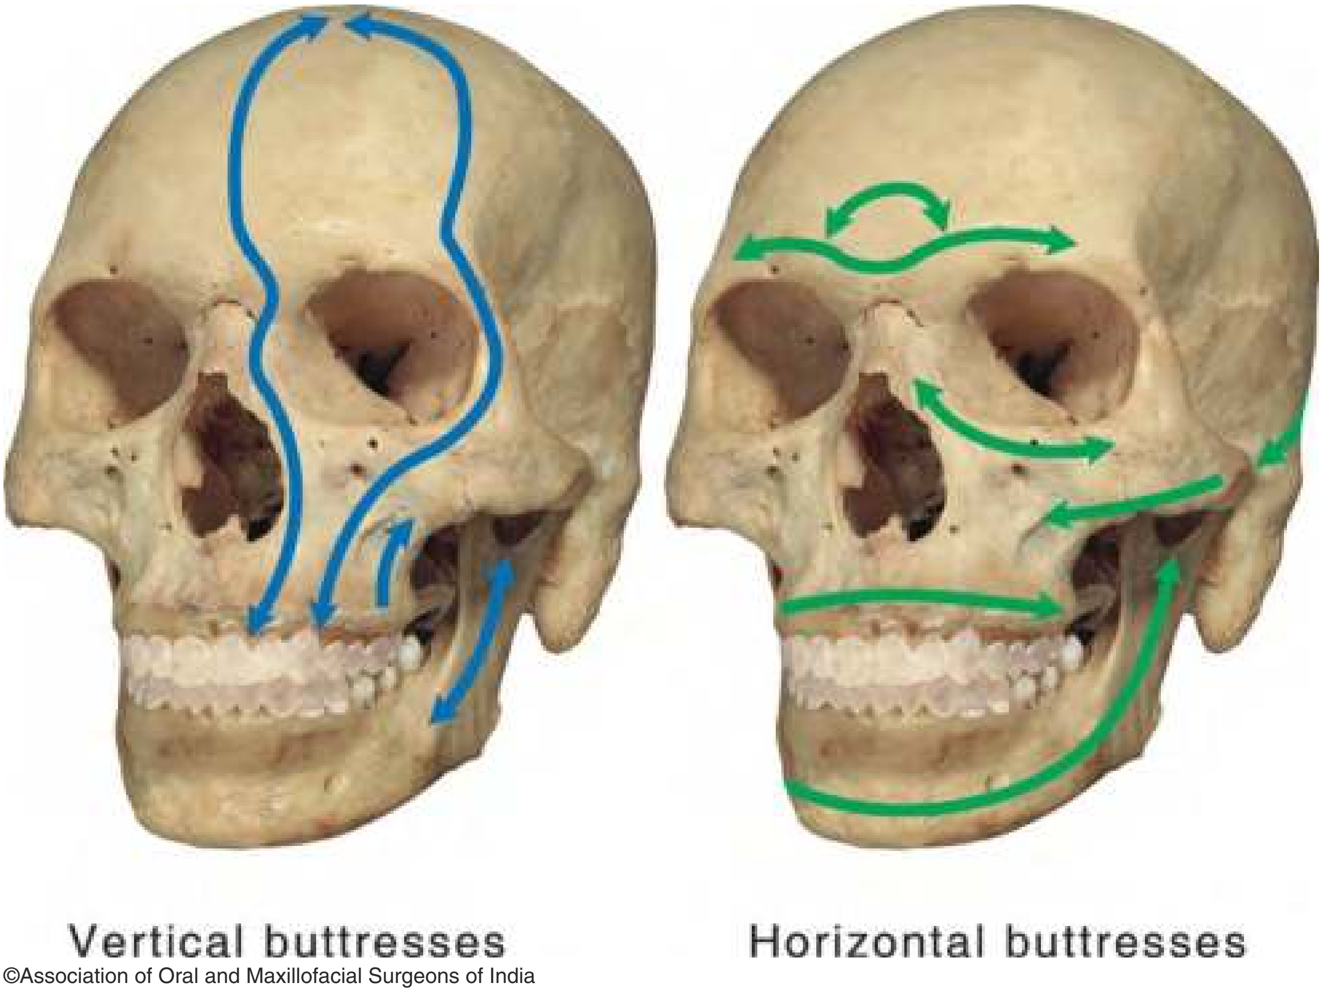

Fig. 55.2 Vertical and horizontal buttresses of the facial skeleton (Also refer Fig. 60.9 and Table 60.2)

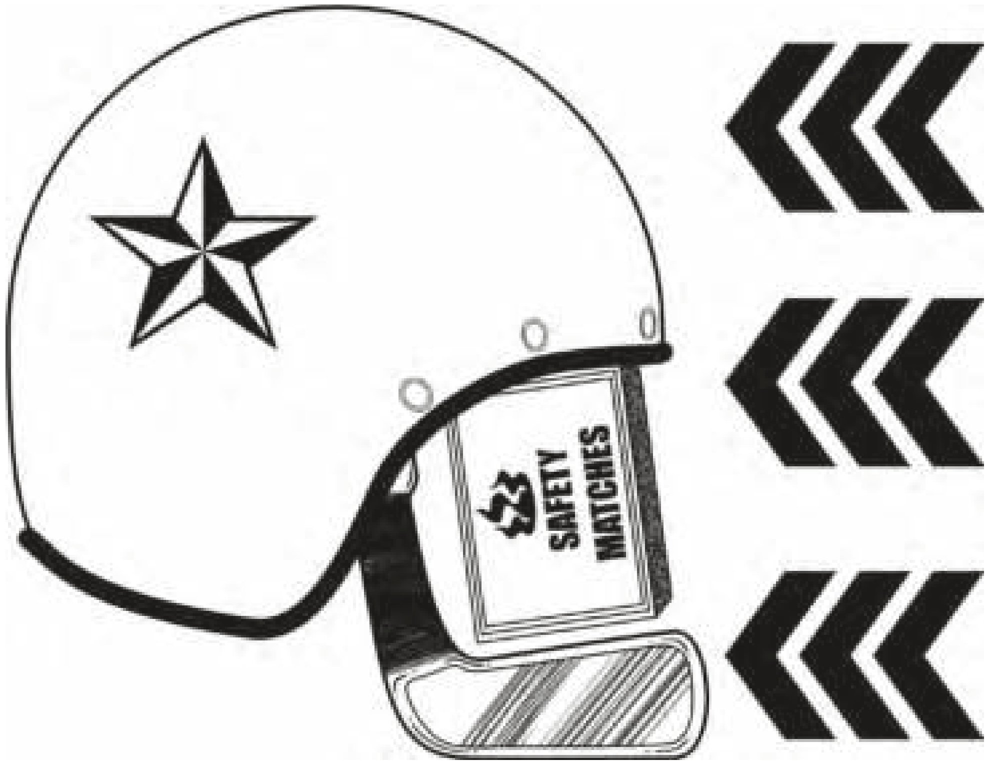
55.1.3 Applied Anatomy of the Midfacial Bones

The midface is composed of the nasal, zygoma, maxilla, ethmoid and its conchae, palatine, inferior concha and vomer which are collectively referred to as the middle third of the facial skeleton. The facial bones in isolation are comparatively fragile but gain strength and support as they articulate with each other. It is this strength that has often been described as the facial buttresses which Manson alluded to when describing the vertical and horizontal struts that support the facial skeleton [6]. The horizontal pillars are formed by the frontal bar (composed of the supraorbital rims and nasal process of the frontal bone), the zygomatic arch, the infraorbital rims and the nasal bridge and finally the alveolar process of the maxilla. The vertical pillars are the medial pillar formed by the piriform rims which continues superiorly as the frontal process of the maxilla. The zygomatic buttresses which continue superiorly with the lateral orbital rims form the lateral pillars, and the most caudal pillars are the pterygoid plates.

55.1.3.1 Maxilla

The maxilla consists of a central body and four processes, namely, the frontal, zygomatic, alveolar and palatine process. The body is hollowed out and contains the maxillary sinus. It is pyramidal shaped with the base being the medial surface facing the nasal cavity and the apex being elongated into the zygomatic process. It has an orbital or superior surface which forms the floor and rim of the orbit, a malar or anterolateral surface which forms part of the cheek and a posterolateral or infratemporal surface which contributes to the infratemporal fossa. The base is rimmed inferiorly by the alveolar process. The alveolar process houses the dental arch with the sockets varying in size according to the teeth. The palatine process is a horizontal process from the body to the alveolar process and medially articulates with the palatine process of the opposite maxilla, while posteriorly it articu-



©Association of Oral and Maxillofacial Surgeons of India

Fig. 55.3 Helmet, matchbox and hockey stick to illustrate relative bone strength (the matchbox is the crumble zone)

lates with the horizontal plate of the palatine bone. The zygomatic process is an extension of the anterolateral surface of the body which contributes to the zygomaticomaxillary suture. The frontal process projects upwards to articulate with the maxillary process of the frontal bone as well as the nasal bone anteriorly and the lacrimal bone posteriorly.

55.1.3.2 Vascular Supply and Innervation

The blood supply to the maxilla and the palatine bones is through the periosteum, the incisive artery and the greater and lesser palatine arteries. The internal maxillary artery lies posterior to the maxillae and the palatine bones and anterior to the pterygoid plates of sphenoid.

The maxillary nerve enters the caudal maxilla ventral to the orbit via the maxillary foramen and runs through the maxilla in the infraorbital canal giving off branches to supply the maxillary cheek and teeth. The nerve then exits the maxilla at the infraorbital foramen.

55.2 Classification

55.2.1 René Le Fort1901 [2]

Maxillary fractures were classified by René Le Fort based on his experiments on cadavers with low velocity unidirectional frontal trauma. Although the present-day maxillary fractures are caused due to high velocity multi directional trauma, the Le Fort classification is still widely followed due to its simplicity and the levels of anatomic differentiation it offers. Other authors have attempted classifications based on the anatomical sites and based on the involvement of the occlusion. Marciani modified the basic Le Fort classification by adding frontal bone and zygomatic fractures.

55.2.1.1 Le Fort I

Low Level Fracture/Guerin Fracture

The fracture line extends backwards from the lateral margin of the anterior nasal aperture below the zygomatic buttress to cross the lower third of the pterygoid laminae. The fracture also passes along the lateral wall of the nose and the lower third of the septum to join the lateral fracture behind the tuberosity (Fig. 55.4a–c).

55.2.1.2 Le Fort II

Pyramidal or Sub-zygomatic Fracture

This fracture runs from the thin middle area of the nasal bones down either side, crossing the frontal processes of maxillae into the medial wall of each orbit; the fracture line crosses the lacrimal bone behind the lacrimal sac before turning forwards to cross the infraorbital margins slightly medial to or through the infraorbital foramen. The fracture now extends downwards and backwards across the lateral wall of the antrum below the zygomaticomaxillary suture and divides the pterygoid laminae about half way up.

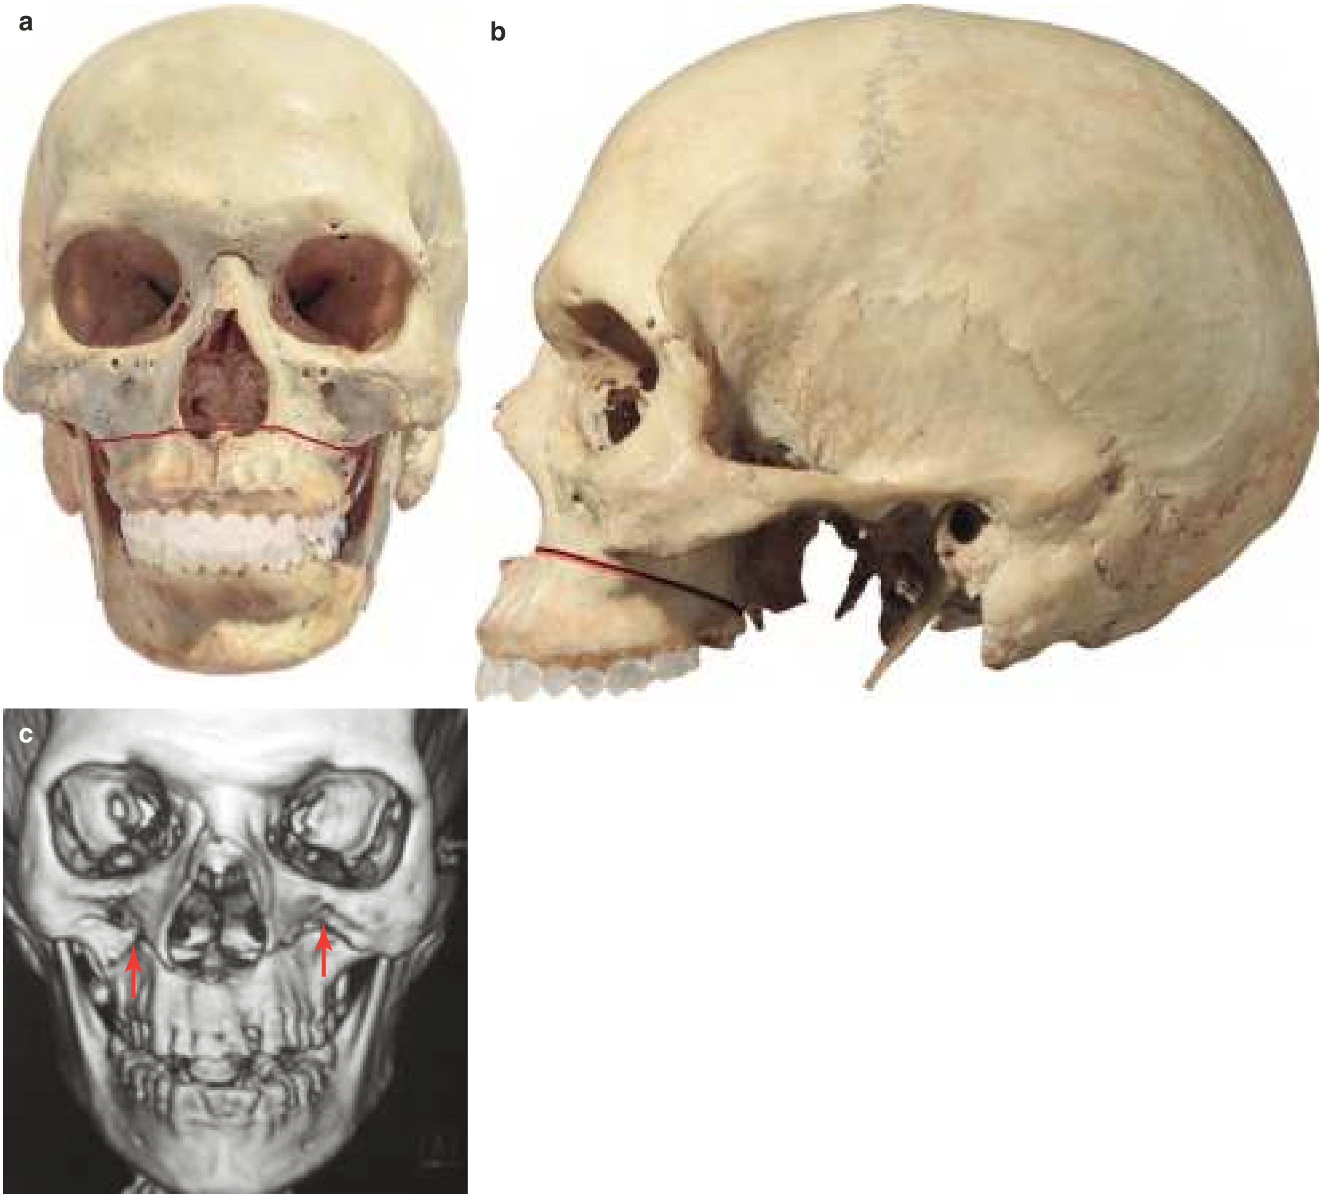


Fig. 55.4 (**a**, **b**) Le Fort I fracture lines. (**c**) CT of Le Fort I fracture

Separation of the block from the base of the skull is completed via the nasal septum and may involve the floor of the anterior cranial fossa (Fig. 55.5a–d).

55.2.1.3 Le Fort III

Transverse or Supra-zygomatic Fracture

The fracture runs from near the frontonasal suture transversely backwards and parallel with the base of the skull and involves the full depth of the ethmoid bone including the cribriform plate. Within the orbit the fracture passes below the optic foramen into the posterior limit of the inferior orbital fissure. From the base of the inferior orbital fissure, the fracture line extends in two directions: backwards across the pterygomaxillary fissure to fracture the roots of the pterygoid laminae and laterally across the lateral wall of the orbit separating the zygomatic bone from the frontal bone. In this way the entire middle third of the facial skeleton gets separated from the cranial base (Fig. 55.6a–c).

Le Fort classification does not take into consideration:

- Dentoalveolar fractures
- Palatal fractures
- Bone loss

7. Extended Le Fort fractures	

55.2.3 Rowe and Williams's Classification (1985) [2] (Table 55.3)

Addenda

(i) These fractures may occur unilaterally or be associated independently with a fracture of the zygomatic complex.

(ii) There may be a midline separation of the maxillae and/or extension of the fracture pattern into the frontal or temporal bones.

55.2.4 Marciani (1993: Modification of Le Fort Fractures) [1]

Fractures involving the cranial base and other midface fracture configurations, including severely comminuted segments of the facial skeleton, were not classifiable by the

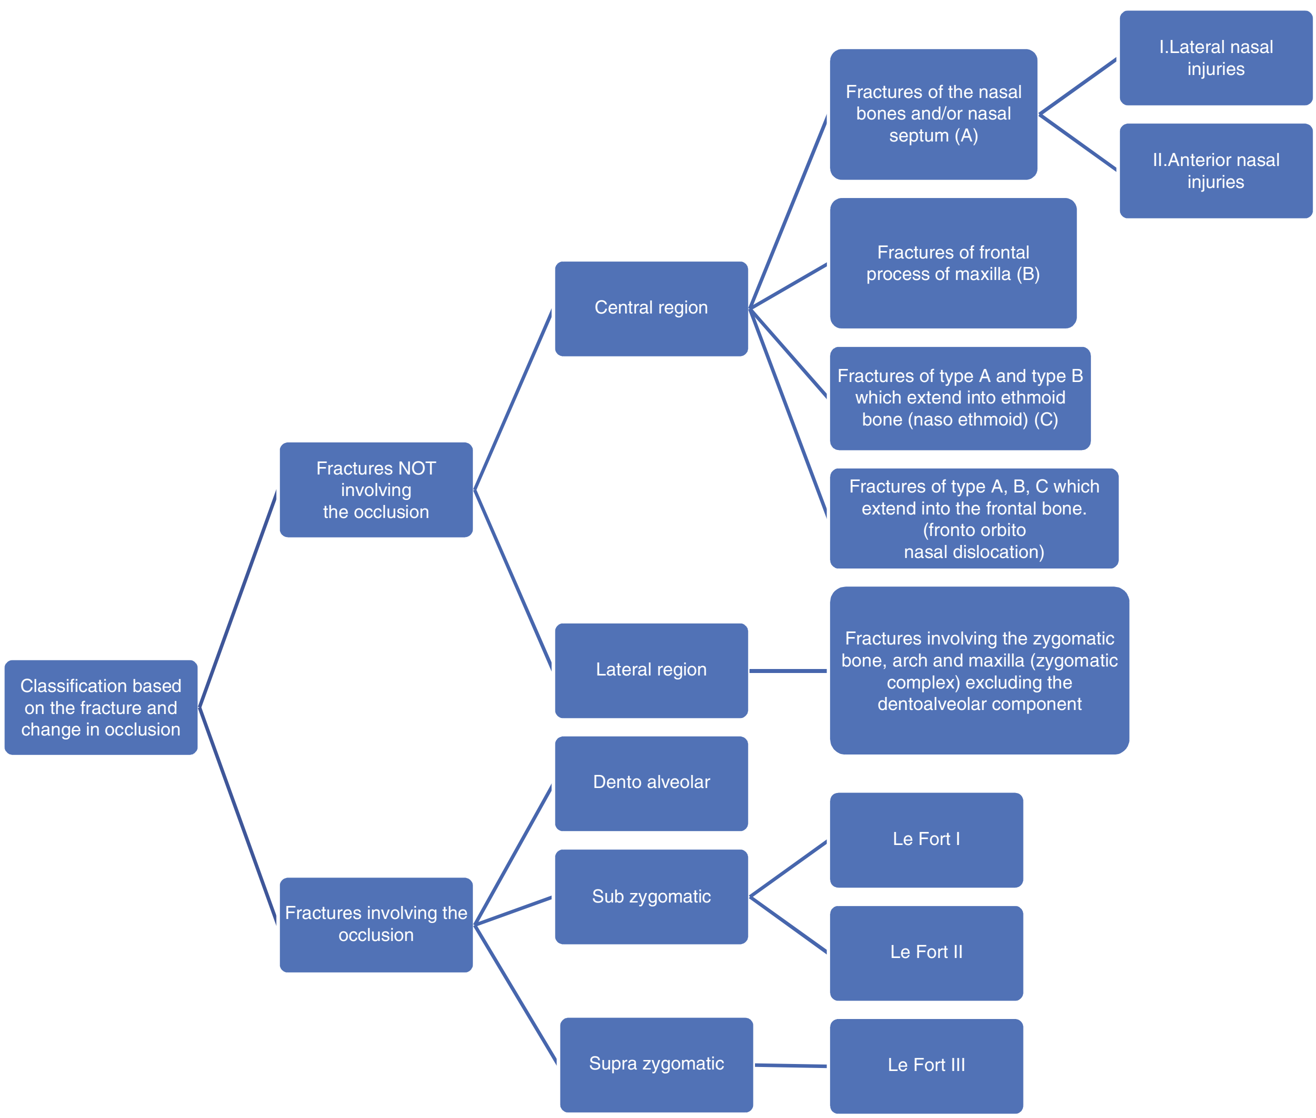

Table 55.3 Rowe and Williams's classification

traditional Le Fort scheme. Hence Marciani proposed a more precise system of describing fracture patterns to define the fracture configuration, establish an accurate diagnosis and to determine potential surgical approaches (Table 55.4).

Table 55.4 Marciani's modification of Le Fort fracture classification

Marciani (1993-modification of Le Fort fractures)	Le Fort I—Low maxillary fracture	Ia—Low maxillary fracture/ multiple segments
	Le Fort II—Pyramidal fractures	IIa—Pyramidal and nasal fracture
		IIb—Pyramidal and NOE fracture
	Le Fort III—Craniofacial dysjunction	III a—craniofacial dysjunction and nasal fracture
		III b—craniofacial dysjunction and NOE
	Lefort IV—Le Fort II or III and cranial base fracture	IV a—supraorbital rim fracture
		IV b—anterior cranial fossa and supraorbital rim fracture
		IV c—anterior cranial fossa and orbital wall fracture

55.2.5 Palatal Fractures Classification: Hendrickson's Classification (1998) [7] (Figs. 55.7, 55.8, and 55.9; Table 55.5)

55.3 Clinical Features (Box 55.1)

55.3.1 Le Fort I Fractures

Gross facial swelling or facial disfigurement is generally not a feature of Le Fort I fractures, but oedema around the upper lip may occur. Soft tissue injury along the upper lip along with tearing of gingivae may occur due to the causative impact. There can be mobility of the upper dentoalveolus when digital pressure is applied. Mobility of the maxilla at the Le Fort I level must be differentiated from extended maxillary dentoalveolar fracture. Malocclusion may occur if the fracture is displaced or impacted. Dorsal and caudal pull of the medial pterygoid muscles can contribute to the posterior displacement of the maxilla and the resultant anterior open bite (Fig. 55.10a, b). Bilateral epistaxis is rare although emphysema may occur if the patient blows his nose. Ecchymosis in the upper buccal sulcus is a frequent finding. Percussion of the maxillary teeth produces a dull cracked cup sound. In case of inferiorly displaced Le Fort I fractures, the patient may have to keep the mouth open to accommodate the increased vertical dimension. Due to the extreme downward displacement of the maxilla, the nasal base is lost, leading to stretching of the soft tissues of that area, which makes it possible to see directly into the nares.

The posteriorly impacted Le Fort I fracture may result in an anterior open bite and in these cases the maxilla may be immobile. Usually the impacted maxilla can be mobilized by grasping the maxillary teeth and applying a firm anterior pull. A grate may be felt due to the movement between the fractured segments. In posteriorly impacted fractures, there may be damage to the cusps of maxillary teeth usually in the premolar region, caused by the upward impact of the mandibular teeth at the time of the trauma. The complete Le Fort I fracture may be associated with a split along the median palatal suture. Sometimes more than one fracture line may be present in the palate, so that either one or both fragments may be mobile (Fig. 55.11a–c).

55.3.2 Le Fort II Fractures

Marked facial disfigurement resulting from circumorbital ecchymosis and gross oedema can be a feature of Le Fort II fractures. Frequently the patient will not be able to open

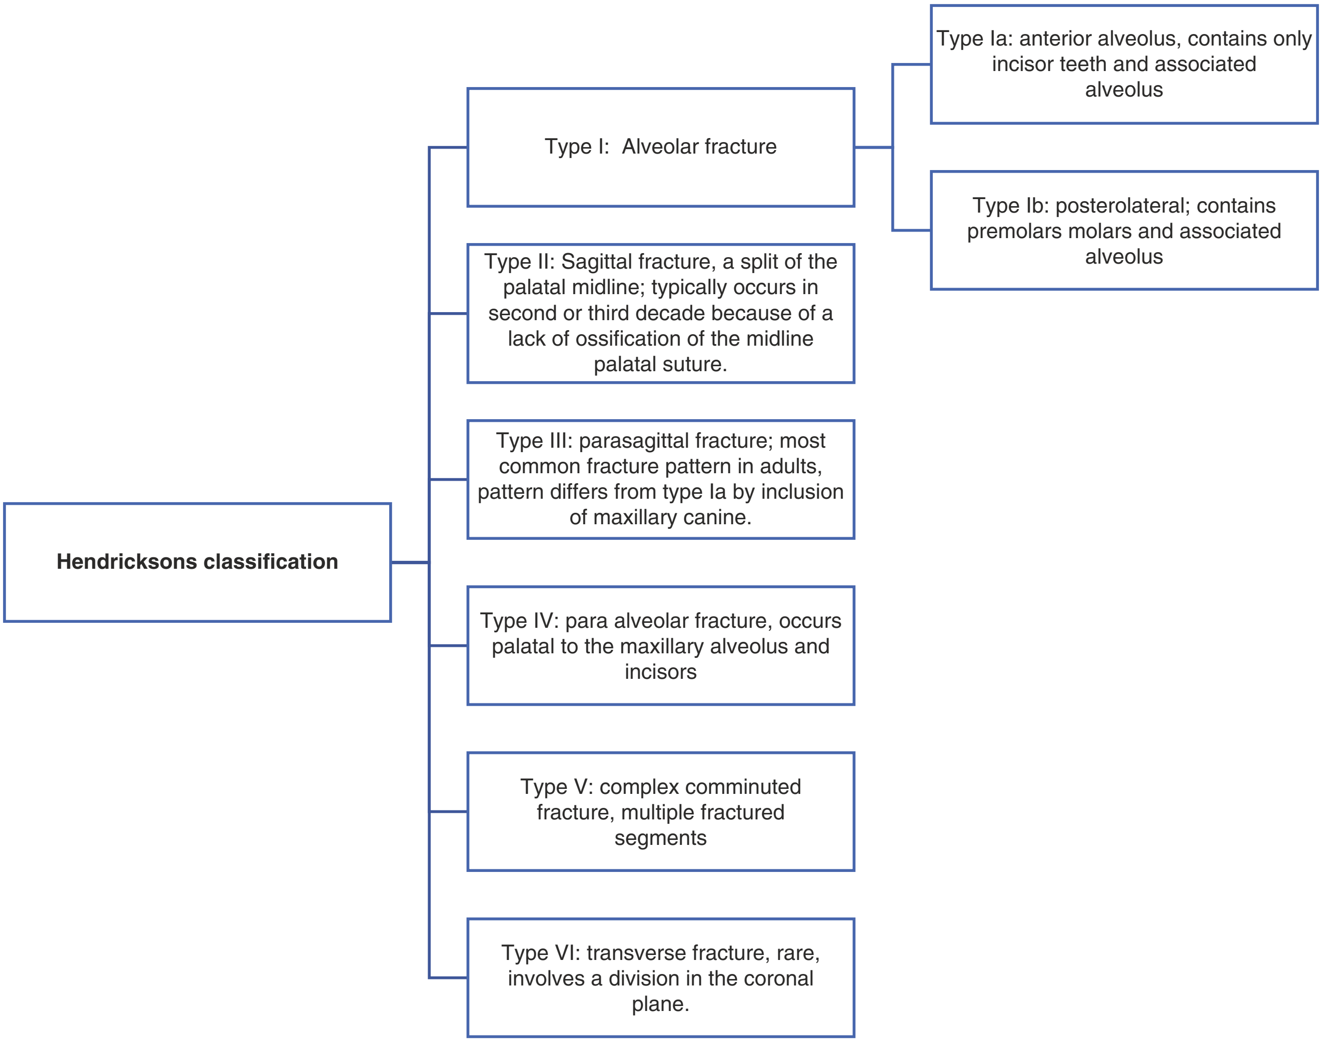

Table 55.5 Hendrickson's classification: of Palate fractures

Box 55.1 Clinical features of Le Fort fractures

Clinical features	Le Fort I	Le Fort II	Le Fort III
Intraoral	• Floating maxilla • Impacted or telescopic fracture • Anterior open bite • Deranged occlusion • Guerin's sign • Palatal fracture in some cases	• Deranged occlusion • Posterior gagging of occlusion • Possible airway obstruction	• Deranged occlusion • Posterior gagging of occlusion • Possible airway obstruction
Extraoral	• Mild swelling and oedema of midface and upper lip • Epistaxis in some cases • Increased visibility of anterior nares	• Moon face appearance • Peri-orbital oedema • Circumorbital ecchymosis • Subconjunctival haemorrhage • Infraorbital step deformity • Altered sensation of cheek • CSF rhinorrhea • Diplopia	• Separation at FZ suture • CSF rhinorrhea • Hooding of eyes • Anti-mongoloid slant • Dish face deformity

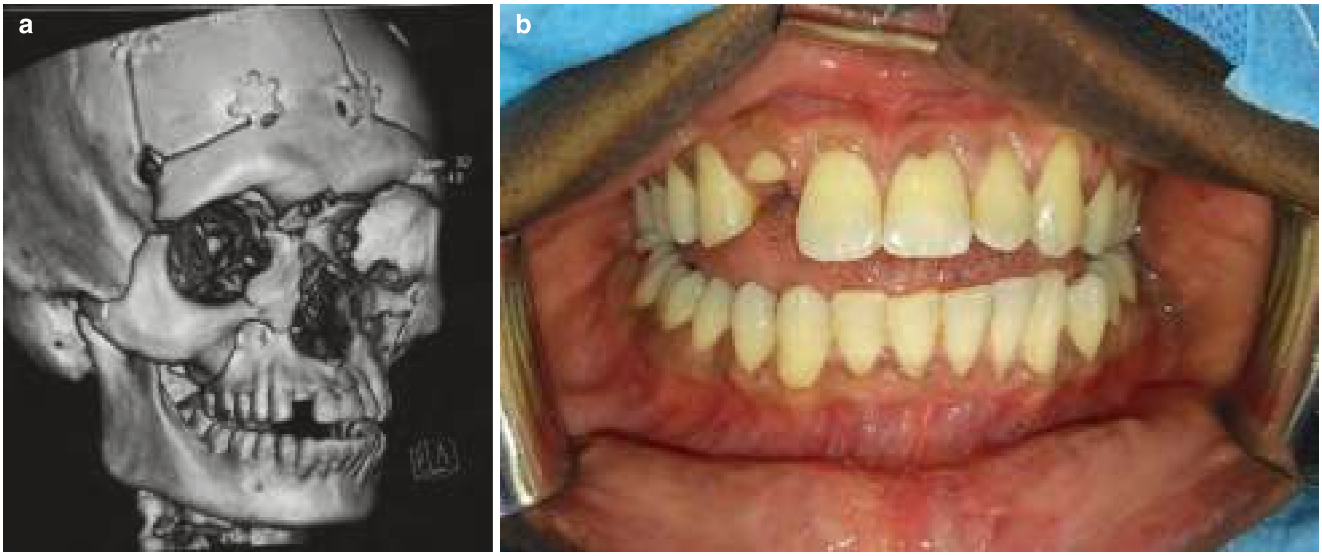

Fig. 55.10 (**a**, **b**) A posteriorly telescoped Le Fort I fracture maxilla clinically manifesting as anterior open bite

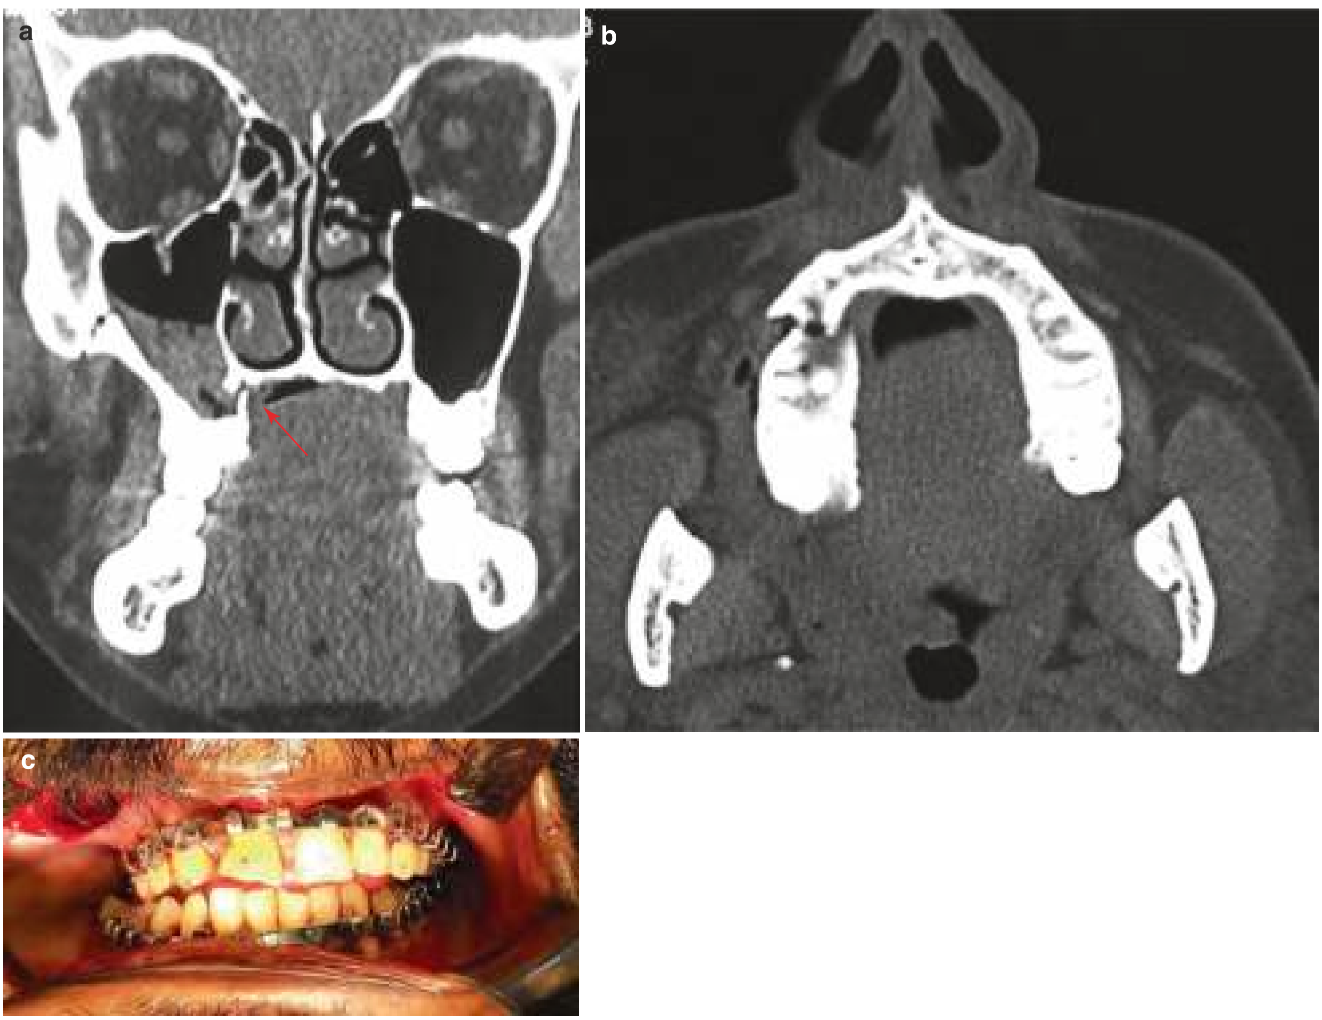

Fig. 55.11 CT images (**a**, **b**) showing a right zygomatic complex fracture associated with a Hendrickson's type B fracture where the right posterior alveolar and palatal segment was displaced palatally and extruded, causing the occlusal discrepancy (crossbite) as seen in **c**

his eyelids to allow an ocular examination. Subconjunctival haemorrhage may be present, the posterior limit of which cannot be identified. Bilateral peri-orbital oedema and circumorbital ecchymosis (described as circumorbital as it follows the shape of the orbicularis oculi muscle) are described as racoon eyes or panda facies. There can be severe oedema of the face which is sometimes described as moon facies. Enophthalmos in case of orbital floor fractures may go undetected due to oedema. Considerable lengthening of face with posterior gagging of teeth can also occur. Bilateral epistaxis is common, and CSF leak may be present. The loss of maxillary prominence may result in a dish face appearance. If the fracture line passes through the infraorbital canal there can be associated paresthesia in the infraorbital nerve region. While clinically mobilizing the maxilla in a Le Fort II fracture, transmitted mobility may be felt at the infraorbital rim and the frontonasal suture. Figure 55.12 shows a CT image where Le Fort II and III lines are seen

55.3.3 Le Fort III Fractures (Also see Fig. 49.5)

This fracture is clinically similar to the Le Fort II fracture but can demonstrate a more serious condition. Bilateral ecchymosis with circumorbital oedema may close the eyes completely. As in Le Fort II, the posterior limit of the subconjunctival haemorrhage cannot be seen. The lengthening of the face occurs due to the loss of bony fixation to the base of the skull. The flattening of the face from the disrupted zygomatic bones is usually masked by the gross oedema. The fracture passes above the Whitnall's tubercle and so the support by Lockwoods, suspensory ligament is lost. This results in hooding of upper eyelid which becomes obvious when the oedema subsides. Gagging of occlusion and shift of the maxillary midline may occur. Gross posterior displacement of the maxilla can result in the soft palate touching the posterior part of the tongue causing airway and speech impairment. As with other maxillary fractures, percussion of teeth might produce a cracked cup sound. .

The clinical differentiation between Le Fort II and Le Fort III fractures can be assessed by palpating for step deformity in the infraorbital rim in the former.

Fig. 55.12 CT image showing Le Fort I and II fractures. Note that maxilla is rotated to the right side with canting on the left side.

55.3.4 Unusual Fracture Patterns

The Le Fort fractures may manifest without the classic fracture patterns as described above. An unilateral fracture at Le Fort I level may occur (identified through imaging) which warrants no intervention unless accompanied by a palatal fracture causing occlusal derangement and/or mobility. Such a unilateral fracture pattern can cause unilateral gagging causing open bite on the contralateral side

The clinician must be aware of the two types of Le Fort I fractures, the mobile and impacted variants; lack of mobility should not be presumed as absence of fracture.

55.4 Radiographic Examination

It is difficult to diagnose fractures of the middle third of the face with plain films and CT scans have now largely replaced radiographs.

The commonly used radiographs for identifying maxillary fractures are occipitomental view (OMV) 10° and 30° and paranasal sinus view 37° (PNS -Waters view).

While assessing maxillary fractures with these radiographs, Mcgregor-Campbell and Trapnell's lines and Dolan's lines (elephant of Rogers) may be kept in mind [8].

McGregor-Campbell's lines:

These lines were described by McGregor and Campbell for ease of searching on an occipitomental view 10-degree frontal projection.

1. First line across the zygomaticofrontal, the superior margin of the orbit and the frontal sinus
2. Second line across the zygomatic arch, zygomatic body, inferior orbital margin and nasal bone

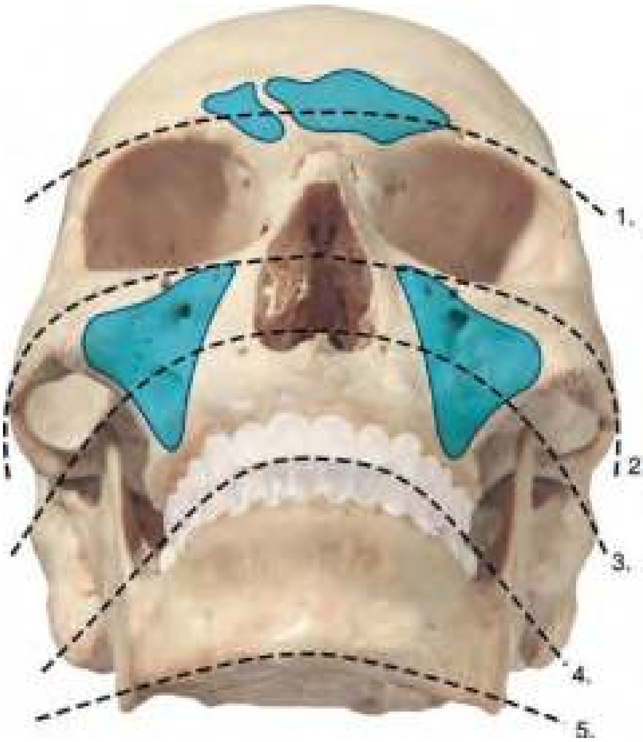

Fig. 55.13 McGregor-Campbell and Trapnell's lines

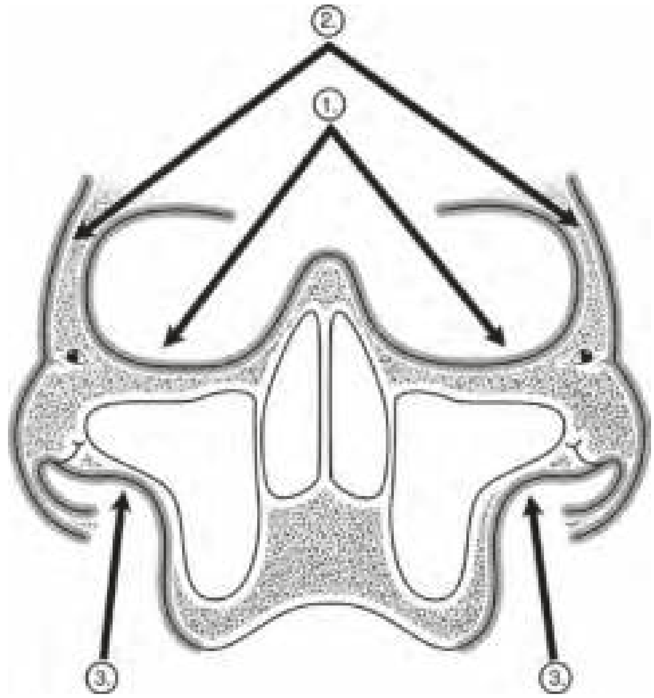

Fig. 55.14 Dolan's lines (also see Fig. 56.22)

3. Third line across the condyles, coronoid process and the maxillary sinus / Zygomatic buttress region
4. Fourth line across the mandibular ramus, occlusal plane
5. Fifth line (Trapnell's line, added later) across the inferior border of the mandible from angle to angle (Fig. 55.13)

The **four S's described by Delbalso, Hall and Margarone** [8]

In PNS view, the following four features are to be verified/compared with the unaffected side

1. Symmetry
2. Sharpness
3. Sinus
4. Soft tissues

Dolan's Lines [8] (Fig. 55.14)

Dolan's lines are the collective name given to three lines described by Dolan and Jacoby that aid in evaluating for maxillofacial fractures on an occipitomental skull radiograph. They are usually used as an adjunct to McGregor-Campbell lines.

- **Orbital line (line 1)** traces the inner margins of the lateral, inferior and medial orbital walls and the nasal arch.
- **Zygomatic line (line 2)** traces the superior margin of the zygomatic arch and body extending along the frontal process of the zygoma to the zygomaticofrontal suture.
- **Maxillary line** (line 3) traces the inferior margin of the zygomatic arch, body, and buttress and the lateral wall of the maxillary sinus.

Elephant of Rogers [8]

Lee Rogers pointed out that the second and third lines of Dolan give the outline of the head of an elephant.

55.4.1 CT Scans

CT scans are now the gold standard for a definitive diagnosis in fractures of the maxilla. A CT scan in all three planes (axial, sagittal and coronal) along with a 3D reconstruction will aid the surgeon in accurate assessment of fracture patterns and also will aid in preoperative planning. The surgeon must never rely on the 3D CT alone but should correlate the images with those obtained in axial sagittal and coronal planes, as there could be reconstruction-related errors which appear as fracture lines or bone defects. CT scan-based fracture patterns may be classified as low, middle or high energy, defined solely by the pattern of segmentation and displacement in the CT scan [9].

55.5 Treatment of Maxillary fractures

The primary aim of treatment of maxillary fractures is to re-establish the dental occlusion and masticatory efficiency. The contribution of the maxilla to the projection and contour of the midface has also to be considered in the management of maxillary fractures and requires a clear understanding of the facial buttress system, subunit anatomy and inter-relationships of the various bones [10]. This aesthetic aspect is often compromised by associated injuries of the zygomatic complex, nose and orbits.

> The basic principles of the treatment of maxillary fractures are:
>
> 1. Direct exposure and manual reduction of the fractures
> 2. Reconstitution of the bony buttresses of the midface so as to prevent elongation of the face and/or antero-posterior collapse of the maxilla
> 3. Re-enforcement of the paranasal and zygomatic buttresses with mini-plates
> 4. Replacement of missing/grossly comminuted bone at the buttresses with autogenous bone grafts [5]

> Factors that influence improved treatment outcome in maxillary fractures are:
>
> 1. Early definitive treatment
> 2. Anatomic and functional repair of naso-orbito-ethmoidal injuries
> 3. Wide exposure of fracture segments
> 4. Anatomic repositioning and stable fixation of fracture segments in all planes of space [11]

55.5.1 General Considerations in Treatment of Maxillary Fractures

Proper reduction of maxillary fractures is the key to achieving good dental occlusion and needs proper clinical examination of the fracture pattern after all the accessible fracture sites are exposed. A repeat study of the CT scans (axial, coronal and 3D) and correlation with the exposed maxilla will aid the surgeon in planning adequate reduction and rigid fixation. It should be kept in mind that the fractured maxilla is usually displaced backwards and downwards and hence the reduction should in the forward and upward direction. To obtain reproducibly good results, even with the most extensive facial dislocations, the surgeon should restore the facial architecture at the Le Fort I Level [12]. In rare occasions, lateral en bloc displacement of the maxilla is seen, and this requires transverse reduction to achieve the correct dental occlusion. A depressed zygomatic fracture can physically prevent reduction of the maxilla. Hence the fractured zygomatic bone should be reduced prior to manipulating the maxilla.

The most useful instruments for reduction of the maxilla are the Rowe's disimpaction forceps. Even in cases where the fractured maxilla appears to be minimally displaced, it is prudent to mobilize the bone with the disimpaction forceps so as to overcome any bony interferences and thus freeing the maxilla completely. When using this paired forceps, care should be taken to avoid injury to the anterior teeth and also to the palatal mucosa. Mobile, extruded and proclined anterior teeth are at particular risk, and an assistant should closely observe the anterior teeth, while the surgeon is manipulating the fractured maxilla. It would also be advisable to obtain informed consent regarding mobility or loss of these teeth. Trauma to the nasal floor is inevitable when mobilizing the maxilla using the reducing forceps, and some nasal bleeding is usually observed, but this rarely requires a nasal pack.

> Adequate reduction of the fractured maxilla is confirmed by:
>
> 1. Good dental occlusion
> 2. Alignment of the paranasal, zygomatic and fronto-zygomatic bony buttresses
> 3. Adequate reduction of all the observable fracture lines

Problems arise when the patient has few or no teeth and when there is gross comminution of maxilla. In these situations the surgeon has to make do with whatever landmarks are available, and in such cases compromised functional and cosmetic results are not uncommon.

Direct manipulation at the fracture lines is sometimes required especially when the fractured maxilla is telescoped into the superior normal bone. Care must be taken to prevent additional fractures at the bony margins during direct manipulation as this would make fixation more demanding. Using tie wires at the zygomatic buttresses, around the second maxillary premolars/first molars bilaterally and through anterior nasal spine is often useful to physically disimpact and pull the maxilla forwards and upwards thus ensuring good reduction.

When the maxilla is fractured in multiple levels (e.g. Le Fort I and III levels), reduction using the disimpaction forceps alone may not be adequate. The dental occlusion can be achieved, but the midface projection may be compromised. Here also a combination of reduction with disimpaction forceps, direct manipulation at the fracture site and the use of the above mentioned tie wires is often indicated.

Once adequate reduction of the fractured maxilla is obtained, it is mandatory that rigid maxillomandibular fixation (MMF) is applied. In almost all cases, well-adapted maxillary and mandibular arch bars are required as this ensures multiple points for the MMF. Failure to obtain rigid MMF or manually maintaining the dental occlusion during fixation can result in post-operative occlusal discrepancies. If surgical reduction and fixation of the maxilla has to be delayed, elastic traction will be helpful in obtaining a functional occlusion. The use of MMF screws definitely saves operating time but can be problematic if elastic traction is required later.

If the mandibular condylar fracture exists, this should be reduced and fixed prior to the MMF. Failure to do so may result in an open bite due to loss of posterior mandibular height.

55.5.2 Suspension Wiring

Internal wire suspension involves sandwiching the fractured portion of the maxilla between the mandible and the superior part of the facial skeleton/skull that is not fractured. The use of internal suspension wires is more or less obsolete unless there is severe comminution which precludes rigid internal fixation. Suspension wiring may also be the surgeon's choice when there is presence of severe infection at the site of surgery (Fig. 55.15).

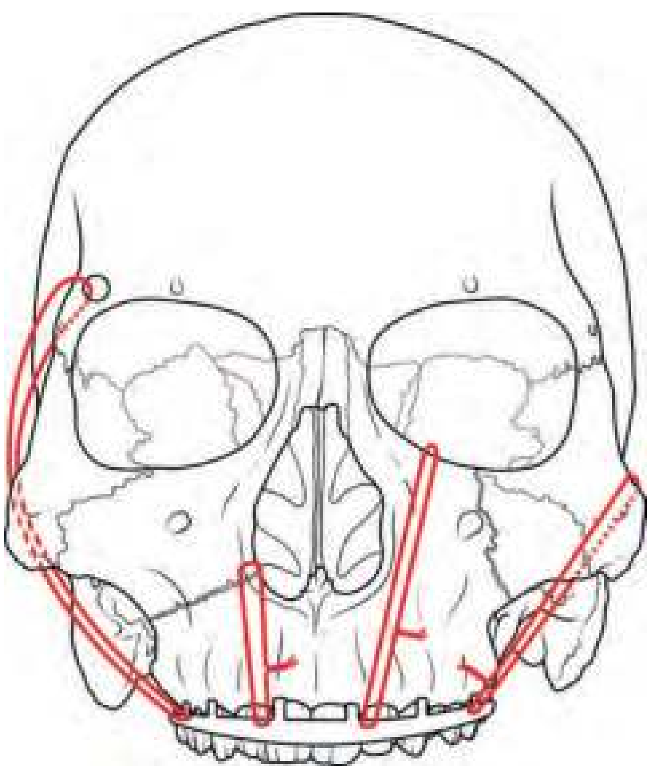

Fig. 55.15 Various types of suspension wiring employed for midface fractures

55.5.3 Rigid Internal Fixation

Although many wiring techniques were practised in the past, rigid internal fixation with titanium bone plates and screws of sufficient rigidity is now the standard of care. For internal fixation of the maxilla, titanium bone plates and screws of sufficient rigidity are used. For providing rigidity, screws with an outer diameter of 1.5 mm is commonly used.

55.5.4 Approaches to the Maxilla

When treating a very high Le Fort I fracture and in Le Fort II and III fractures, it may be necessary to use one or more of the following incisions, which are described in chapter 56 and 57 of this book:

1. Skin incisions for exposure of the infraorbital rim. Extension of this incision medially ensures access to the lateral nasal area, while a lateral extension would give access to the upper portion of the zygomatic body.
2. Upper eyelid or lateral eyebrow incision (blepharoplasty) to expose the fronto-zygomatic suture.
3. An existing laceration with or without conservative extension for increased surgical access.

55.5.4.1 Maxillary Vestibular Approach

The maxilla can be approached through a variety of incisions, the most common being the maxillary vestibular approach. In addition to providing access to the lower part of the entire midfacial skeleton, this approach results in a hidden intraoral scar. This approach may result in disruption of the attachments of the facial muscles of the nasolabial region; hence careful repositioning during closure is recommended to avoid unaesthetic changes to the face. The muscles of importance are the nasalis group, the levator labii superioris alaeque nasi, the levator labii superioris, the levator anguli oris and the orbicularis oris. The vestibular incision and subsequent dissection causes stripping of origin/insertion of most muscles originating in the maxilla. These muscles tend to get reattached in a shortened manner due to the action of the zygomaticus muscle. Deepening of the alar groove and splaying of the alar bases, nostrils and nasal tip may occur following lateral displacement of the nasal modiolus. Soft tissue fullness loss in the naso-alveolar region may result in thinning and retraction of upper lip, reduced vermillion exposure and a obtuse nasolabial angle. Detachment of the levators of the upper lip may cause down turning of the corner of the mouth (Fig. 55.16).

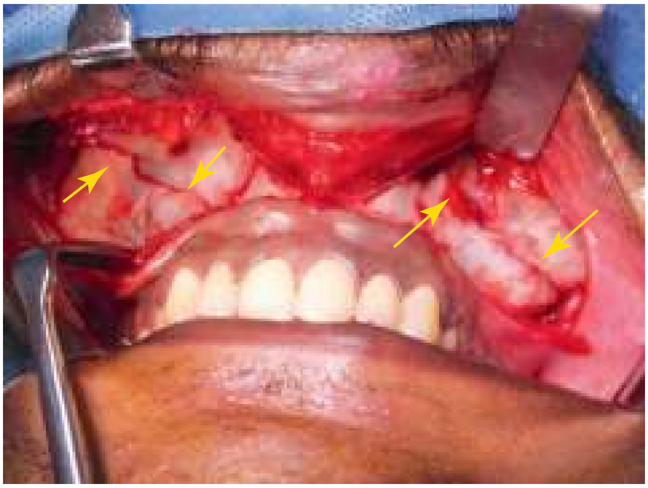

Fig. 55.16 Maxillary vestibular incision with adequate gingival cuff. Yellow arrows denoted the Le Fort I fracture lines

Clinical Tips for approaching the Le Fort fracture via maxillary vestibular incision

- The use of liquid paraffin will minimize trauma to the lips and corners of the mouth especially in patients with a small oral aperture.
- It is important to place a high vestibular incision to ensure a wide gingival cuff of tissue which will aid in closure of the incision.
- "Counter" elevation of the gingival cuff would aid in closure and also expose the root prominences, and this would be helpful during adaptation of the miniplates and the subsequent screw fixation.
- It is also recommended that the opening of the Stenson's duct be identified so that injury to this structure is avoided when the buccal sulcus is stretched while making the incision.
- Some surgeons mark the midline to ensure proper reapproximation of the tissues during closure. This is important in cases where one is forced to use an oral endotracheal tube exiting from one corner of the mouth which may distort the oral tissues.
- Extension of the posterior end of the incision beyond the first molars may cause buccal fat herniation into the surgical site. This is of minimal concern but can be annoying to the surgeon during plate fixation.
- Sharp elevation of the superior flap will ensure a subperiosteal plane of dissection, but this may not always be possible due to adherent tissue at the fracture sites and the presence of bony fragments in comminuted fractures. As far as possible, sizable fragments of loose bone with soft tissue attachments should be retained to avoid large gaps at the fracture site which might delay healing. Even completely denuded bone can be replaced as free autogenous grafts and fixed in place with tissue glue or fine stainless steel wires.
- As the superior dissection proceeds, care should be taken to identify and protect the infraorbital nerve which may be involved in the fracture. It is also prudent to palpate the infraorbital margin to ensure that inadvertent entry into the orbit is avoided especially when comminution of the infraorbital rim and floor is present.
- Once the flap has been adequately raised, long Langenbeck retractors placed superiorly and cheek retractors at the corners of the mouth will ensure good surgical exposure and adequate lighting and thus aid in reduction and fixation of the fracture (Fig. 55.17).
- A variation which can be done is giving two separate vestibular incisions bilaterally without incising the midline frenal attachment. This variation will not disturb the mid line lip anatomy in cases where exposure of the anterior nasal spine region is not required.

Fig. 55.17 A clinical situation where the separate vestibular maxillary incisions were given to approach anterior maxilla, due to deep through and through lip laceration upper lip extending down to the frenum region

Early intervention (7–10 days) with open reduction and fixation is the treatment of choice for maxillary Le Fort I fractures. Restoration of normal facial contour and occlusion is considered as optimal outcome of treatment. Bone reconstruction should be completed as early as possible to minimize shrinkage, stiffness and scarring of soft tissues [12].

In complex panfacial fracture management, many authors have stressed the importance of managing the Le-Fort fracture while reconstituting the facial architecture [13, 14].

55.5.5 Fixation of Le Fort I

Adequate fixation of the fractured bone depends on two factors, namely, the rigidity of the plate and the friction between the bone fragments (buttressing of the bony segments). When a gap exists between the bone ends, the latter factor is missing. In these cases, non/fibrous union can result if the masticatory forces are greater than the rigidity of the plate. As a general principle, the paranasal and zygomatic buttresses must be rigidly fixed. The plates should be well adapted especially where the bone stock is poor. At least two screws must be present on either side of the fracture and more the number of screws, better the, load sharing, between the plate and the subjacent bone. Opposed to this is when there is no bone buttressing and the plate has to be 'load bearing'. Also a minimum of two threads of the screw should engage the cortical bone. This may be a problem in thin areas as the anterior wall of the maxillary sinus and the alveolus where roots are present. In the edentulous maxilla, the bone quality is often compromised, and the lower end of the plate may need to be placed on the alveolus. This may necessitate removal of the plate prior to prosthodontic rehabilitation.

Obtaining rigid fixation becomes difficult when the buttresses are comminuted. If only one buttress is amenable for plating the reduction at this fracture interface along with reconstitution of the occlusion must be used as the template for repositioning the maxilla. When all the buttresses are comminuted, the surgeon has to "eye ball" the maxilla into the reduced position. In these situations, a long-span plate extending from the body of the zygomatic bone to the relatively thick bone in the area of the anterior nasal spine with or without a bone graft is often the only option available to maintain the vertical position of the floating maxilla. It has been stated that the lip-tooth relationship is helpful in deciding the position of the reduced maxilla, but in practice this is of limited use.

Loss of bone at the buttresses may require the use of primary bone grafts [10]. Though it has been suggested that a gap of more than 5 mm at the buttresses requires a graft, rigid plate fixation followed by MMF is often enough to ensure bony healing.

Primary bone grafting can be done using iliac bone (Fig. 55.26), split calvarium or split ribs. The calvarium is the preferred source because of the following reasons:

1. Large amount of graft available
2. Proximity to the operative field
3. Minimal donor site morbidity

The disadvantage is that these grafts are brittle and cannot be contoured. The bone graft has to be mortised to fit the defect and must be fixed rigidly to the plate or lag screwed.

In essence the decision to graft will depend on:

1. The extend of the bony gap
2. The quality of the bone available for plate fixation
3. The rigidity of the fixation
4. Use of post-operative MMF
5. Loss of a large part of the anterior wall of the maxillary sinus (Fig. 55.18) (causing the overlying soft tissue to fall into the sinus causing a contour defect)

Fig. 55.18 A clinical situation where the defect in the anterior wall maxilla due to comminution of the wall was partly covered by fixing the free segment (red arrow). The long-span plate from the buttress to the anterior maxilla region can also be seen

Incisions for open reduction can be placed from first molar to first molar regions through a vestibular approach for wide exposure of the fracture sites. Rowe's disimpaction forceps and/or Hayton-Williams forceps can be used for mobilizing and reducing the fracture into position. The impacted type of Le Fort I fracture manipulation has to be done by grasping the maxilla with two pairs of Rowe's disimpaction forceps. Osteotomizing the maxilla should be considered if there is significant interval between the time of trauma and surgery. Whenever possible a passive reduction of the maxilla with condyles firmly seated in their correct position should be ensured to avoid post-operative anterior open bite (Figs. 55.19, 55.20, and 55.21).

Fig. 55.19 The surgeon stands behind the patient and applies the disimpaction force, while the head is stabilized by the assistant surgeon

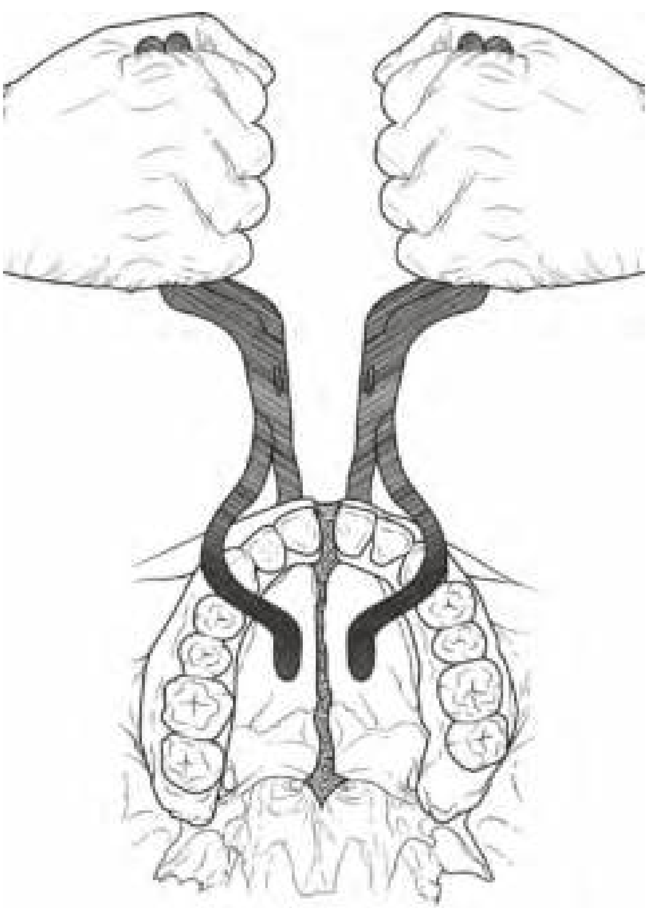

Fig. 55.20 Use of Rowe's disimpaction forceps

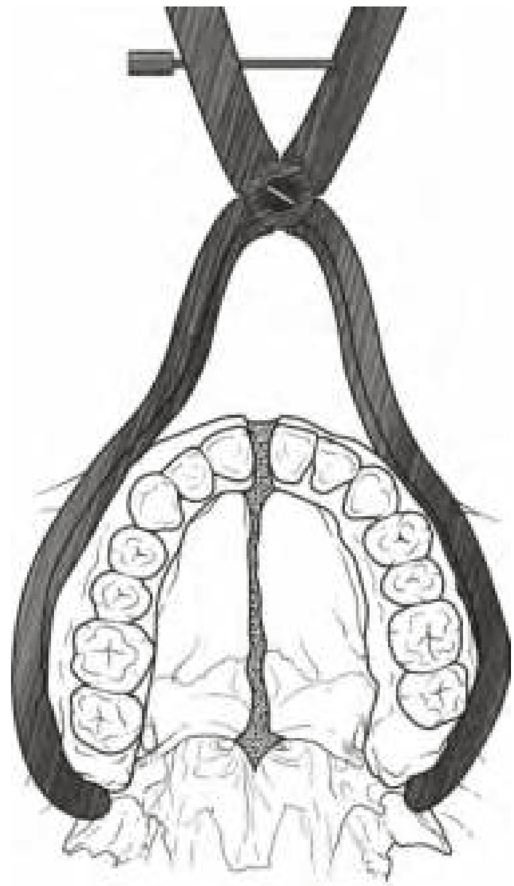

Fig. 55.21 Use of Hayton-Williams forceps

Use of Rowe's disimpaction forceps	Rowe's disimpaction forceps are available as paired (right and left) instruments
	Each instrument has two blades, one for engaging the palate (to be padded before use to avoid injury to the palatal mucosa) and one to be inserted through the nostril
	The instrument has an outward bend at the handle which aids in the use of two forceps simultaneously
	After engaging the forceps, the maxilla has to be moved in all planes to ensure adequate mobilisation

Use of Hayton-Williams forceps	The Hayton-Williams forceps is used to hold the fractured maxilla together	
	The instrument is inserted after vestibular incision and is engaged at the pterygoid region	
	This is the instrument of choice especially in cases with palatal bone fracture	

After reduction the maxilla should be placed into maxillomandibular fixation. The fixation of the fracture sites (four-point fixation) is done at the vertical pillars of nasomaxillary and zygomaticomaxillary (lateral piriform rim and zygomatic buttress regions) for which the preferred plates and screws used are 1.5-mm thickness with 6-mm long screws. In the zygomatic buttress regions, 2.0-mm profile plates also can be used. The mini-plates are fixed as close as possible to the lateral pyriform rim as the bone is thickest there. Usually stabilization of the fracture is achievable even if any three of the four buttresses are fixed. Apparently, gross communition at one of the buttress regions will not cause a significant risk of inadequate stabilization. The associated anterior wall of the maxillary sinuses is generally not fixed due to the relative thin nature of bone in this region. The larger free bone fragments can be repositioned and immobilized using wires or be used for reconstruction of orbital floor defects. The circumvestibular incision is closed with running resorbable sutures after ensuring that the midline of upper lip coincides with the facial midline (Fig. 55.22).

Maxillomandibular fixation of up to 6 weeks also can be considered as alternative for treatment though the results may be less satisfactory with added morbidity to the recovering patient. The readers are advised to refer chapter 50 to read about closed reduction / wiring and intermaxillary fixation techniques.

Fig. 55.22 The zygomatic buttress and paranasal buttress fixed in a classical Le Fort I fracture maxilla

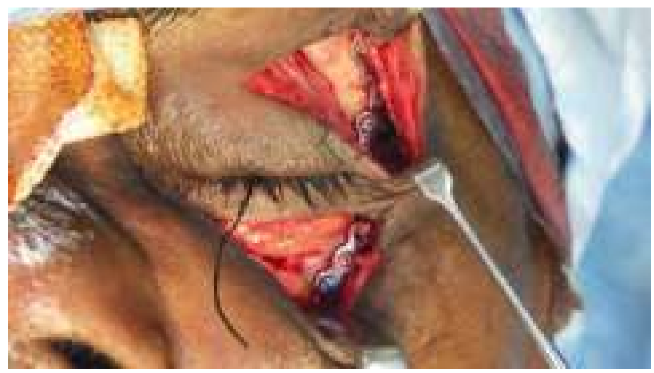

Fig. 55.23 Le Fort II fracture lines at the infraorbital rim area may have to be accessed directly, if required, especially with associated zygomatic/orbit fractures. In this case the lateral orbital rim reconstruction is done via combined access from left sub ciliary incision and left supra tarsal incision

55.5.6 Fixation of Le Fort II Fractures

The pyramidal fracture has the apex of the fracture located at the nasofrontal suture region or at the midnasal bone level. The Le Fort II fractures are ideally fixed at the frontonasal suture region, bilateral infraorbital rims and also both zygomaticomaxillary buttresses. However in majority of the clinical situations fixation at the infra orbital rims and the zygomatic buttress regions gives reasonably good results. Most Nasal bone fractures associated with Le Fort II fractures can be adequately managed by closed reduction techniques. This may require the anaesthetist to change nasal intubation to oral intubation. A submental intubation may also be considered at the beginning of the procedure. If the nasofrontal segment is unstable, fixation of the area can be done through various approaches (existing laceration, Gull wing approach, etc.). A maxillary vestibular incision can frequently provide access to infraorbital fracture alignment and fixation in some cases. The lower eyelid approaches are not always mandatory for fixation unless simultaneous exploration and reconstruction of orbital floors are also planned.

In Le Fort II fractures that are complicated by an associated palatal fracture, surgical splints may be helpful in obtaining adequate reduction. Placement of maxilla mandibular fixation will ensure accurate alignment of midface structures (Fig. 55.23).

55.5.7 Fixation of Le Fort III Fractures

These are complex fractures which rarely occur in isolation and results in a dysjunction of the facial skeleton from the base of the cranium. The ideal repair time should be within 10–14 days following the injury but may get delayed due to neurosurgical issues and other comorbidities.

Incision design for Le Fort III fractures should facilitate adequate access for reduction as well as fixation of the naso-frontal, frontozygomatc and in some cases the zygomatic arches. Using existing lacerations for access avoids need of a coronal incision, as this allows for complete visualization, reduction and fixation of the frontal area and zygomatic arches. A lateral brow or upper blepharoplasty (supra-tarsal fold) incision may be used to approach the lateral orbital rims. Also in such cases, a thicker plate (2.0) placement at the lateral orbital rim may be beneficial. A coronal approach may have to be considered if bilateral fronto-zygomatic and nasofrontal fracture fixation is planned.

The occlusion is a reliable indicator of adequate reduction in cases where direct visualization of the fractured segment is not possible.

In Le Fort III fractures associated with other fractures (open facial/condyle fractures), various surgical sequences can be followed, which is discussed in chapter 60 on Panfacial fractures.

Rarely, Le Fort fractures may present without mobility, but show occlusal disturbances like crossbite, open bite or loss of intercuspation. These can be managed by using traction elastics but at times warrant mobilization and subsequent rigid fixation [15].

Fig. 55.24 Infraorbital plate exposure

55.6 Complications of Le Fort Fractures (Table 55.6)

General	Le Fort I	Le Fort II	Le Fort III
• Bleeding • Enopthalmous • Infection • Altered vision • Non-union • Mal-union • malocclusion • Epiphora (due to obstruction of nasolacrimal duct) • Scarring • Sinusitis • Exposed hardware (Fig. 55.24) • Foreign body reactions	Maxillry hypoperfusion • Wound dehiscence Necrotic teeth	• CSF leak (rhinorrhea and /or otorrhea) • Palatal fistula • Nasal Septal deviation • Infra orbital paraesthesia	• CSF leak (rhinorrhea and /or otorrhea) • Facial Nerve paralysis • Trigemminal nerve injury

Table 55.6 Complications of Le Fort fractures

55.7 Palatal Fractures

Unlike many other areas of the midface, the palatal bone is relatively thick, and hence palatal fractures are not common. A palatal split makes reduction and fixation of maxillary fractures more difficult mainly due to the transverse instability which can cause medial collapse or outward splaying of the maxilla. The use of the Hayton-Williams forceps along with the disimpaction forceps will control outward splaying of the maxilla but at the risk of medially displacement of the dentate segment of the maxilla. Moreover, the use of all the three forceps effectively requires some amount of surgical expertise.

Moss et al. [16] have proposed a classification for palatal fractures. There is no consensus regarding the management of palatal fractures, but various options have been suggested.

1. Transpalatal wires in the first molar region.
2. Direct exposure of the fracture through an existing palatal laceration or an incision and rigid plate fixation.
3. External fixation by fixing a screw on either side of the fracture and immobilization with a wire connecting the screws. Alternatively a palatal splint can be fabricated after sectioning a plaster model of the palate.
4. Plating the labial fracture line.
5. Plating the nasal floor.

Transpalatal wires are simple to apply and do not have the problems of soft tissue dehiscence and infection seen in the more invasive methods [17]. However, the reduction of the palatal fracture cannot be ensured, and the wires can be cumbersome to the patient as it affects speech and swallowing. If the palatal wires are passed through an infant feeding tube or a small gauge urinary catheter, injury to the dorsum of the tongue can be minimized. It is also noticed that palatal wires tend to become slack after a few days, and then their value in reduction and fixation of the fracture is questionable. Moreover, these wires are not an option in the edentulous maxilla.

Direct exposure and plate fixation are surgically demanding, but the fracture can be reduced and fixed under direct vision. Ceinfuegos et al. have described the technique of fixing the plate over the palatal mucosa, but this plate would have to be removed at a later date [18]. An alternative would be to use a resorbable plate and screws.

Ma et al. has documented the use of self-drilling screws on either side of the palatal fracture with wires to fix the fracture [19].

Fig. 55.25 Oronasal fistula in a patient who had sustained palate fracture

Palatal fractures of the sagittal or parasagittal variety can be stabilized by placing a mini-plate across the fracture line on the labial side. Occasionally the prominence of the anterior nasal spine has to be reduced to facilitate mini-plate placement.

The transpalatal reduction should be supplemented by fixation at the zygomaticomaxillary and nasomaxillary buttresses and the use of an arch bar [20].

Palatal fractures accompanied by soft tissue lacerations often cause a serious challenge to the surgeon regarding its management. The healing of the palatal soft tissue laceration is dependent on the exact reduction of the palatal vault and stabilization. Overzealous attempts at closure of the laceration without accurate reduction may compromise wound healing. A tension-free closure of the palatal mucosa is imperative for wound healing. In some cases, the ensuing oronasal communication will have to addressed secondarily (Fig. 55.25).

55.7.1 Surgical Splints

Concomitant fractures of the palate present additional challenges to the treatment of Le Fort fractures. They complicate the re-establishment of proper width and height of the maxilla. Depending on the fracture type, patient comorbidities and associated injuries, either closed reduction and wiring or rigid fixation may have to be performed. Dental impressions can be obtained and occlusion assessed prior to surgery.

Fabrication of an acrylic splint may help in re-establishing the transverse width of the palate.

In cases of gross comminution with partial dentition, palatal splints are helpful. Splints are fabricated on casts on which model surgery has been performed. They are designed such that they cover the occlusal surfaces and heights of contour, and care should be taken as to not disturb the soft tissues. Holes placed in the occlusal surfaces in the splint aid in separately ligating it to the arch bar [21]. In case of edentulous patients, Gunning splints are usually used.

55.8 Special Considerations

55.8.1 Maxillary Fractures in Geriatric Patients

Advanced age and compromised medical fitness may increase the morbidity associated with surgical management of maxillary fractures. Loss of teeth leading to reduced alveolar bone, reduced vascularity of maxilla and greater pneumatisation of the maxillary sinuses, should be taken into consideration before attempting an open reduction and internal fixation. Modification of existing dentures or Gunning splints are viable options in this population.

55.8.2 Maxillary Fractures in Children

The long-term effects of maxillary fractures on skeletal growth are inconclusive at present. Mobile-displaced maxillary fractures in paediatric patients warrant open reduction and fixation. Removal of hardware in growing patients may be considered to overcome complications of plate translocation (shifting of the position of metal plate due to appositional bone growth), extrusion and possible growth restriction. Resorbable plating systems may offer a solution to overcome such complications.

55.8.3 Haemorrhage Control in Maxillary Fractures

Branches of the internal maxillary artery provide much of the vascular supply to the midface. In patients with epistaxis or bleeding, ligation of this artery may be necessary. Due to anastomoses from other branches of the internal and external carotid circulation, vascular insufficiency of the maxilla is unlikely even after ligature of maxillary artery. In certain conditions of intractable bleeding not amenable to control by normal packing methods, embolization methods have been used effectively.

55.9 Recent Advances

The use of pre-surgical stereolithographic models helps in plate contouring and precise positioning of fractured segments. Facilitation of the intraoperative three-dimensional bone positioning is possible due to development of sophisticated computed tomography, computer graphics hardware and image processing software capable of reproducing anatomic templates. Automated preoperative "mirroring" of the contralateral uninjured orbito-zygomaticomaxillary complex to the affected side can result in improved results. The use of intraoperative surgical navigation systems along with mobile cone beam CT improves intraoperative quality control. Endoscopic midface fracture management facilitates smaller incisions, reduced recovery time and minimal post-operative complications. These developments are discussed in the Chap. 41.

55.10 Conclusion

Maxillary fractures can sometimes occur with significant cosmetic and functional implications. Accurate diagnosis and early surgical intervention is essential for successful management of these fractures. The surgeon should keep in mind that the surgical management of maxillary fractures primarily aims at restoration of the vertical and horizontal support buttresses.

55.11 Case Scenario - A case of maxillary Lefort I fracture where bone grafting was done (Fig. 55.26a–g)

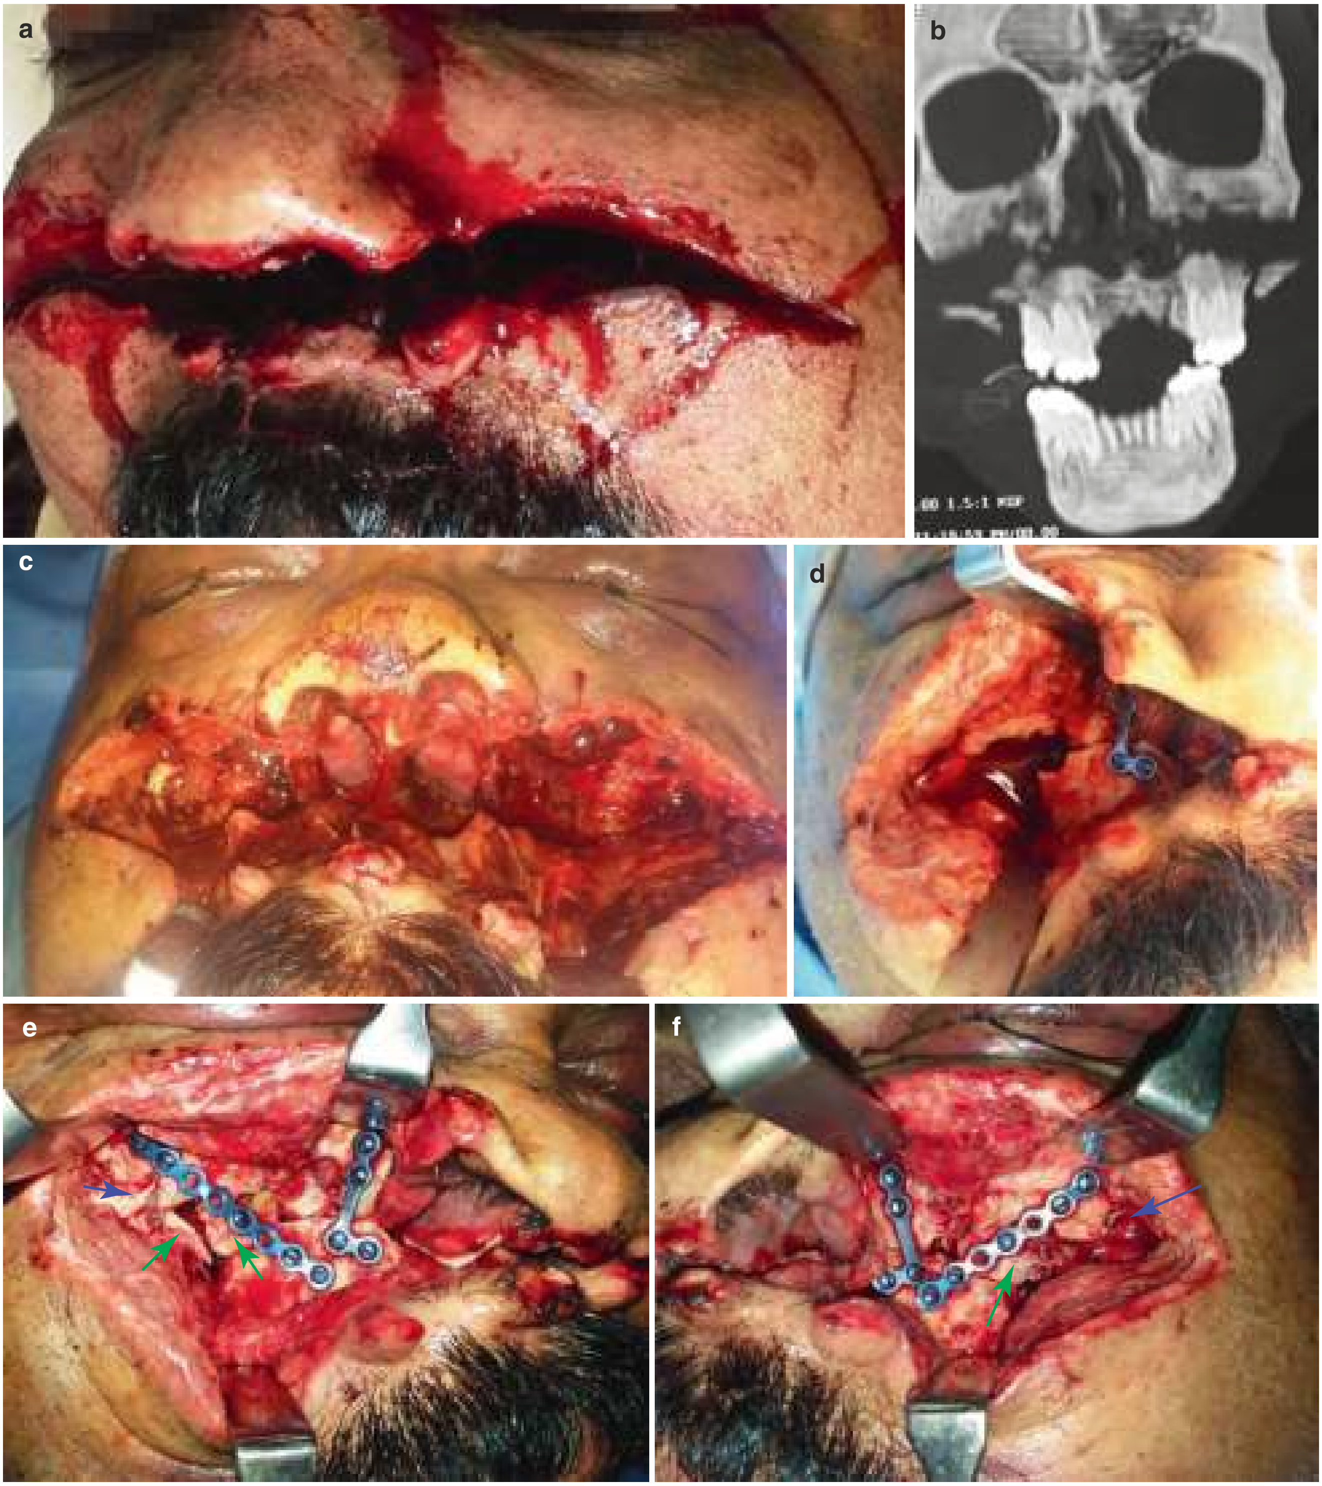

Fig. 55.26 Case scenario (fracture maxilla fixation done with grafting in the anterior maxillary sinus wall). (**a**) 43-year-old man sustained bone deep laceration on face causing Le Fort I like fracture pattern. In the emergency department, oral intubation was required due to heavy bleeding. Nasal packs were placed, and the wound was primarily tacked as adjunct measures. (**b**) MIP view of CT scan showing the maxillary segment displaced downwards will loss of anterior maxillary wall height. (**c**) Intraoperative view showing the severely displaced maxillary segment. Access for the fixation was via the existing laceration. A maxillary vestibular incision was not placed. (**d**) The paranasal buttress was maintained, but loss of bone structure seen at the anterior wall sinus region. To attain primary healing and to avoid malunion, iliac crest bone grafts were procured and split into separate pieces. (**e**) (Right side maxilla) the green arrows point to the graft segments. Initially the graft segment was fixed with wire (blue arrow) and was attached to the titanium plate with screws (the plate was spanned from the zygomatic body to the displaced main fracture segment). (**f**) Similar technique done on left side. (**g**) Immediate post-operative view after closure of the laceration. Patient had arch bars fixed and underwent a period of intermaxillary fixation to help in primary union. Post-operative review showed good stability for maxilla and the occlusion was maintained

56 Fractures of the Zygomaticomaxillary Complex

Elavenil Panneerselvam, Poornima Ravi, and B. Sasikala

56.1 Introduction

The zygomaticomaxillary complex (ZMC) refers to the skeletal unit [1] formed by the zygomatic bone and maxilla (Fig. 56.1). These two bones are referred to as a complex, because of the structural and functional relationship between them; they articulate with each other over a wider area, and any traumatic impact on one bone generally influences the other. This duo complex also constitutes a major part of the orbit, spanning the infra-orbital rim, lateral wall, and floor. Hence the ZMC is also termed *orbitozygomaticomaxillary complex* [2]. Because of its multiple articulations, various names are commonly used to describe ZMC fractures such as "tripod, tetrapod, or pentapod" [3, 4] fractures.

Fractures of the ZMC commonly result in severe cosmetic and functional deficits because of the prominent anatomical position of the zygoma and its proximity to adjacent vital structures such as the globe. Precise reduction and fixation of these fractures is challenging due to their complex anatomic form, multiple articulations, and deformation in multiple planes. The scope of this chapter encompasses the biodynamics of ZMC fractures, clinical implications, and guidelines for successful management.

56.2 Surgical Anatomy

The term zygoma denotes a "yoke or bar," in Greek. Quite aptly, the zygoma extends as a prominent, sturdy bar across the face, contributing to its transverse width and anteroposterior projection. The clinical significance of this bony complex is attributed to its role in defining facial esthetics and globe function.

56.2.1 Articulations

The zygoma articulates with four bones [5]; superiorly frontal, medially maxilla, laterally temporal bone, and posteriorly sphenoid, through five processes [4] (Fig. 56.1), namely, the zygomaticotemporal (ZT), zygomaticomaxillary (ZM), infra-orbital (IOR), fronto-zygomatic (FZ), and sphenozygomatic (SZ) or zygomaticosphenoid (ZS). These processes are clinically significant in establishing the three-dimensional structural integrity of the upper lateral face.

Fractures of the ZMC have been traditionally called the "tripod or trimalar fractures" because it involved separation at the three processes of the zygoma—the FZ, IOR, and the ZM processes (Fig. 56.2a). The terminology was later modified to "quadripod or quadramalar fracture" to include separation at the fourth point of articulation, the ZT process (Fig. 56.2b). However, the importance of SZ articulation along the lateral wall of the orbit has been recognized lately, and, hence, ZMC fracture is currently called a pentapod fracture (Fig. 56.2c), to emphasize the necessity of restoring the five articulations during fracture management.

56.2.2 Relations

- Zygoma and orbit: ZMC forms the lateral and inferior part of the orbit, protecting as well as supporting the globe and associated soft tissues. The Whitnall's tubercle present on the zygoma (inferior to the FZ suture) provides

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_56

attachment to the suspensory ligament of Lockwood that maintains the horizontal axis of the globe [6] (Fig. 56.3a). A fracture line located above the Whitnall's tubercle leads to inferior displacement of zygoma as well as the lateral attachment of Lockwood ligament resulting in anti-mongoloid slant to the eye (Fig. 56.3b). Thus ZMC fractures greatly influence the structure and function of the orbit. Further, the contents of the orbit including the globe, extraocular muscles, and orbital fat are intimately related to the zygoma and may be affected in fractures of the ZMC or its surgical manipulation.

- Zygoma and mandible: The zygoma and zygomatic arch are anatomically close to the coronoid process of the mandible. Therefore, a fractured zygoma or arch, when retro/medially positioned, may impede mandibular movements [7]. A displaced and untreated fracture of zygoma/arch which is in close proximity to the coronoid process can result in extra-articular ankylosis [8].
- Zygoma and maxillary sinus: Fractures of the ZMC (except the isolated zygomatic arch fractures) involve the maxillary sinus and show features of hemosinus [4] or sinusitis [3].

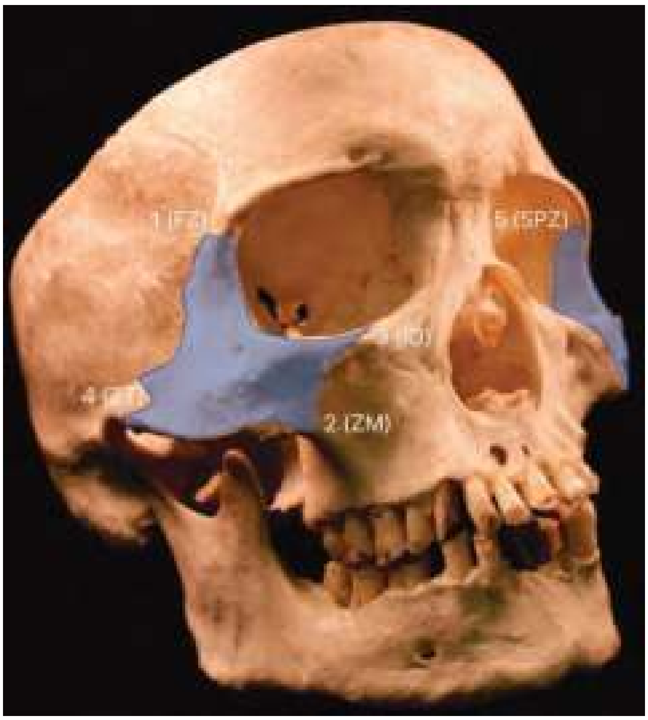

Fig. 56.1 ZMC skeletal unit. Articulations of zygoma with facial skeleton and articulating processes

56.2.3 Muscle and Fascia Attachments

The muscles attached to ZMC are the zygomaticus major, zygomaticus minor, orbicularis oculi, and masseter [9]. Masseter is attached to the zygomatic arch on the lateral and inferior aspect as well as the zygomatic tuberosity (Fig. 56.4a). The downward displacing forces of the masseter have been considered by many as the principal cause of post-reduction instability [10].

The temporal fascia attached to the arch superiorly plays a major role in resisting the downward displacement of fractured ZMC or arch due to the inferior pull of the masseter (Fig. 56.4b) [1].

56.2.4 Zygomatic Arch

The arch is the key parameter for re-establishing the sagittal projection as well as transverse width of the face [11]. An arch which is bent outward or inward gets shortened [4]. This leads to retrodisplacement of zygoma resulting in altered facial width (Fig. 56.5b). It is important to remember

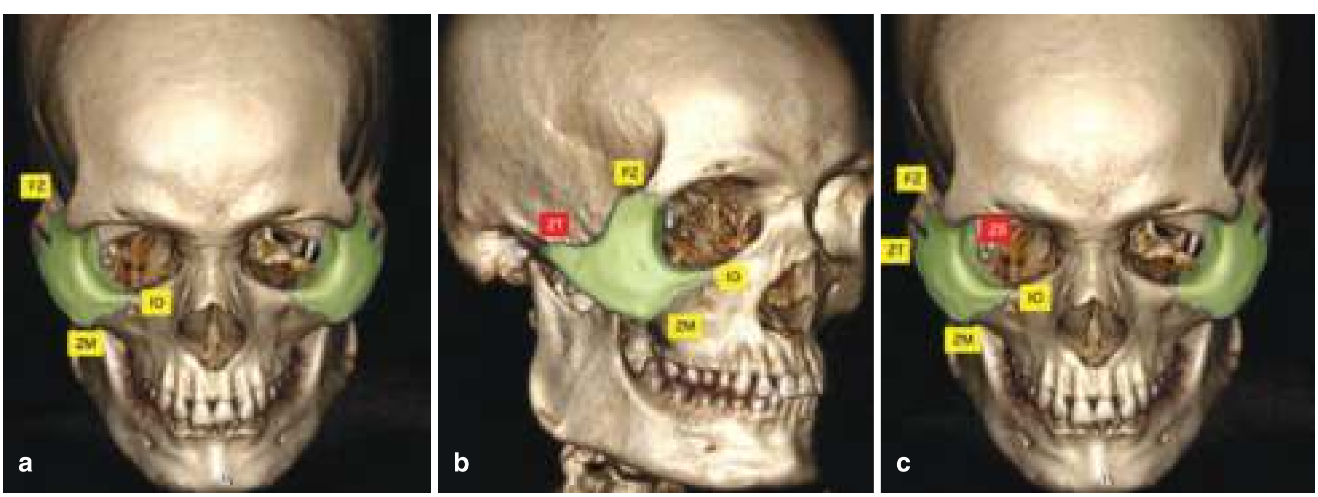

Fig. 56.2 Types of ZMC fractures. (**a**) Tripod fracture. (**b**) Tetrapod fracture. (**c**) Pentapod fracture

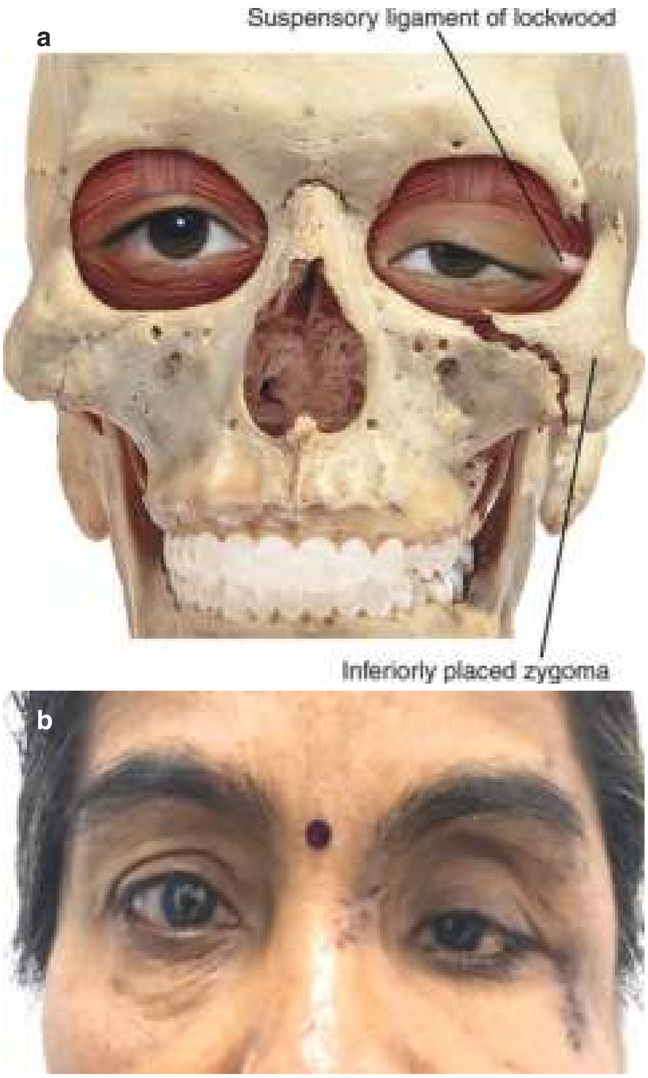

Fig. 56.3 Relation of suspensory ligament to zygoma. (**a**) Displacement of suspensory ligament of Lockwood leading to anti-mongoloid slant. (**b**) Clinical appearance of anti-mongoloid slant

that in spite of being referred to as an arch, it does not have an exaggerated curvature. Therefore, overzealous contouring during reduction of zygomatic arch fractures can result in compromised esthetics. The arch is encased by a thick periosteal and fascial envelope which counteracts the displacing forces of the masseter [1]. However, when the periosteal envelope is damaged due to high-velocity injuries, the fracture segments show more displacement.

56.2.5 Nerves and Blood Vessels

The nerves in close proximity to the ZMC are (1) infra-orbital nerve and (2) zygomatic nerve [12] (Fig. 56.6a). The infra-orbital nerve runs along the ION groove and enters the

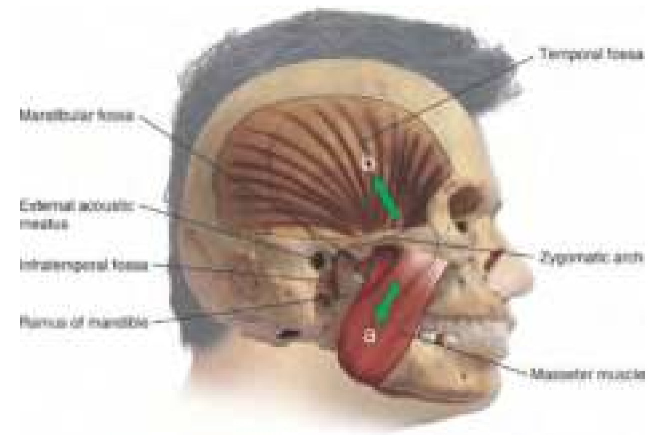

Fig. 56.4 Displacing forces acting on the zygoma and arch. (**a**) Masseter exerting downward force. (**b**) Temporalis with a superior vector

ION canal giving off the superior dental plexus of nerves before exiting through the ION foramen onto the face. Here it innervates the lower eyelid, lateral aspect of the nose, and upper lip of the ipsilateral side. The zygomatic nerve which enters the orbit through the inferior orbital fissure divides into two branches, the zygomatico-facial and zygomatico-temporal which emerge onto the face through their respective foramina. The zygomaticofacial nerve innervates the skin over the malar area, while the zygomaticotemporal nerve supplies the skin over the anterior temporal region. These nerves may be injured due to trauma or during surgery. The severity of paresthesia which arises is generally proportional to the degree of displacement of a fractured zygoma [13]. The other nerves whose function may be affected in ZMC fractures are the optic nerve [14] and facial nerve [15]. Blood vessels of importance related to the ZMC are infra-orbital artery and vein [16] (Fig. 56.6b) which accompany the infra-orbital nerve. Uncontrolled forces delivered during elevation of zygoma may injure these vessels resulting in severe intra-op bleeding.

56.3 Classification

56.3.1 Classification of ZMC Fractures

Numerous classifications have been proposed for ZMC fractures; this chapter would discuss the most practical ones which help in understanding the biodynamics of fracture as well as facilitate quick decision-making regarding the treatment.

- The classification proposed by Rowe and Williams [1] (Fig. 56.7) is based on the axis of rotation of ZMC and the

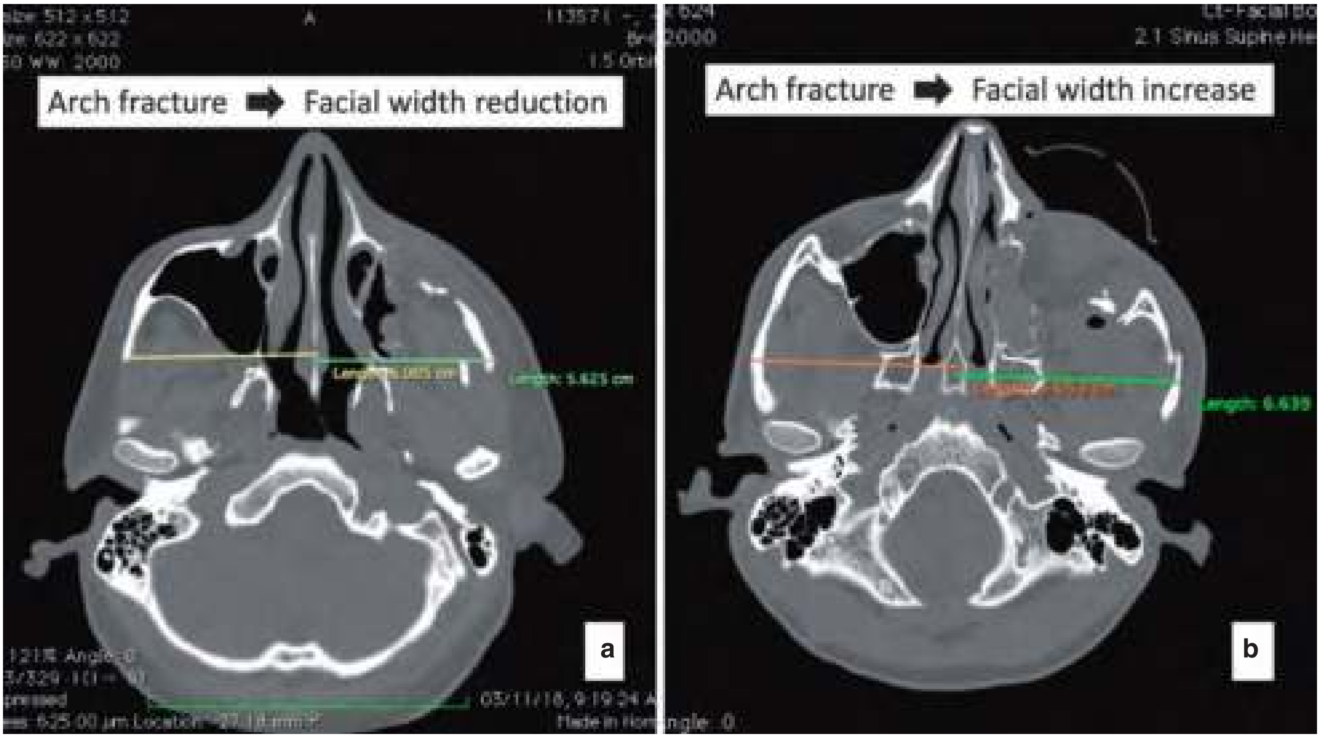

Fig. 56.5 Change in facial dimension in zygomatic arch fractures. (**a**) Inward bowing of arch. (**b**) Outward bowing of arch

stability after reduction. Following trauma, the zygoma may undergo rotation along two axes: vertical axis extending through the FZ suture and first molar and horizontal axis running across the infra-orbital foramen and zygomatic arch. According to this classification, fractures were considered as *stable after elevation* when they demonstrated (1) arch only fracture with medial displacement and (2) rotation around vertical axis (medially/laterally), while fractures were categorized as *unstable after reduction* when the following features were observed: (1) arch only fracture with inferior displacement (Fig. 56.8), (2) ZMC fracture rotated around horizontal axis (Fig. 56.7), (3) dislocated en bloc (inferiorly/laterally/medially) (Fig. 56.9a), and (4) comminuted (Fig. 56.9b).

This classification provides clinical guidance regarding the stability of fracture after reduction and the necessity for fixation.

- ZMC fractures have also been classified on the basis of "severity of traumatic impact" [4] into low-, medium-, and high-energy patterns, as demonstrated on CT; low-energy type is associated with non-displaced/minimally displaced "en bloc" fractures, medium-energy type is displaced fractures with or without fragmentation, and high-energy type is associated with fractures with massive displacement, comminution, or fragmentation.
- Zing et al.'s [17] classification (Fig. 56.10a–e) is a simple but practically useful method based on the anatomic site involved; type A1 refers to isolated zygomatic arch fracture, and types A2 and A3 are separation at the FZ suture and IOR, respectively. Type B is a complete monofragment type with separation at all five sites of articulation and type C which is multifragmented.

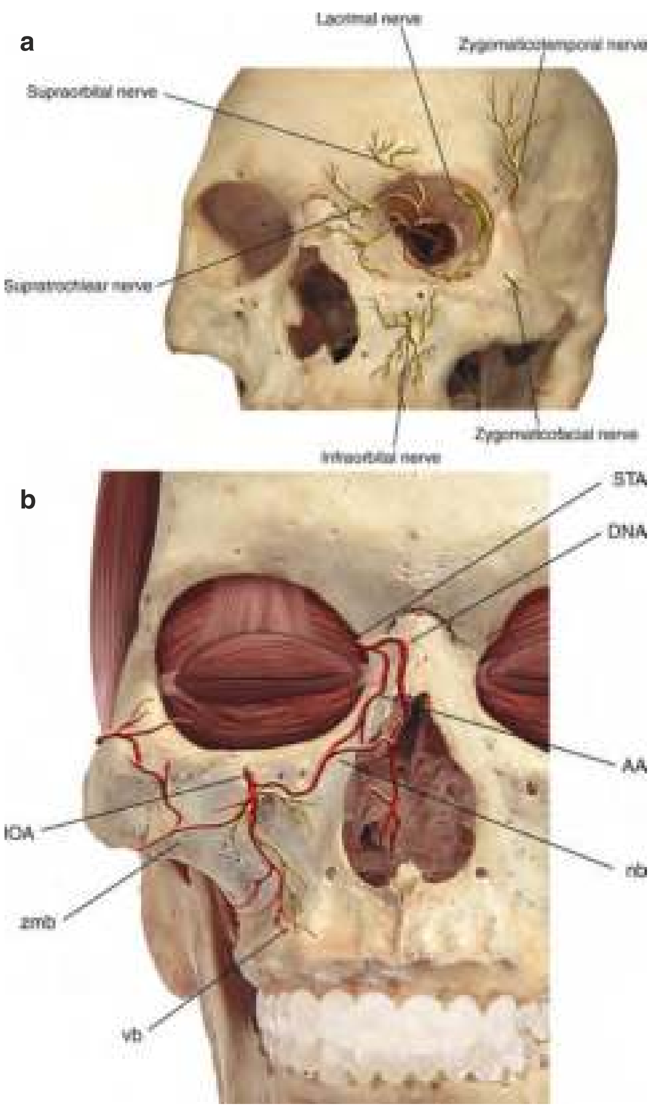
A special and rare variant of zygoma injuries includes ***avulsion*** of zygoma [18] (Fig. 56.11). These injuries result from tangentially directed forces with high velocity or greater energy. The fractured zygomatic fragment characteristically becomes a non-vascularized-free graft whose management is complex.

56.3.2 Classification of Arch Fractures

The fractures involving the zygomatic arch constitute a separate entity.

The various patterns of zygomatic arch fractures have been described by **Ozyazgan et al.** [19] (Fig. 56.12) based on the number of fracture lines and displacement of fracture fragments:

- Type 1 constitutes the isolated zygomatic arch fractures which are subdivided into (1) dual fracture (type I A) and (2) more than two fractures (type I B). This is further classified into V-shaped (type I B-V) and displaced fracture (type I B-D).
- Combined zygomatic arch fractures are referred to as type II, which can present as two variants: single (type II A)



©Association of Oral and Maxillofacial Surgeons of India

Fig. 56.6 **a**, **b** Neurovascular structures related to ZMC fractures. OA, ophthalmic artery; nb, nasal branch; zmb, zygomatico-malar branch; vb, vestibular branch

and plural fracture (type II B). Plural fractures are termed type II B-R when they are approximated or reduced and type II B-D, when displaced.

Yamamoto et al. classification [20] (Fig. 56.13) differentiates fractures based on displacement: type I, no displacement; type II, displacement with bone contact at all fracture lines; type III, displacement without bone contact at one fracture line; type IV, displacement without bone contact at two fracture lines; and type V, comminution or displacement without bone contact at three or more fracture lines. **Honig Merten et al**. [21] (H-M classification) (Fig. 56.14) classified zygomatic arch fractures based on CT findings as class I which indicated isolated tripod fracture, class II as an isolated stick fracture of the arch, and class III a combined fracture of the malar bone and the zygomatic arch.

56.4 Clinical Assessment

The clinical assessment of ZMC fractures is performed by a thorough examination of the face and the eye. As the zygoma forms an integral part of the orbit (floor and lateral wall), any trauma to the ZMC may have profound impact on the integrity of the globe and vision [2, 22]. This mandates a primary ophthalmic examination prior to facial examination.

56.4.1 Examination of the Eye

The globe is meticulously assessed for its form, position, and function. This is performed by a comprehensive examination protocol called “8-point eye exam” [23] provided by the American Academy of Ophthalmology (refer to Chap. 57).

56.4.2 Examination of the Face

The facial examination should focus on assessment of (1) facial symmetry and morphology and (2) functions such as mouth opening, vision, sensory perception, and occlusion.

The clinical characteristics of ZMC fractures [1, 4, 5] may be divided based on their cosmetic and functional implications (Box 56.1) .

Box 56.1: Clinical Features of ZMC Fractures

Cosmetic deficits	Functional deficits
• *Facial asymmetry due to* – Periorbital edema – Hematoma – Emphysema • *Facial asymmetry due to malpositioned zygoma* – Depression of malar prominence – Transverse facial widening – Changes in AP projection – Orbital dystopia • *Discoloration* – Subconjunctival hemorrhage – Periorbital ecchymosis • *Altered morphology/position of eye* – Anti-mongoloid slant – Increased scleral show – Hypoglobus/hyperglobus – Enophthalmos/ exophthalmos	• *Vision* – Diplopia – Loss of vision (partial/ total) • *Restricted mouth opening* • *Malocclusion* • *Neurological deficit* – Paresthesia (i) Infra-orbital nerve (ii) Zygomaticofacial nerve (iii) Zygomaticotemporal nerve – Paresis/palsy (i) Facial nerve • *Epistaxis/nasal congestion* • *Compartment syndromes* – SOF syndrome – Orbital apex syndrome

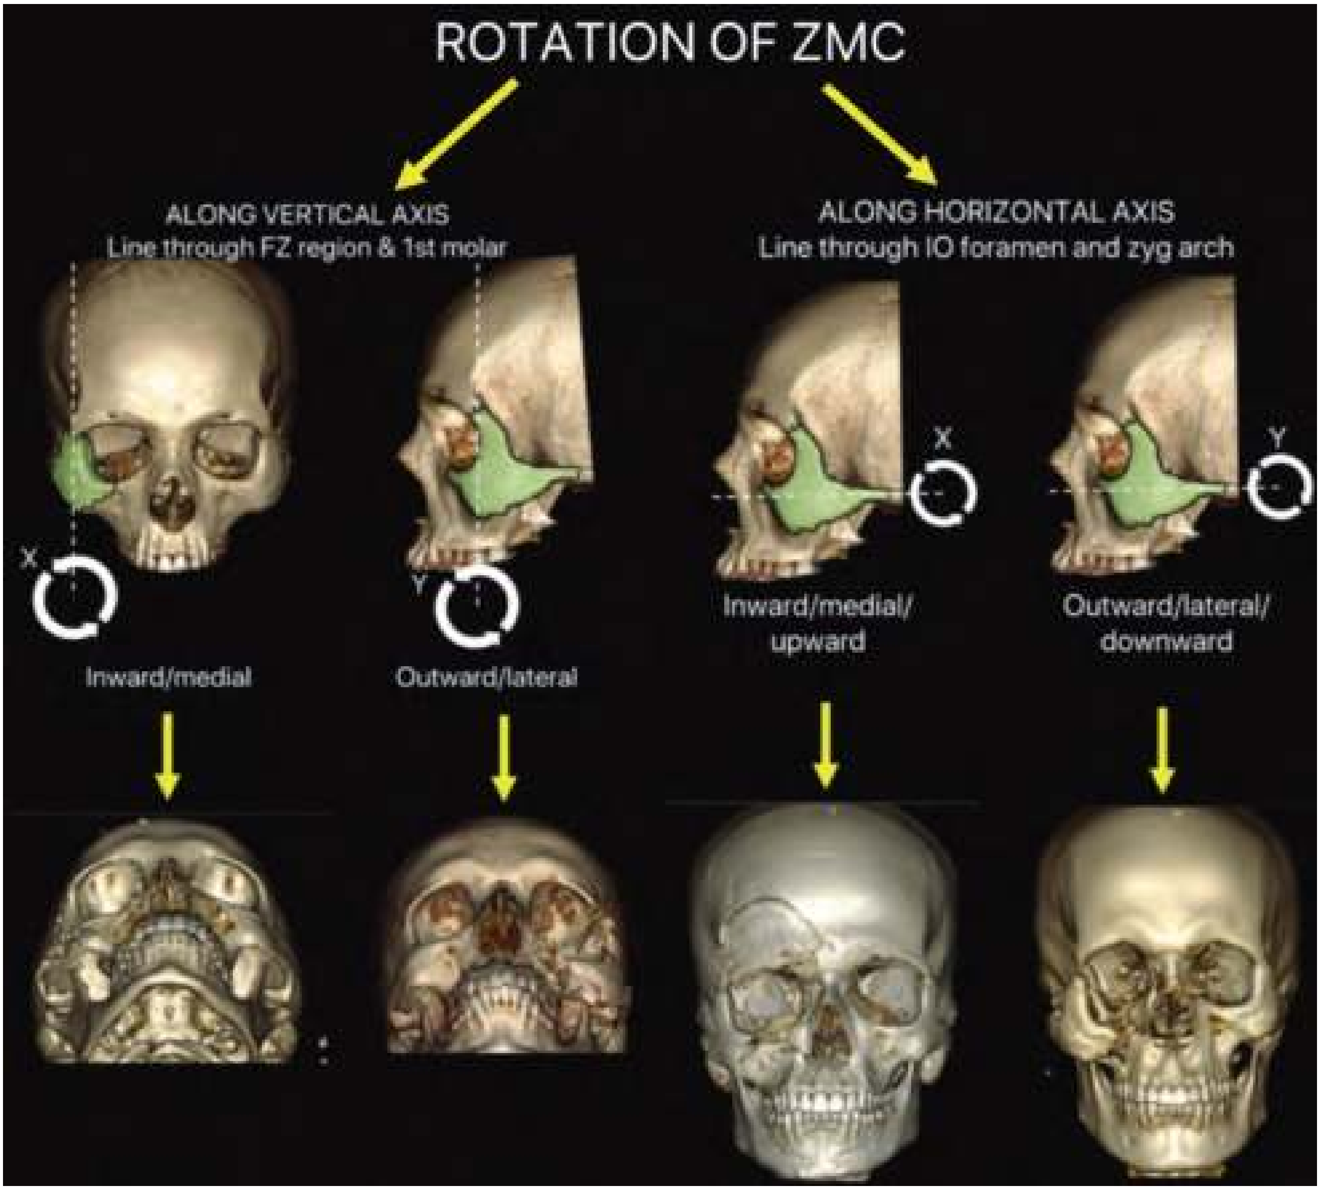


Fig. 56.7 Axes of rotation of ZMC fractures

A description of clinical features with their associated pathophysiology is provided below.

- *Periorbital edema and ecchymosis:* The edema and ecchymosis in ZMC fractures are more dramatic due to the loose connective tissue in the periorbital region. Ecchymosis is commonly seen in the circumorbital region and maxillary buccal sulcus (Fig. 56.15).
- *Subconjunctival hemorrhage (SCH):* Subconjunctival hemorrhage or hyposphagma (Fig. 56.15) often occurs in ZMC fractures due to collection of the blood into the subconjunctival space, secondary to hemorrhage from the surrounding periosteum. Characteristically, SCH in ZMC fractures does not have a posterior limit in contrast to SCH due to globe injuries [24]. It is important to note that SCH without a posterior limit is also seen in skull base fractures [25].Chemosis and hyphema are also seen in some cases.
- *Epistaxis:* Occasional epistaxis may be observed due to escape of pooled blood from the maxillary sinus following ZMC fracture. This is typically ipsilateral. Resultant nasal congestion is a common clinical finding.
- *Loss of facial prominence:* Displacement of zygoma due to trauma leads to the characteristic flattening of malar prominence (Fig. 56.16). This is well observed in bird's eye and worm's view. Examination by palpation is done

from behind the patient to detect malar depression. However, the flattening cannot be appreciated in the presence of moderate or severe edema.

- *Eye signs:* The eye signs are a very striking feature of zygomatic injury especially when rotated and inferiorly displaced. Inferior displacement of zygoma results in hypoglobus and an anti-mongoloid slant to the eye (Fig. 56.3b). Inferior or posterior displacement of the infra-orbital rim also causes lowering of the lower eyelid leading to increased scleral show (Fig. 56.17).

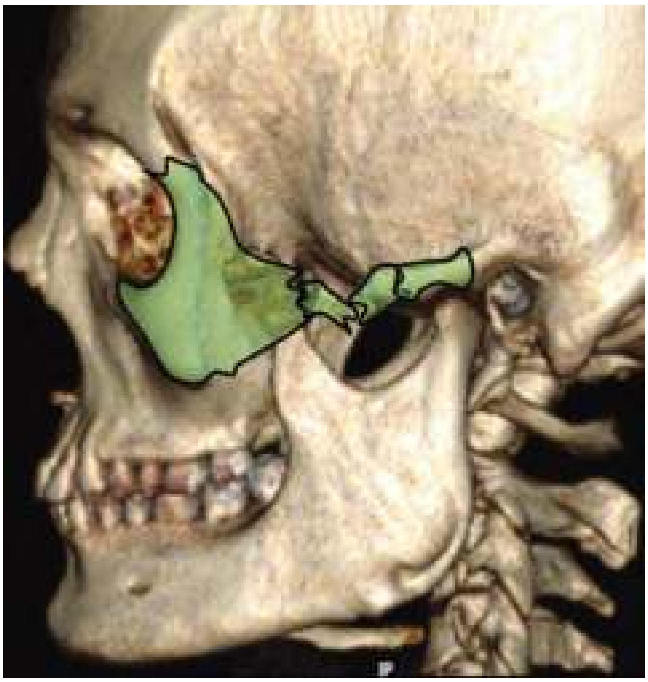

Fig. 56.8 Inferior displacement of zygomatic arch

The commonly observed variations in globe position are exophthalmos in posteriorly/medially displaced zygoma (Fig. 56.18a–c) and enophthalmos in laterally and inferiorly displaced zygoma (Fig. 56.19). En/exophthalmos resulting from ZMC fractures must be differentiated from enophthalmos arising from blow-out fractures involving the orbital floor. The clinical implications of the above are explained under "preoperative planning." Also, it is important to remember that the traditional assessment of en/exophthalmos by Hertel's exophthalmometer does not reflect the true position of the globe in displaced ZMC fractures because it uses the orbital rim as a point of reference. Naugle's which utilizes supraorbital rim as a reference is ideal in such cases [26]. However CT evaluation is the most preferred modality [27] (refer Chap. 57 on orbital fractures).

- *Tenderness* and *step deformity:* When edema is severe and inspectory findings are not conclusive, palpation gives more details. Tenderness on digital palpation, step deformity at the fronto-zygomatic, zygomatic buttress, and IOR are good indicators of fracture.
- *Air emphysema:* Palpation also helps to elicit air emphysema in the form of subcutaneous crackling. This occurs when there is a fracture through a sinus wall which allows air escape into the facial soft tissues. It usually disappears spontaneously, in 2–4 days [28]. However, this can be a potential cause of infection [29].
- *Reduced mouth opening:* Restriction in mouth opening can arise because of two reasons [30]: (1) mechanical obstruction to movement of the mandible by a retrodisplaced zygoma or a fractured zygomatic arch (Fig. 56.20a, b) and (2) a fractured arch impinging on the temporalis muscle causing reflex spasm/trismus. Likewise, injury to the masseter also can lead to trismus.

Fig. 56.11 Avulsion of zygoma

- *Paresthesia:* Infra-orbital nerve being closely related to the zygoma gets compressed or pulled in displaced or comminuted ZMC fractures leading to paresthesia along the lower eyelid, upper lip, and lateral aspect of the nose. Occasionally, a patient may also have altered sensation involving the maxillary teeth leading to a perception of altered dental occlusion [5]. The other theory put forward for altered occlusion is the flexing of the ipsilateral maxillary alveolus leading to premature molar contact [31]. Paresthesia involving the zygomaticofacial and zygomaticotemporal nerves may be present. In rare occurrences, injury to the facial nerve leading to paresis has been observed in severely displaced or high-velocity injuries of the zygoma [15].
- *Altered/loss of vision:* Binocular diplopia is a common finding. The diplopia that develops following trauma can be the result of soft tissue (muscle or periorbital) entrapment, neuromuscular injury, intra-orbital or intramuscular hematoma/edema, or a change in orbital shape, with displacement of the globe [32]. A forced duction test (FDT) (Fig. 56.21) would confirm any physical impediment to ocular motility [4]. Diplopia due to edema/hematoma resolves in a few days, while that due to muscle entrapment does not, necessitating surgical correction.

  Another rare but serious sequel to ZMC fractures is traumatic optic neuropathy which may present as total or partial loss of vision [33].

56.5 Imaging for ZMC Fractures

Radiological assessment is essential for accurate diagnosis and assessment of severity of the fracture.

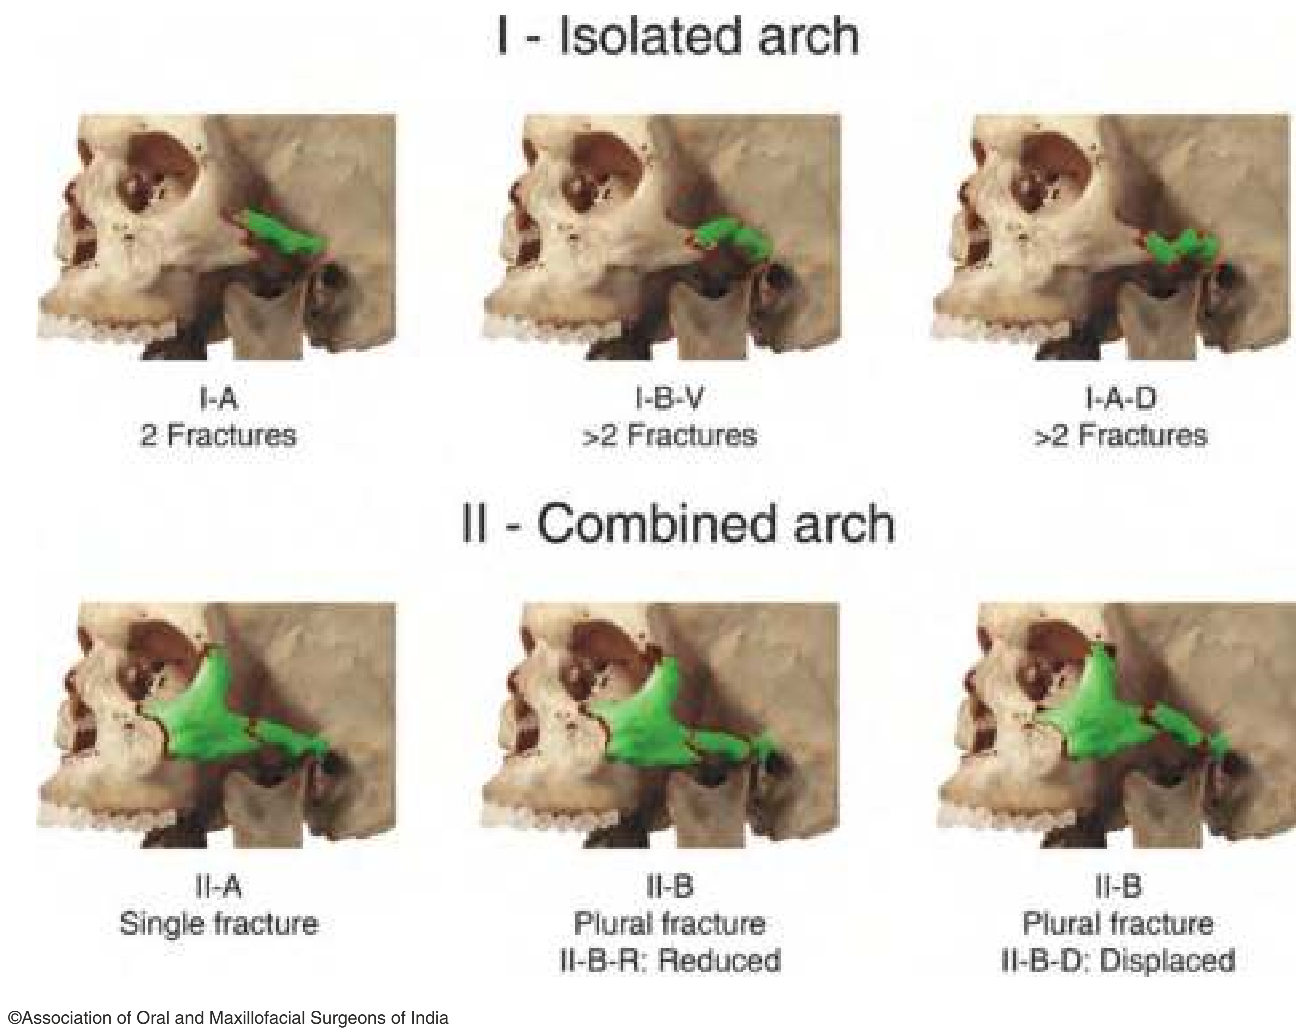

Fig. 56.12 Ozyazgan et al. classification of zygomatic arch fractures

- *Plain radiographs* [31]*:* Conventional radiographs continue to remain the mainstay of imaging at some centers. Conventional radiographs may also be useful in the post-operative phase, to assess fracture reduction. However conventional radiographs are limited by superimposition of structures.

  The commonly used views include the waters view (37° occipitomental) (Fig. 56.22) which provides good visualization of the fractured zygoma and helps in comparing with the contralateral side. Tracing the McGrigor-Campbell lines [34] (refer Chap. 55) or the Dolan's lines [35] are useful in identification of fractures on the Water's view (Box 56.2).

Box 56.2 (Fig. 56.22): Radiographic Appearance in ZMC Fracture

- The submentovertex/jug handle view [31] (Fig. 56.23) offers the best representation of fractures of the arch. Loss of elephant trunk appearance which is indicative of arch fracture is well appreciated in this view.

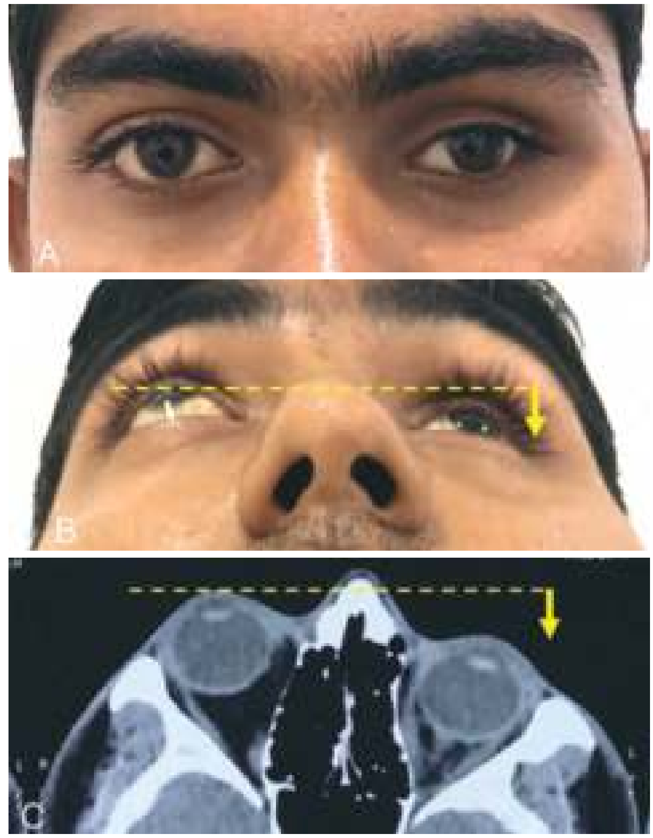

Fig. 56.19 Enophthalmos. (**a**) Frontal view showing enophthalmos on left side. (**b**) Basal view of the same patient showing enophthalmos on left side. (**c**) Axial CT section demonstrating enophthalmos of the left eye

- *Computed tomograms:* CT remains the gold standard [31]. It enables a three-dimensional assessment of the fracture along with demonstration of soft tissue entrapment between the fracture fragments. Identification of sphenozygomatic diastasis is best appreciated on CT scans. They also aid in volumetric analysis of the orbital cavity and deficits of the orbital floor. The features demonstrated in different CT sections are highlighted (Fig. 56.24a–d). Figure 56.25 demonstrates CT scan image with volume rendering, which is useful in assessing the spatial orientation of fractured ZMC.
- *USG* is a useful tool for diagnosis of ZMC fractures with high degree of sensitivity for fractures of the arch and infra-orbital rim with the significant advantage of "zero" radiation exposure [36].

The role of intra-operative imaging is discussed in the later segments of the chapter.

56.6 Principles of Management

56.6.1 Indications and Contraindications for Intervention [5, 37]

Surgical outcome of ZMC fractures is greatly influenced by two important factors: (1) choosing the right indications for intervention and (2) ideal time for surgery. Not all fractures of the ZMC require surgical intervention. The decision to intervene should be based on signs and symptoms and presence of functional impairment (Fig. 56.26).

1. It is not necessary to intervene surgically if the fracture is incomplete, undisplaced, or minimally displaced with no compromise in esthetics or function. But such patients must be advised to follow soft, non-chewy diet for 2–6 weeks and monitored to identify displacement [38].
2. Indications for surgery include (1) presence of cosmetic defects in the form of facial deformity, loss of lower eyelid support, or ocular dystopia; (2) functional deficits such as limitation of mouth opening, sensory nerve deficit, and impaired ocular movements; and (3) ZMC fracture associated with OCR reflex in children (please refer to Chap. 57).
3. Postponement of surgical intervention is considered when the general neurologic status of the patient is questionable.
4. Surgical intervention is relatively contraindicated when the involved side has the only seeing eye. In a patient willing for surgery, "potential loss of vision" has to be included in the informed consent.

56.6.2 Timing of Intervention [39]

ZMC fractures are not emergencies, and treatment can be delayed, if necessary.

- When the decision is "no immediate intervention," surgery may be postponed for up to 2 weeks, following which a reassessment may be made.
- When the indications are questionable, for example, presence of severe edema or fractures with minimal displacement, it is advisable to wait for the edema to subside so that the deformity may be assessed better.
- When the indications are definite, immediate intervention provides better outcomes due to minimal soft tissue scarring and easier reduction of fractures.

56.6.3 Surgical Objectives

Management of ZMC fractures is aimed at achieving the surgical objectives highlighted in Box 56.3 [37].

Box 56.3: Surgical Objectives in ZMC Fracture

- Restoration of facial esthetics
- Restoration of premorbid ocular function
- Correction or prevention of enophthalmos/exophthalmos
- Restoration of premorbid antral function
- Restoration of mandibular range of motion
  Mouth opening of 40 mm, excursion – 4–6 mm

56.6.4 Need for Prophylactic Antibiotics

ZMC fractures may be categorized into three classes based on their propensity to develop postsurgical infection: clean fractures (isolated arch fractures), clean-contaminated (ZMC fractures compound into the antrum), and dirty (fracture which is open to exterior). While type three fractures require regular antibiotic prophylaxis, types 1 and 2 show minimal rates of infection and may either need "no" antibiotic prophylaxis [40] or a modified single-day postsurgical regimen [41].

56.7 Preoperative Planning [42]

ZMC fractures show high propensity for over or under reductions due to lack of objective intra-operative measures to assess reduction. This may be overcome with accurate pre-

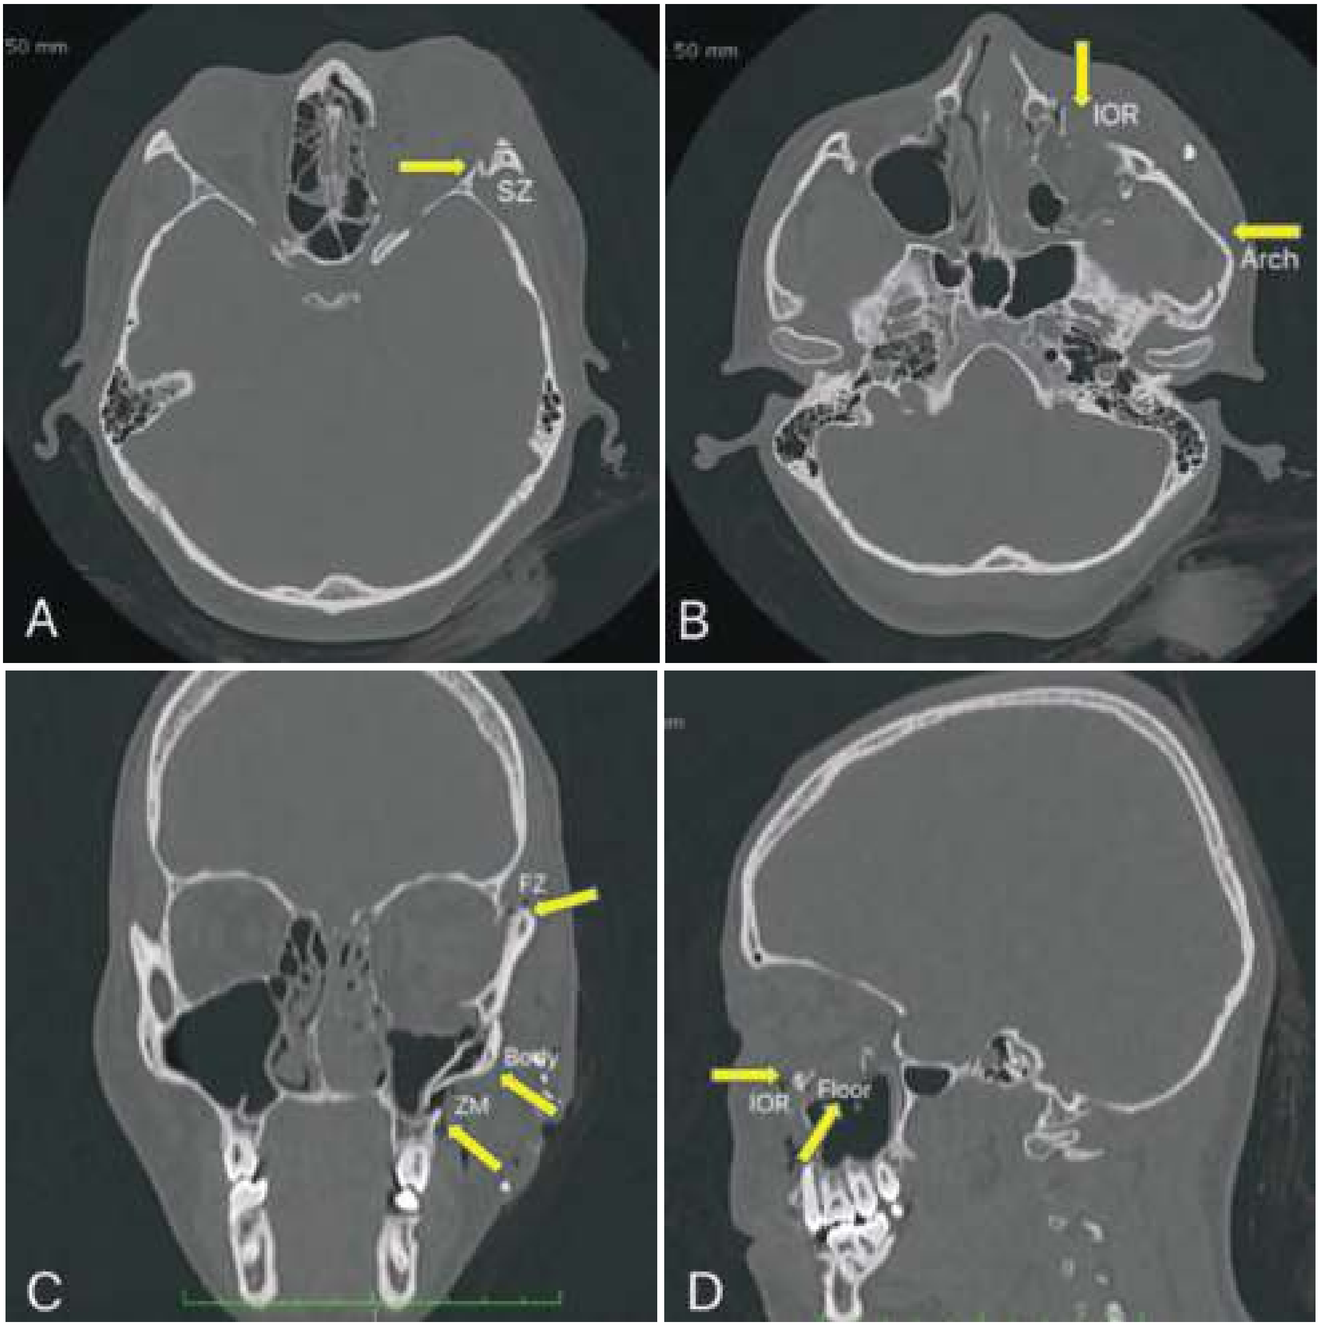

Fig. 56.24 CT scan of patient with left ZMC fracture. (**a**) Axial view demonstrating overriding of fracture fragments at SZ suture. (**b**) Axial section demonstrating fracture at the IOR and buckling of arch. (**c**) Coronal section showing separation at the FZ and ZM sutures with medial displacement of the body of zygoma. (**d**) Sagittal section demonstrating posterior displacement of IOR and large blow-out fracture of orbital floor

operative planning which helps in realizing surgical objectives in a predictable manner.

Preoperative planning includes three vital steps:

(i) CT evaluation
(ii) Model surgery
(iii) Soft tissue analysis

56.7.1 CT Evaluation

Proper CT evaluation is absolutely essential for choosing the ideal treatment; CT plays a very important role in differentiating en/exophthalmos due to ZMC fractures from those due to orbital fractures. This helps in arriving at a decision regarding internal orbit reconstruction (Box 56.4).

Box 56.4: Relative vs. Absolute En/Exophthalmos

	Enophthalmos in ZMC **Relative**	Enophthalmos in ZMC +orbit fracture **Absolute**
Etiology	Change in globe position due to displaced zygoma	Change in globe position due to fracture of orbital floor
Surgical management	Restoration of orbital rims by reduction and fixation of ZMC fracture alone	Restoration of orbital rims by reduction of ZMC fracture as well as reconstruction of orbital floor

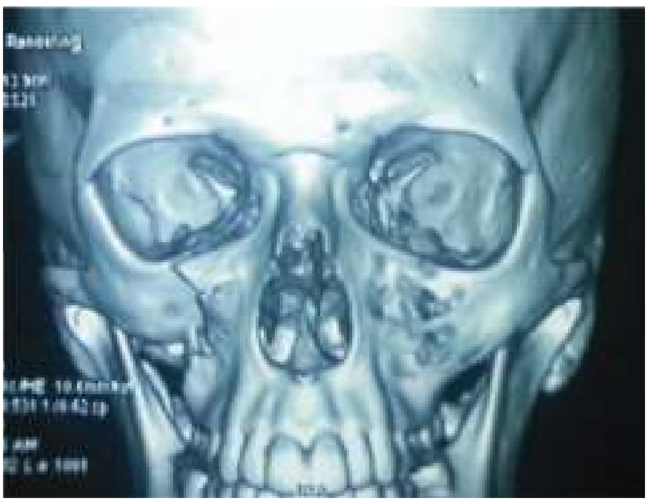

Fig. 56.25 CT with 3D volume rendering demonstrating medially rotated right ZMC fracture

56.7.2 Model Surgery

The process begins with obtaining CT scans of the patient with minimum slice thickness of 0.6 mm. This is followed by two different sequences of workflow (Fig. 56.27) which are described below.

(A) **Planning Using Physical Models**
The first step involves generation of a physical stereolithographic model (STL) from the CT scan of the patient. There are two methods by which this can be done.

1. **STL model with the actual deformity:** This model presents the post-traumatic deformity, as observed clinically. A routine model surgery is then performed, by which the displaced fragments are cut and repositioned to obtain optimal anatomical form.

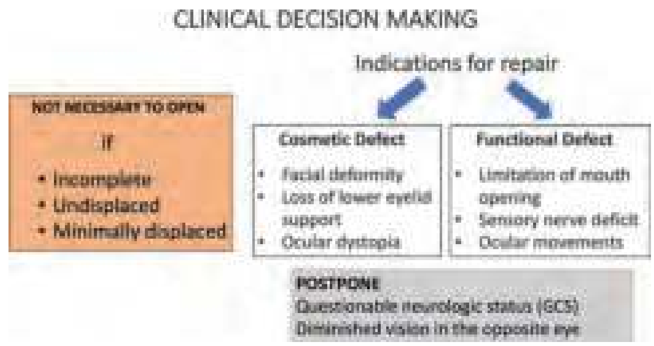

Fig. 56.26 Indications and contraindications for intervention

The repositioned fragments are stabilized temporarily with wax. The fixation devices (miniplates) are then pre-contoured over the model. Such pre-contoured implants are used to guide intra-operative fracture reduction as well as fixation. Figure 56.28a–d demonstrates the sequence described.

2. **STL model after mirroring:** CT scan is used to generate a virtual model wherein the normal side is mirrored onto the fractured side. The virtual model is used to print a physical model which demonstrates the skull which is bilaterally symmetrical, mimicking ideal reduction status. Similar to the earlier method, implants for fixation are pre-contoured over this model to help achieve optimal results intra-operatively. Figure 56.29a–d demonstrates a similar clinical scenario.

(B) **Planning Using Virtual Models**
This method utilizes the complete spectrum of computer-assisted surgical planning. A CT scan is obtained to create a virtual model on which the entire surgical sequence of reduction is performed and on which the stents for intra-operative guidance are designed. Intra-operative stents are printed from these virtual designs. There is no physical "handheld" model here (Refer Chap. 41).

- In the case of a unilateral ZMC fracture, the normal side is mirrored to the fractured side to obtain bilateral symmetry. CAS technology is then utilized to design "guidance stents" on the mirrored side. These stents can be utilized intra-operatively to (1) verify ideal reduction position in primary trauma or (2) design the osteotomy and repositioning, in secondary corrections. Another important advancement in recent years is the design and printing of "patient-specific implants" (PSI) using virtual planning. These customized fixation devices double up as guidance stents also (Refer Fig. 57.54).
- In bilateral ZMC fractures [43], mirroring is not an option, and the ideal sequencing for such cases is discussed in Sect. 56.14, of this chapter.

56.7.3 Soft Tissue Analysis

Li et al. [44] have described a technique for 3D simulation and prediction of soft tissue—outcome analysis in ZMC fractures. This process enables prediction of postoperative soft tissue changes in patients with ZMC fractures who are indicated for primary/secondary surgical interventions. The planning involves utilization of CT data and 3D stereophotography for the analysis. The technique may also be utilized for evaluation of postsurgical results.

56.8 Reduction of ZMC Fractures

Reduction of zygoma is unique in two aspects:

1. Unlike the other facial bones, “reduction alone” may be the sole treatment in many cases of ZMC fractures.
2. The surgical approach for reduction may be different from that for fixation.

Fracture reduction may be done either by direct or indirect method, and the approaches may be extraoral or intraoral [1].

56.8.1 Direct vs. Indirect Method

The indirect method is a blind technique where fracture is reduced without exposure of the fracture site (e.g., Gillies reduction), while direct method involves reduction of the fracture under direct visualization (e.g., coronal approach to reduce arch fracture). The differences between the two methods are shown in Fig. 56.30. However, indirect method is more commonly practiced. Open method is resorted to when the ZMC fracture is (1) severely displaced, (2) complex or comminuted, (3) when stable reduction is doubtful, and (4) there is a need for internal orbit reconstruction. However, no “single technique” is superior, and sometimes, a combination of techniques is more effective.

56.8.2 Extraoral Techniques

The extraoral reduction techniques may be either percutaneous, temporal, or endoscopic [1, 45].

- ***Temporal approach*** [46], commonly called the Gillie's (Figs. 56.31a–f and 56.32a), is the most popular method of ZMC reduction. This approach is favored because the incision is placed within the hairline which does not leave a visible scar. It also offers a very predictable force during reduction and may be used for reduction of both the arch as well as the zygoma. The technique is based on the anatomical basis that the plane between the temporalis fascia and the temporalis muscle offers direct access to the zygomatic arch and zygoma. The only contraindication to this approach is the presence of concomitant temporal bone fracture. The incision is placed at a level 2 cm above the helix of the ear, paralleling the anterior branch of the superficial temporal artery, well within the hairline (Fig. 56.33). Dissection is carried down through the skin, subcutaneous tissue, and galea aponeurotica (temporoparietal fascia—TPF) to reach the temporalis fascia.

INDIRECT / CLOSED	DIRECT / OPEN
# site is not visualized Incision & Instrumentation away from # site	# site is visualized Instrumentation at # site
Difficult to assess reduction	Can assess reduction
Precise fixation is not possible	Precise fixation is possible
Surgical outcome- not predictable	Predictable results

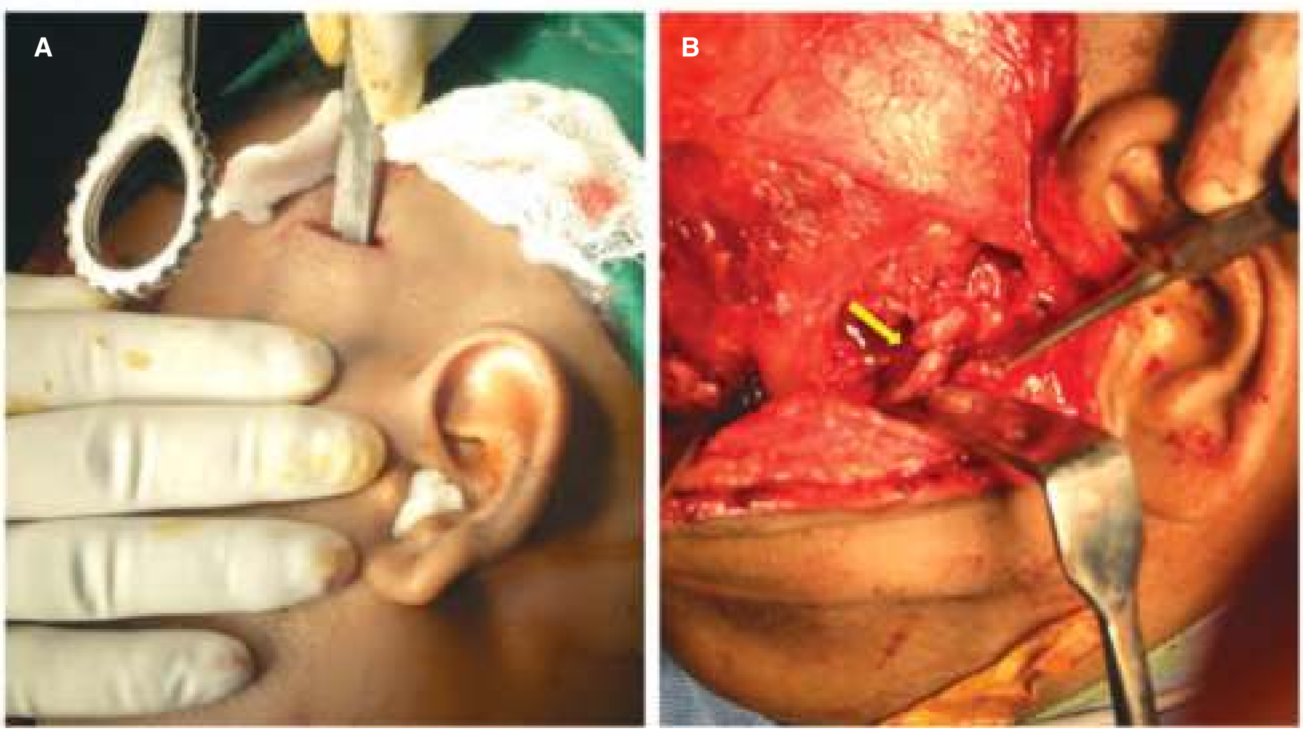

Fig. 56.30 (**A**) Indirect vs (**B**) direct reduction

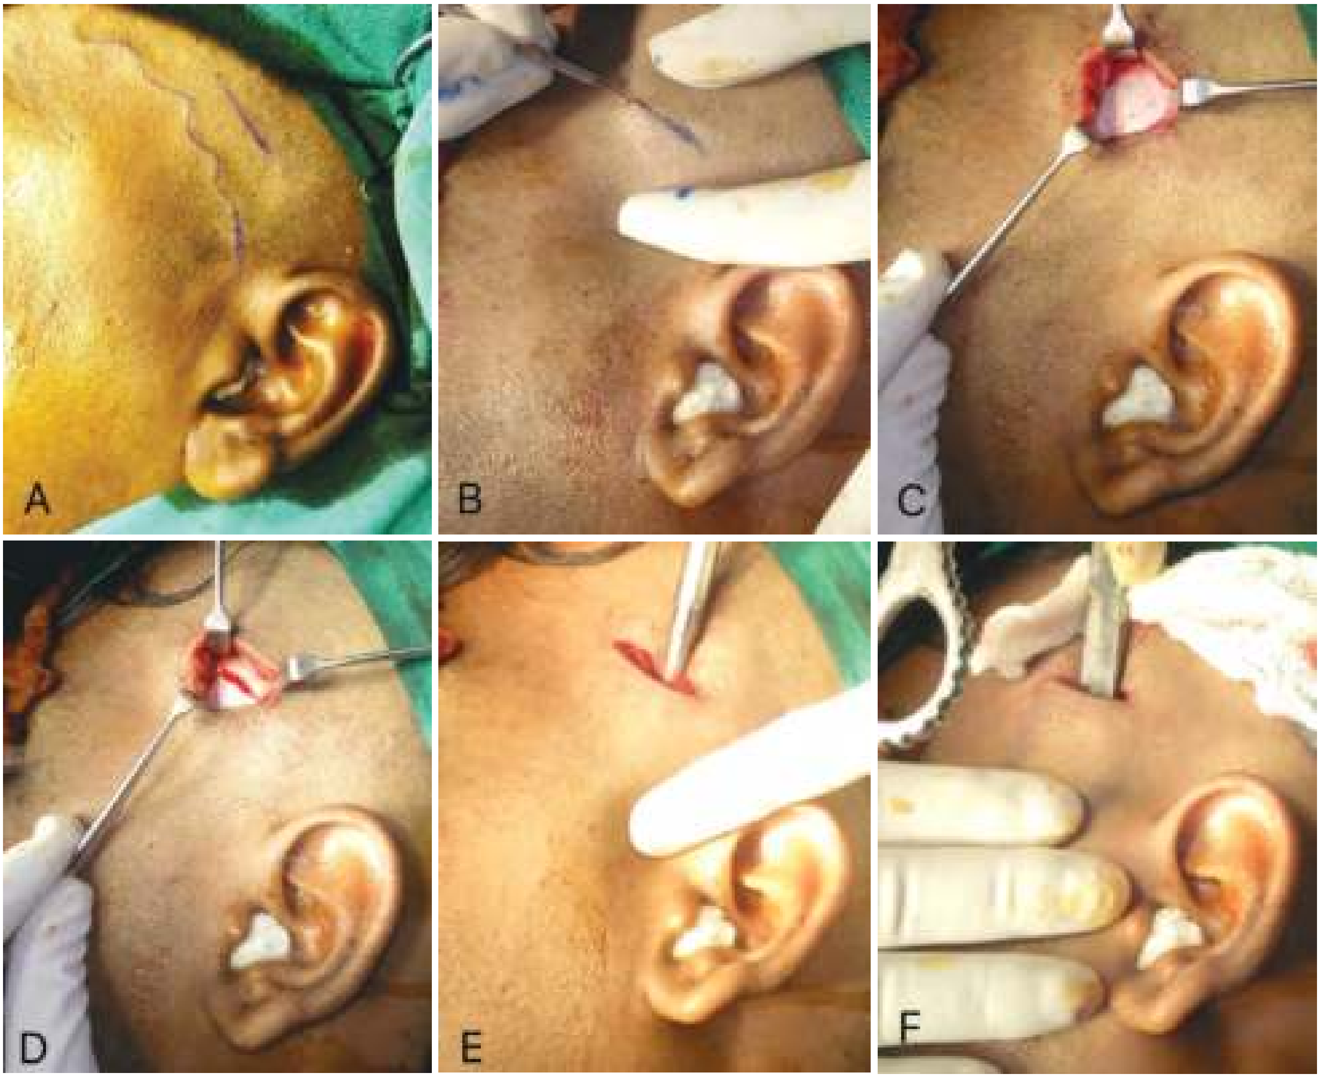

Fig. 56.31 Gillies temporal approach. (**a**) Marking of incision parallel to frontal branch of superficial temporal artery. (**b**) Placement of incision. (**c**) Exposure of deep temporal fascia. (**d**) Incision through deep temporal fascia exposing temporalis muscle. (**e**) Developing plane of elevation with periosteal elevator. (**f**) Placement of Rowe's zygomatic elevator for elevation

An incision is made through the temporalis fascia to reveal the underlying temporalis muscle. A Howarth's elevator is inserted between the temporalis fascia and the muscle, to create a plane for the zygomatic elevator. Two types of zygomatic elevators, namely, the Bristow's and Rowe's (Fig. 56.34a), are commonly used; the Bristow' s has a single flat and elongated working tip attached to a handle and is used like a spatula for elevation, while the Rowe's elevator has an additional arm attached to the working tip which serves two purposes: (1) to provide the necessary countertraction during elevation so that it relieves the fulcrum off the temporal bone and (2) to evaluate the approximate depth of insertion of the working tip when inserted into the tissue. The zygomatic elevator is positioned in the plane created, directed inferiorly to reach the deeper surface of the zygoma and carefully elevated, while an ironing motion is used to smoothen the collapsed arch form. Care is taken not to lever the elevator against the skull (Video 56.1).

Clinical Tip

1. It is good practice to keep a roll of gauze under the zygomatic elevator to prevent injury to the temporal bone.
2. Instead of extensive shaving of the temporal hair for a Gille's approach, a small patch (1cm by 3cm) of shaving/close trimming of hair can be done for better cosmesis.

- **Percutaneous methods** make use of a minimal facial skin incision, usually right over the zygoma or the lateral brow (Dingman's method) through which instruments may be inserted to manipulate and elevate the displaced zygoma.

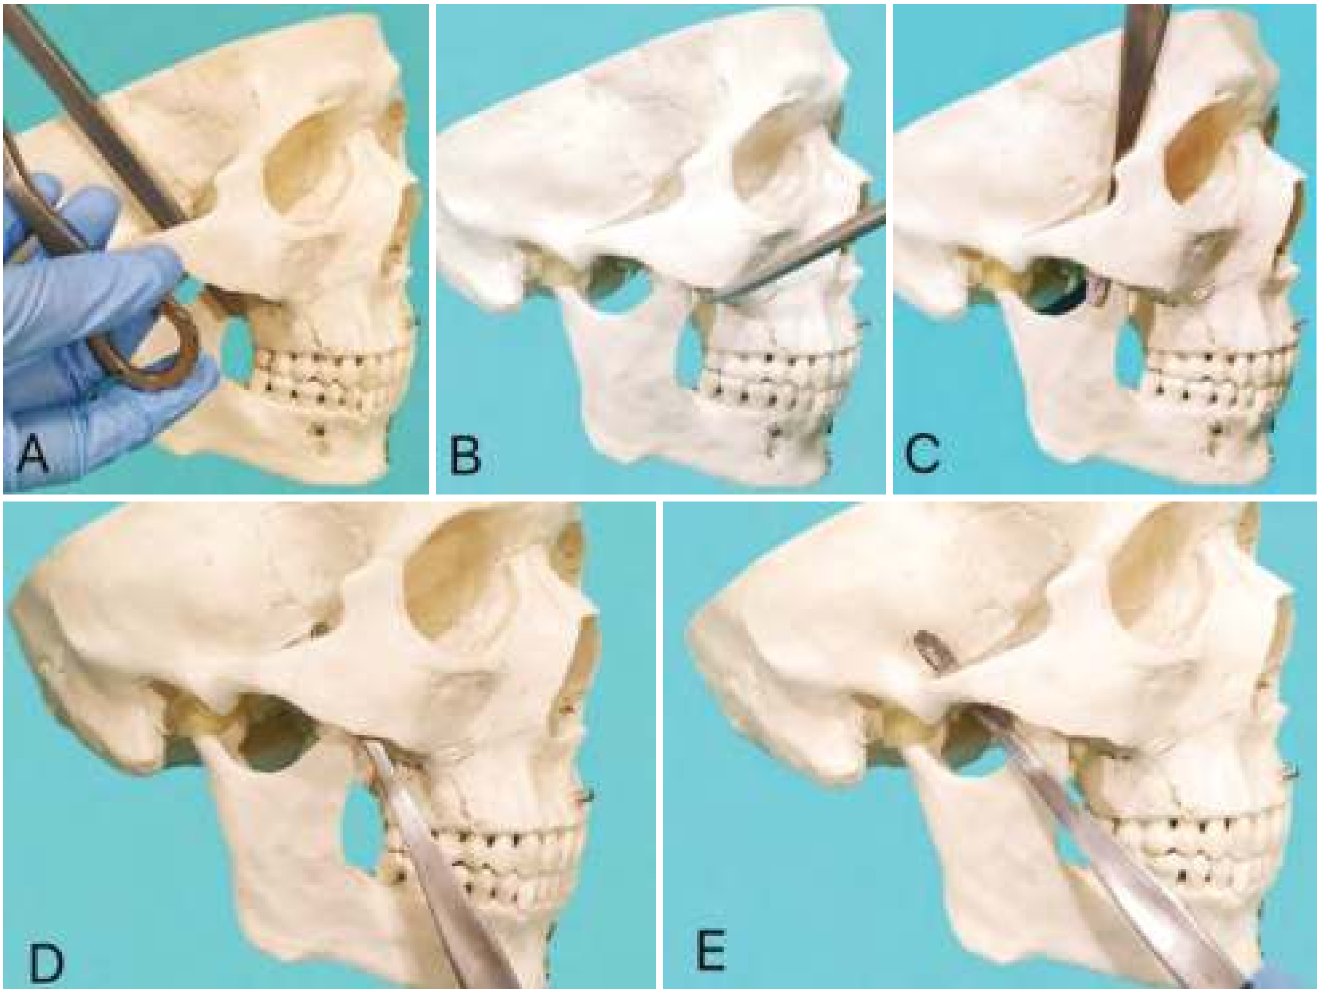

Fig. 56.32 Different approaches for reduction of fractured ZMC. (**a**) Gillie's. (**b**) Poswillo. (**c**) Dingman. (**d**) Balasubramaniam. (**e**) Quinn

– *Poswillo's* approach. This involves a stab incision made at the point of intersection of two imaginary lines—a horizontal from the base of the nose and a vertical from lateral canthus (Fig. 56.35a, b). The incision is oriented along the skin crease, just enough for a Poswillo hook [47] to be engaged underneath the body of the zygoma (Fig. 56.32b and Fig. 56.34b). And the impacted zygoma is pulled upward or outward. Skin incision is closed with a single suture. Reduction through a zygoma approach may also be performed by using a Carroll-Girard screw [48]/universal bone reduction screw (Fig. 56.34c).
– *Dingman's lateral brow approach* [49] (1964) (Fig. 56.32c)

  This technique is performed through a standard lateral brow approach where the fracture is visualized by a direct approach to the bone after incising through the skin, subcutaneous tissue, and periosteum. An elevator is then passed laterally and posterior to the orbital rim into the temporal fossa. The temporal aponeurosis (attachment of the deep temporal fascia to the lateral orbital rim) is incised, and the elevator is passed beneath it to lift the arch or the body of the zygoma in an upward, forward, and outward fashion. The original description by Dingman utilized trans-osseous wiring for stabilization of the front-zygomatic suture. However current methods incorporate the use of miniplate osteosynthesis through this approach.

56.8.3 Intraoral Techniques

The greatest advantage of intraoral techniques is "no skin incision." Commonly followed methods are:

- *Balasubramaniam's/Keen's approach* (upper buccal sulcus approach) [50] (Fig. 56.32d)

  This approach uses a vestibular incision behind the zygomatic buttress. A Howarth's periosteal elevator is inserted in a supraperiosteal plane to engage the infratemporal surface of the zygoma. Reduction is achieved with an upward, forward, and outwardly directed force. When greater force is needed to elevate as in impacted zygomas

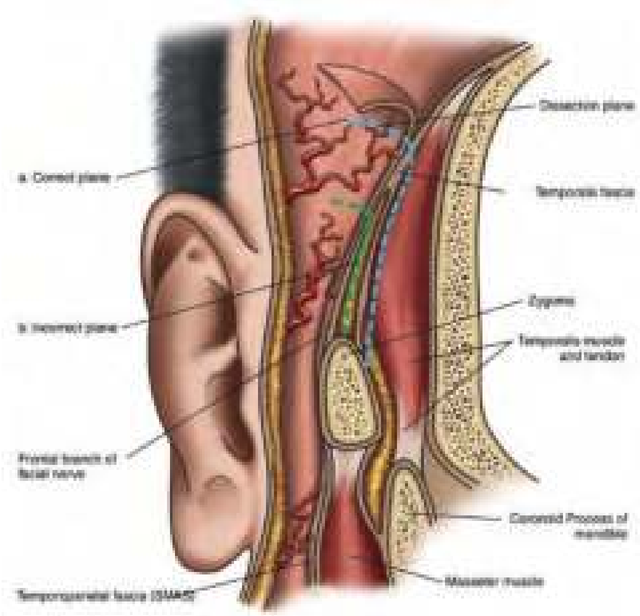

Fig. 56.33 Gillie's correct plane for elevation. It is important to understand that the deep temporal fascia divides into two, to enclose the zygomatic arch and the fat above, approximately 2 cm above the arch. An incision placed too low may mislead the young surgeon into the fat plane (b, lateral to the arch) rather than the subfascial plane (a, medial to the arch) (Also refer Fig. 85.1a)

or delayed presentation, a Bristow's/Rowe's zygomatic elevator (Fig. 56.36) or the arm of an upper anterior forceps may be used. The technique offers more mechanical advantage than the extraoral method; less force is needed to elevate, because the force is directed entirely at the center of the zygomatic body, which is considered more effective.

- *Quinn's procedure* (lateral coronoid approach) [51] (Fig. 56.32e) employs an incision over the anterior border of the ramus. An elevator is inserted in a supraperiosteal plane, lateral to the coronoid process and paralleling the temporalis tendon to reach the medial surface of the zygomatic arch. Elevation of the arch may be done in an ironing fashion.

Both the abovementioned intraoral techniques are supraperiosteal methods.

56.8.4 Reduction of Zygomatic Arch

Elevation of the depressed arch is usually performed in an indirect manner, using the Gillie's technique. However numerous techniques have been advocated in literature. These include the "roller-coaster" lateral brow technique [52] and methods using percutaneous towel clip [53], traction suture [54], Foley's catheter [55], K wire [56], and Dingman elevator [57] to restitute the arch anatomy.

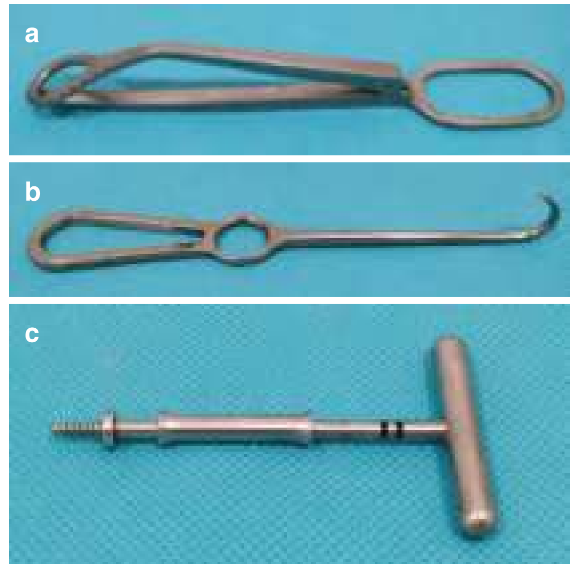

Fig. 56.34 Instruments for reduction. (**a**) Rowe's . (**b**) Poswillo hook. (**c**) Universal bone reduction screw

56.8.5 Intra-operative Assessment of Reduction

The intra-operative assessment of reduction is a critical step in zygoma management, especially in closed reduction. The methods commonly used are (1) clinical assessment, (2) imaging, and (3) use of prefabricated guides/stents.

1. ***Clinical assessment*** is usually done by eyeballing, comparing with the normal side or palpation of the rims for steps. However, the adequacy of reduction may be difficult to assess intra-operatively because of edema as well as patient position. Audible click during manipulation is also indicative of reduction [58]. Surgical exposure of multiple suture sites is the other method to confirm reduction [59] but is less favored because of surgical morbidity. However, exposure at all sites of articulation is not required; two sites are considered perfect indicators of accurate reduction [5] (Box 56.5).
2. ***Intra-operative imaging*** [58] such as C-arm [60] (Fig. 56.37a, b), CT [59], O arm [61], or endoscopes [45] are valuable guides in confirming reduction of ZMC fractures. However, use of intra-op imaging other than endoscopes mandates use of lead aprons by operating room personnel to prevent radiation exposure.
3. ***Prefabricated guides/ stents*** [62] are valid tools which ensure accuracy of reduction, intra-operatively.

Box 56.5: Indicators of Accurate Reduction of ZMC #

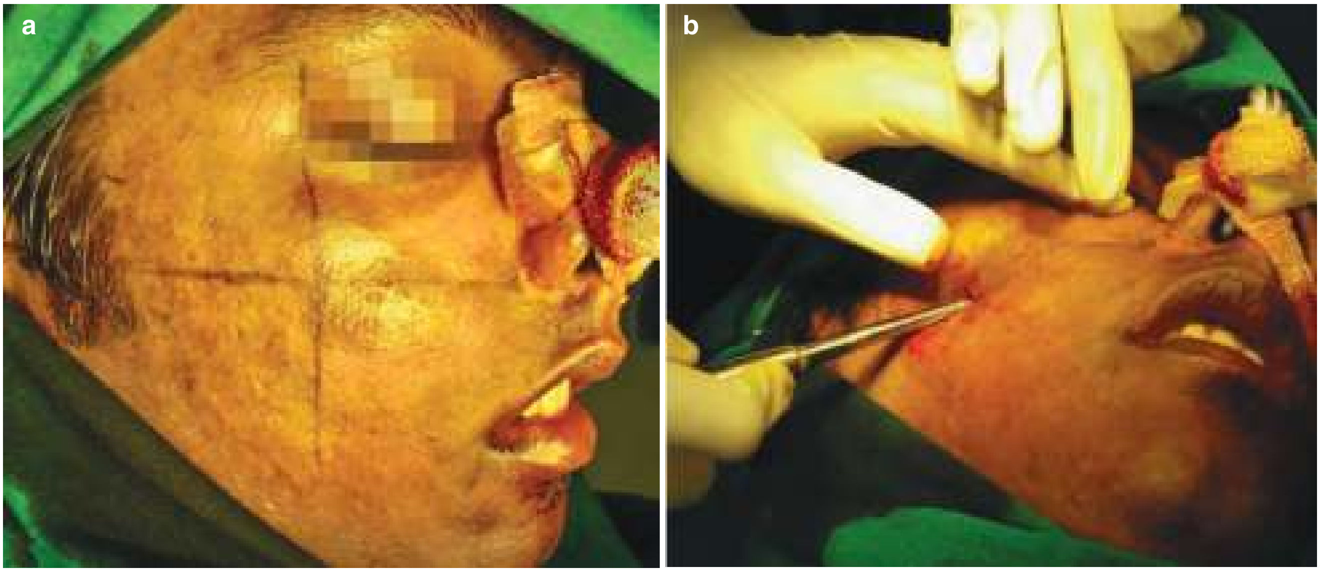

Fig. 56.35 Percutaneous reduction with Poswillo's technique. (**a**) Marking on skin. (**b**) Percutaneous insertion of bone hook

Fig. 56.36 Balasubramaniam's technique

56.8.6 Precautions During and After Reduction

Manipulation of zygoma during reduction has been known to cause certain complications such as bleeding from infra-orbital vessels [16]. Use of controlled force during indirect reduction greatly reduces such complications. It is prudent to watch out for stimulation of Oculocardiac reflex (OCR) [63] as described later in the text. OCR may also be prevented by administering regional blocks before elevation [64].

Once the reduction is completed and found satisfactory, the fracture fragments need to be maintained in the reduced state. A Zimmer splint [65] (preformed aluminum splint with foam on the undersurface) may be adapted to the reduced arch and secured with sutures. It is maintained in situ for 2–3 weeks.

Finally, it is mandatory to do a force duction test (FDT) after elevation of zygoma [5] (Box 56.6).

Box 56.6: FDT Is Mandatory After Reduction of ZMC Fractures (Fig. 56.21)

During reduction of ZMC fractures, as the fractured bones get realigned to normal anatomical position, entrapment of surrounding soft tissue or muscles may occur between the fragments

This may lead to port-surgical diplopia, necessitating a surgical revisit.

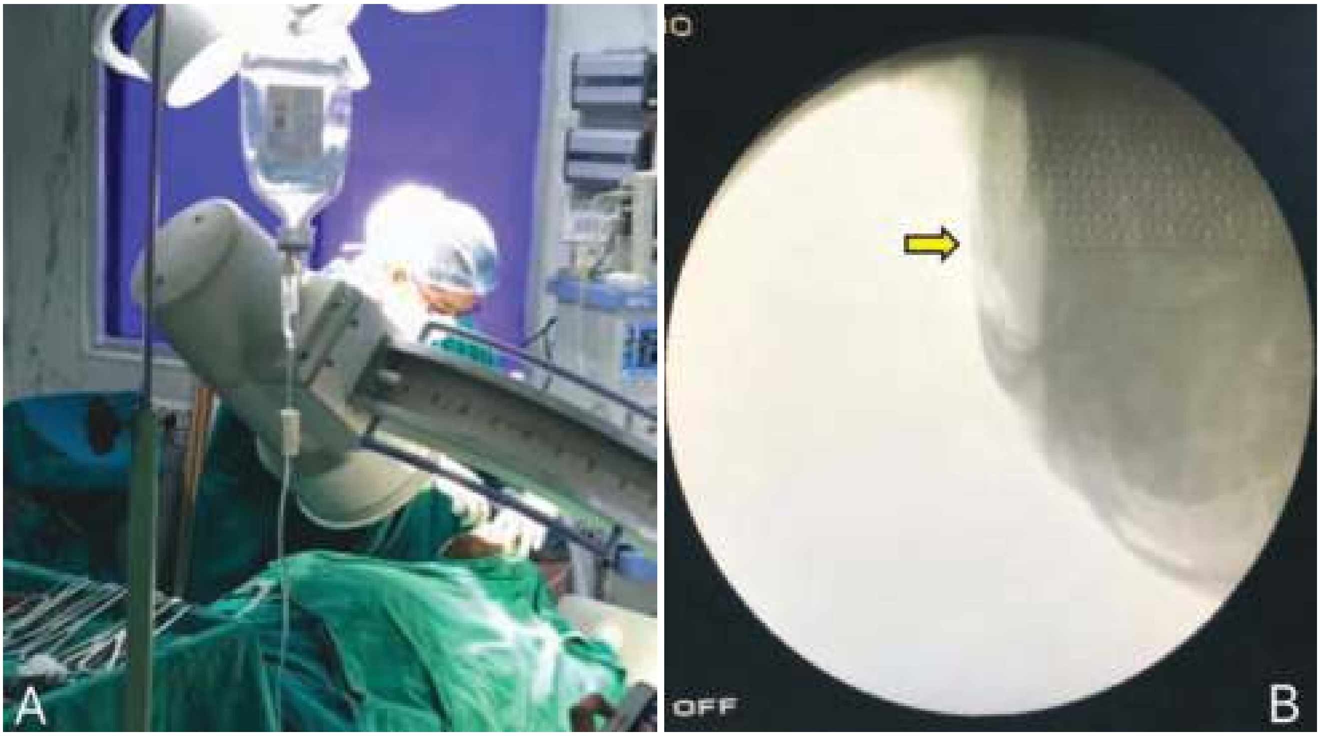

Fig. 56.37 Intra-operative assessment of reduction using C-arm. (**a**) Intra-operative positioning of C-arm. (**b**) Image demonstrating zygomatic arch after reduction

56.9 Fixation and Stabilization of ZMC Fractures

56.9.1 Need for Fixation

Fixation needs of ZMC fractures depend on the post-reduction stability. Classification of fracture patterns by Rowe and Williams [1] provides guidance on assessment of fracture stability after reduction. Any fracture classified as stable after reduction does not require fixation, while those considered unstable, mandate fixation. However, a practical method would be to apply moderate digital pressure on the malar eminence after reduction. Displacement secondary to this maneuver, requires fixation [59]. The algorithm proposed by Rodrigo and Belini et al. is also a practical guide to manage ZMC fractures which are not associated with orbital component [3]. For ZMC fractures with orbital involvement, Ellis and Perez advocate guidelines for orbital reconstruction based on CT evaluation. Most of the studies indicate increase of fixation points from 1 to 2, 3, and 4 points based on the status of intra-operative stability after reduction. Involvement of orbit leading to changes in intra-orbital volume requires orbital reconstruction [59].

Box 56.7: Ideal Sequence of Fixation

1. Vertical buttress—to restore facial height
2. Zygomatic arch—to restore anteroposterior projection

56.9.2 Fixation Principles

The current dictum is “any zygoma which when fractured and displaced must be fixed” [37]. The objectives are to achieve a 3D reconstruction (transverse width, vertical height, and anteroposterior projection) and establish the buttresses. Attention needs to be given to the order of restoration [66, 67]. The results of various biomechanical experiments indicate that the vertical buttress needs to be fixed first, to restore the facial height. Then, the anteroposterior projection may be achieved by restoring the arch (Box 56.7).

56.9.3 Surgical Access to Fixation

Surgical approaches for ZMC fixation are chosen based on the fracture pattern and fixation needs. A single or multiple incision may be used for the surgical exposure of ZMC fractures [30, 68, 69].

The incisions may be broadly classified as:

- Cutaneous (upper eyelid, lateral brow, subciliary, subtarsal, infra-orbital, preauricular, and coronal incisions)
- Conjunctival (transconjunctival with canthotomy/transcaruncular)
- Mucosal (intraoral vestibular)

The list of incisions and the exposure achieved (green shaded areas on Fig. 56.38) by each are highlighted in Box 56.8 (Fig. 56.38)

The following is a description of the various incisions used to access the fixation points in ZMC fractures. It is important to take adequate measures for globe protection while placing any periorbital incisions [70]. The commonly followed methods include either a temporary tarsorrhaphy (Fig. 56.39) or a corneal shield (Fig. 56.40). The tarsorrhaphy also offers the additional advantage of being used as a retraction suture during surgery.

Box 56.8: Approaches to ZMC Fractures

Intraoral vestibular incision	ZM, IOR
Lower eyelid cutaneous incisions (Subtarsal, subciliary, infraorbital)	IOR, orbital floor
Transconjunctival	SZ, FZ, IOR, floor
Lateral brow	FZ, SZ
Upper eyelid	SZ, FZ
Coronal	SZ, FZ, arch
Preauricular	Arch

56.9.3.1 Supraorbital/Lateral Brow Incision (Fig. 56.38)

The lateral brow incision is otherwise called as "in the brow" incision and offers a fast and direct access to the fronto-zygomatic suture and lateral part of the supraorbital rim. The extensions for the incision must be well within the eyebrow which provides an ideal camouflage (Fig. 56.41a). However, this incision may not be ideal in people who are cosmetically inclined to maintain a higher eyebrow. Absence of any important neurovascular structures in this area makes this incision easy to perform, even by beginners.

After infiltration of LA solution containing vasoconstrictor, a 2 cm long incision is placed along the curve of the

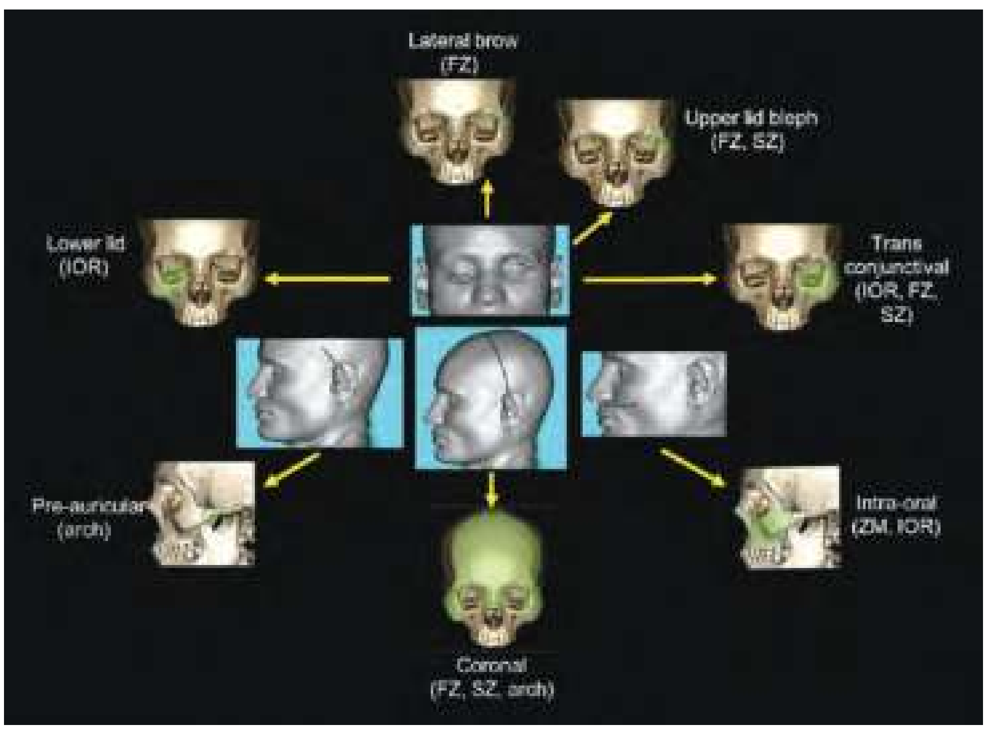

Fig. 56.38 Incisions to access ZMC fractures

Fig. 56.39 Tarsorrhaphy

Fig. 56.41 Periorbital incisions for FZ suture. (a) Lateral brow incision. (b) Lateral brow extension (shown in dotted lines). (c) Upper lid blepharoplasty

superolateral part of the orbital rim. Care is taken to incline the blade parallel to the hair so that the shafts are not transected. Failure to do so may cause linear alopecia along the incision line, which may be unaesthetic. Incision is carried through the skin, subcutaneous tissue, and the orbicularis oculi muscle. The flap is undermined in the supraperiosteal plane to permit ease of retraction. A periosteal incision is then placed above the fronto-zygomatic suture for reduction and fixation (Fig. 56.42a, b).

When additional exposure is needed on the medial aspect, the incision is extended up to the supraorbital nerve. For additional inferior extension, a gradual 90° turn into the

Fig. 56.40 Corneal shield

crow's feet wrinkle which is restricted to the skin only, is utilized to provide a much wider access [70] (Fig. 56.41b). This extension must remain 6 mm superior to the lateral canthus. Inferior limit of the incision along the lateral orbital rim should not cross the RSTL (resting skin tension lines) to avoid unaesthetic scars.

Closure is performed in layers with approximation of the periosteum and subcutaneous tissues (Video 56.2).

56.9.3.2 Upper Eyelid Blepharoplasty Incision (Fig. 56.38)

The upper lid blepharoplasty incision is otherwise called as the ***supratarsal fold*** or ***upper eyelid crease*** incision. It offers the most esthetically favorable approach to the fronto-zygomatic suture region. The incision is made along the eyelid crease, 10 mm above the free margin of the eyelid (Fig. 56.41c). As the incision extends laterally, it should be at least 6 mm above the lateral canthus. When eyelid anatomy is distorted with edema or hematoma, the contralateral lid crease measurements are used to mark the incision.

The incision is placed through the skin and muscle and is raised as a skin-muscle flap for good viability of the overlying skin. The plane of dissection is below the orbicularis oculi in a superior and lateral fashion to reach the periosteum (Fig. 56.43a, b). The periosteum is sharply incised to expose the bone underneath. Further dissection along the bony margins is strictly subperiosteal; any violation of the periosteum may cause herniation of the lacrimal gland which is present in the superolateral concavity of the orbit. Closure of the incision is done in layers, starting with periosteum, followed by the orbicularis oculi, and the skin.

An important advantage of the upper lid blepharoplasty incision is the extensive access it offers to the entire superolateral aspect of the orbit. It also permits good visualization and access to the spheno-zygomatic suture which is the most important indicator of reduction of ZMC fractures.

56.9.3.3 Subciliary Incision [71, 72] (Figs. 56.38, 56.44a and 56.45a, b)

The subciliary incision is a commonly used transcutaneous approach which offers good exposure of the infra-orbital rim along with the entire orbital floor. This may be a very useful approach in the management of ZMC fractures which involve the orbital floor also.

The skin incision is placed along the entire length of the lower eyelid, 2 mm below the level of the eye lashes to conceal the future scar.

The incision must not be extended more than 2 cm lateral to the lateral canthal ligament. This prevents any inadvertent damage to the temporal branch of the facial nerve which is present about 3 cm lateral to the lateral canthal ligament.

Once the skin is incised, the dissection may proceed in three different ways [30, 70] (Fig. 56.45b) (Box 56.9):

(i) ***"Skin-alone" flap technique*** where the plane of dissection is along the *subcutaneous plane between the skin of the eyelid and the orbicularis oculi.* On reaching the facial surface of the infra-orbital rim, the orbicularis muscle along with the periosteum is incised to reach the rim. The periosteal incision is generally placed at least 3–4 mm below the level of the infra-orbital rim (Fig. 56.45a and 56.45b1).

(ii) ***"Skin-muscle" technique:*** the incision is carried down from the skin into the pre-tarsal fibers of the orbicularis oculi, and the flap is dissected along the *plane deep to the muscle but superficial to the tarsal plate*. The dissection is then carried out superficial to the orbital septum till the rim is reached. Exposure of the rim is performed after sharp dissection of the periosteum just below the level of the rim (Fig. 56.45b2).

(iii) ***"Step" approach*** is performed in two different levels and is considered the best approach as it prevents most of the complications which are associated with the two former approaches. The incision is first placed through the skin, and the plane of dissection is carried in the *subcutaneous plane*, *maintaining the pre-tarsal fibers of the orbicularis oculi.* As the lower end of the tarsal plate is reached, the orbicularis oculi muscle is divided, and the plane is changed to include the muscle along with the skin as a "skin-muscle" flap (Fig. 56.45b3).

The development of a skin-alone flap at the marginal level and a "skin-muscle" flap at the subtarsal level creates a ***step*** in the plane of dissection. The dissection then proceeds caudally toward the infra-orbital rim in a submuscular plane superficial to the orbital septum. On reaching the rim, the periosteum is incised sharply about 3–4 mm below the level of the rim on the facial aspect.

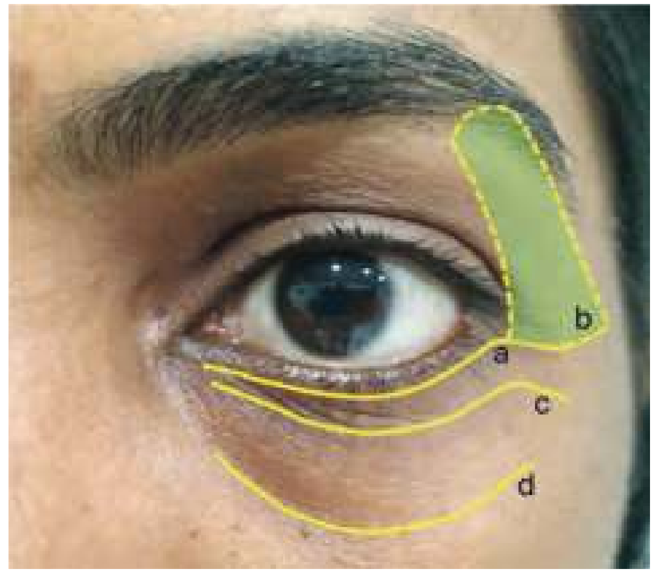

Fig. 56.44 Lower eyelid incisions. (a) Subciliary. (b) Extended subciliary showing area of exposure shaded. (c) Subtarsal incision. (d) Infra orbital

Box 56.9: Comparison of Variants of Subciliary Incisions

	Skin flap	Skin-muscle flap	Stepped skin-muscle flap
Skin incision	2 mm below the cilia	2 mm below the cilia	2 mm below the cilia
Muscle incision	Just below the infra-orbital rim	Same level as skin incision	2–3 mm below the skin incision
Periosteum incision	Just below the infra-orbital rim	Just below the infra-orbital rim	Just below the infra-orbital rim
Plane of dissection	Between skin and orbicularis muscle	Between orbicularis muscle and septum	• Stepped • Between skin and orbicularis muscle in pre-tarsal region • Between orbicularis muscle and septum—inferior to the tarsal region
Preservation of pre- tarsal fibers of orbicularis oculi	Preserved	Incised	Preserved
Complications	Skin buttonholing, discoloration	Septal perforation Ectropion Lid shortening Scleral show	Lesser incidence of complications

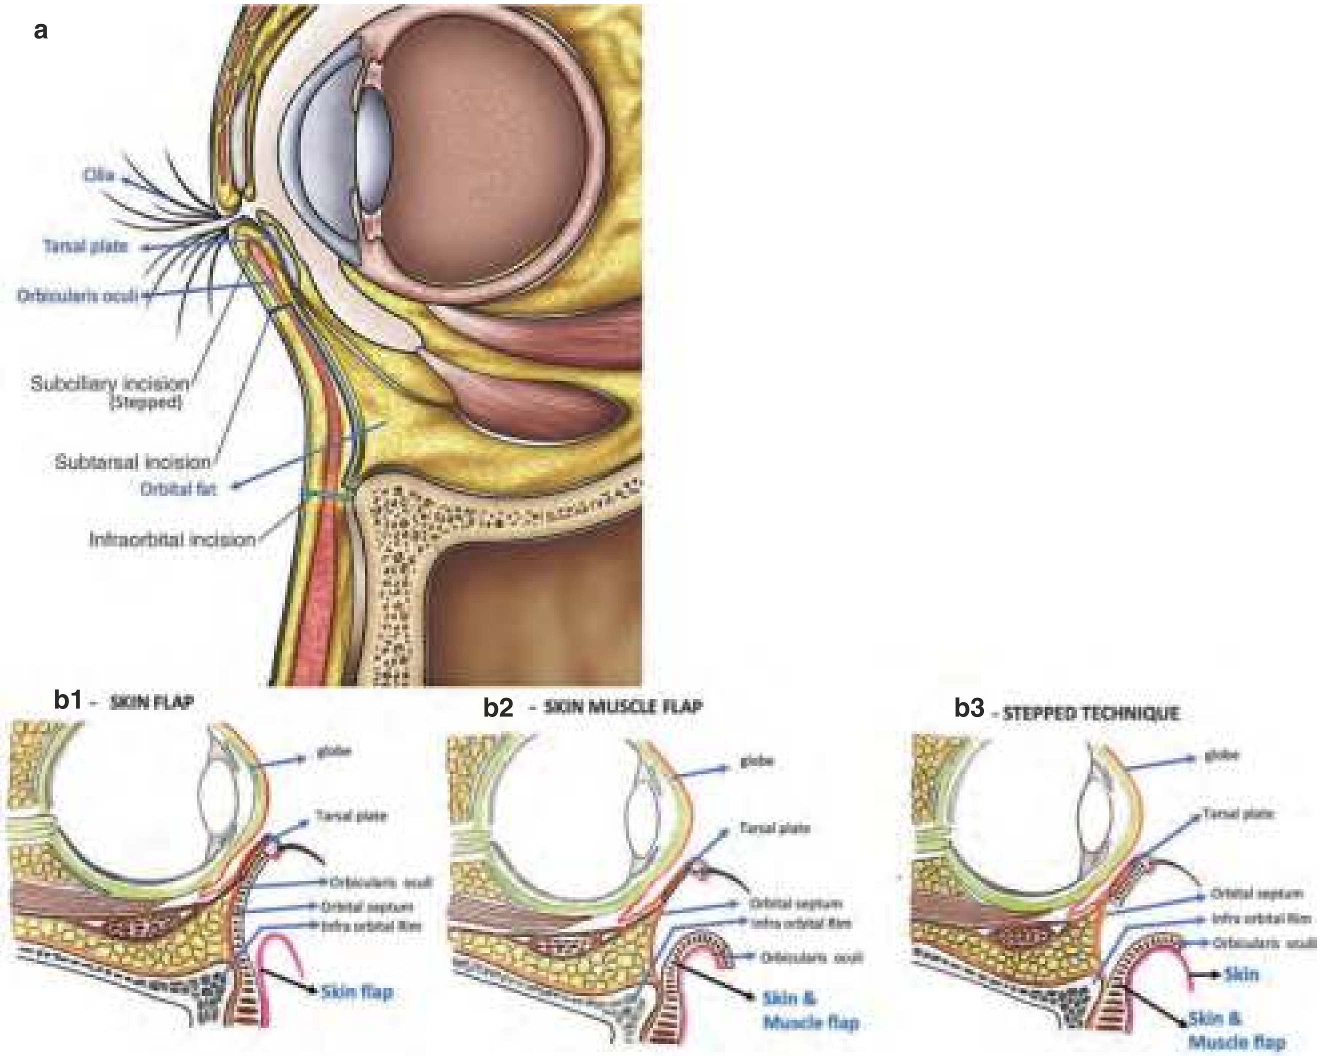

Fig. 56.45 Lower eyelid incisions—sagittal view. (a) Subciliary, sub tarsal and infra-orbital (b) Variants of sub-ciliary incision

The incision of the periosteum at this level not only helps preserve the attachment of the orbital septum along the rim margin but also lies above the level of the infra-orbital foramen which is seen about 7–8 mm below the level of the rim. Dissection of the periosteum can be performed along the entire length of the infra-orbital rim, anterior maxilla, and the zygoma to provide excellent exposure.

> Advantages of the stepped approach include (1) minimal chances of buttonholing or darkening of the skin due to vascular compromise (2) lesser incidence of ectropion and entropion (3) reduced scarring at the eyelid margins due to preservation of the pre-tarsal orbicularis oculi fibers.

The differences between the three variants of subciliary incision are highlighted in Box 56.9 (Figs. 56.45b).

56.9.3.4 Extended Lateral Exposure with the Subciliary Approach Fig. 56.46 [70]

After placing a standard subciliary incision, supraperiosteal dissection is performed along the lateral orbital rim in the cephalic direction till the FZ suture or a few millimeters beyond (Figs. 56.44b and 56.46). This releases the skin flap and makes it amenable to easy retraction to reach the FZ region. The periosteum is then divided in the center of the lateral orbital rim along its length. In most cases the lateral canthal ligament may be stripped in a subperiosteal fashion to facilitate comfortable access to the FZ suture. This approach may be used to avoid an additional incision for exposure of the FZ suture.

56.9.3.5 Subtarsal Approach [73] (Figs. 56.38, 56.44c and 56.47)

Subtarsal or ***mid-lid incision*** was also described by Converse. The incision is marked 5–7 mm below the inferior lid margin corresponding to the lower border of the tarsal plate, along

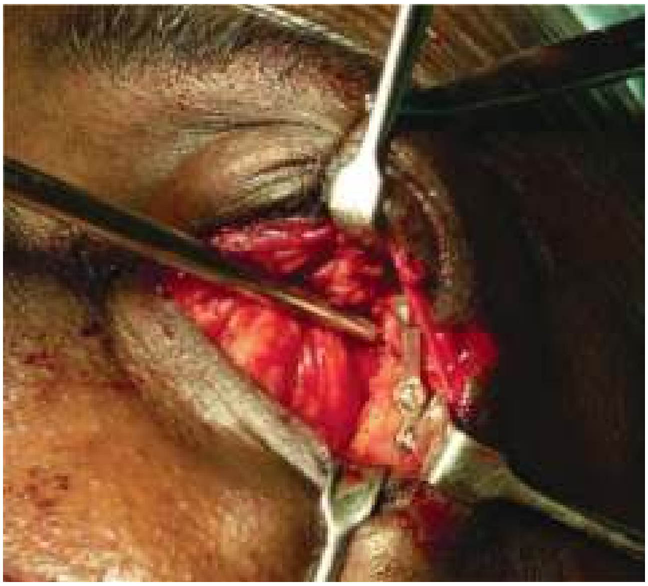

Fig. 56.46 Subciliary with lateral extension demonstrating exposure of the FZ suture after ORIF

Fig. 56.47 Subtarsal marking intra-operative

the subtarsal crease (Fig. 56.47). The lateral extension of the incision may be extended up to 2 cm beyond the lateral canthal ligament similar to the subciliary incision, along one of the resting skin tension lines. The incision is made through the skin and subcutaneous tissue. The *pre-septal fibers of the orbicularis oculi are also divided at the same level*, and the plane of dissection is maintained superficial to the orbital septum. The dissection is carried out caudally to reach the infraorbital rim, and the periosteum is divided below the level of the rim on the anterior surface of the maxilla and zygoma.

The subtarsal approach is favored more than the subciliary [73] due to its easier technique and lesser incidence of complications (Box 56.10).

Box 56.10: Subtarsal vs. Subciliary Incision

	Subtarsal	Subciliary
Ease of technique	Easy	Technically demanding due to • Stepped dissection and closure • Interference of lashes in the surgical field
Time taken for the approach	Quick	Takes almost twice the amount of time
Incidence of scleral show or ectropion	2.7–7.7%	17–42%
Cutaneous scar	More visible	Less visible

Fig. 56.48 Figure demonstrates use of frost suture for ZMC fracture approached by transconjunctival and upper lid blepharoplasty incision. *Technique for frost suture. A 4-0/5-0 nonabsorbable suture on a 3/8th circle needle is passed to engage the inferior tarsal plate, at the middle of the lower eyelid margin. The suture is taken either through the gray line or through the pre-tarsal skin to include the skin, orbicularis, and the tarsus. Appropriate tension is applied in superior direction by the anchoring the suture ends, to the supraorbital skin, 5 mm above the eyebrow using adhesive tapes*

An important consideration following lower eyelid approaches is the application of the "frost suture" [74] (temporary lower eyelid suspension suture) (Fig. 56.48), to prevent postoperative ectropion. Frost suture also permits visualization of the globe in the postoperative phase, when required (Refer Fig 11.13).

Nevertheless, lower rim incisions are often associated with postoperative ectropion and scleral show. While scleral show/lid traction refers to abnormal exposure of sclera (1 mm or more) with contact between bulbar conjunctiva and the lid, ectropion refers to eyelid eversion with no contact between bulbar conjunctiva and lid [75]. Ectropion requires correction for cosmetic reasons as well as functional problems arising from keratinization of exposed conjunctiva. Treatment varies from conservative modalities to surgical procedures [76, 77] (Box 56.11).

Box 56.11: Measures to Correct Ectropion and Scleral Show

- *Conservative measures*
  Corneal protection measures; artificial tears, ointment, temporary tarsorrhaphy
- *Surgical procedures*
  Release of cicatrization, sutures, skin/mucosal grafts, cartilage grafts, rotation flaps

56.9.3.6 Infra-orbital Incision (Figs. 56.38 and 56.44d)

This is performed as an incision which simultaneously divides the skin, orbicularis muscle, and periosteum, along infra-orbital rim. Though the infra-orbital incision offers the most direct approach to the infra-orbital rim and orbital floor, it is seldom preferred in contemporary surgery due to the unsightly postoperative scar and prolonged edema of the lower lid region due to disruption of lymphatic drainage.

56.9.3.7 Transconjunctival Incision [78, 79] (Figs. 56.38 and 56.49)

Transconjunctival incision has gained popularity because it completely negates the unesthetic scarring associated with skin incisions. This incision offers good access to the infra-orbital rim and SZ regions with either a pre-septal or retro-septal approach. Refer to the Chap. 57 for a detailed description of the approach. The modified transconjunctival incision with a cutaneous Y extension when combined with lateral canthotomy offers excellent exposure to the IOR, SZ, as well as the FZ region [80–82]. The complications of transconjunctival incisions include entropion [82], in-curling of lashes (trichiasis) [83], or growth of the eyelashes in two layers (distichiasis) [84]. Malposed lateral canthus has also been observed following improper repositioning of the lateral canthus after canthotomy [82].

56.9.3.8 Vestibular [85] Incision (Figs. 56.50 and 55.16)

The vestibular incision is the most frequently used approach to access the ZM buttress. The popularity is due to its application for reduction of ZMC fracture as well as fixation at the ZM buttress. Refer to the Chap. 55 for description of the technique. The author of this chapter (EP) uses the vestibular approach to also fix the zygomatic arch fractures which override at the zygomaticotemporal suture, with transbuccal instrumentation (transoral arch fixation technique) (Refer to recent trends section 56.16).

Fig. 56.49 Transconjunctival intra-operative

Fig. 56.50 Vestibular incision demonstrating fracture at ZM buttress

56.9.3.9 Preauricular [86] (Figs. 56.38, 56.51, 53.17a, b and 65.6) (Refer Video on pre auricular approach in Chap. 53)

Preauricular incision is useful for open reduction and fixation of arch fractures. After the routine skin incision, adopting the deep subfascial approach provides better protection to the facial nerve as compared to the other commonly used approaches, namely, the subfascial and suprafascial procedures [87]. Figure 56.51 demonstrates the use of preauricular incision with deep subfascial dissection to expose a malunited zygomatic arch fracture.

Fig. 56.51 Preauricular approach demonstrating exposure of malunited zygomatic arch fracture

56.9.3.10 Coronal Incision [88] (Figs. 56.38, 56.52a, b and 85.1)

Tessier introduced the use of coronal incision to access the superior and lateral orbits bilaterally along with naso-orbito-ethmoid complex in congenital facial reconstruction. The approach can be extended with a preauricular incision to include the exposure of the zygomatic body and the arches bilaterally. This incision also facilitates the temporal approach to the SZ suture [82]. Disadvantages of the approach include the extensive length of incision, dissection, temporal hollowing, scar alopecia, risk of injury to the supraorbital nerve, and temporal branch of the facial nerve.

56.9.4 Fixation Methods

Fixation methods for ZMC fractures have evolved through the ages.

> Three basic fixation methods are available for ZMC fractures [1] (Table 56.1):
>
> 1. Temporary support
> 2. Indirect fixation and
> 3. Direct fixation

The trend has gradually shifted from nonrigid fixation methods such as trans-osseous wiring, external pin fixation, and K wires to functionally rigid fixation methods including

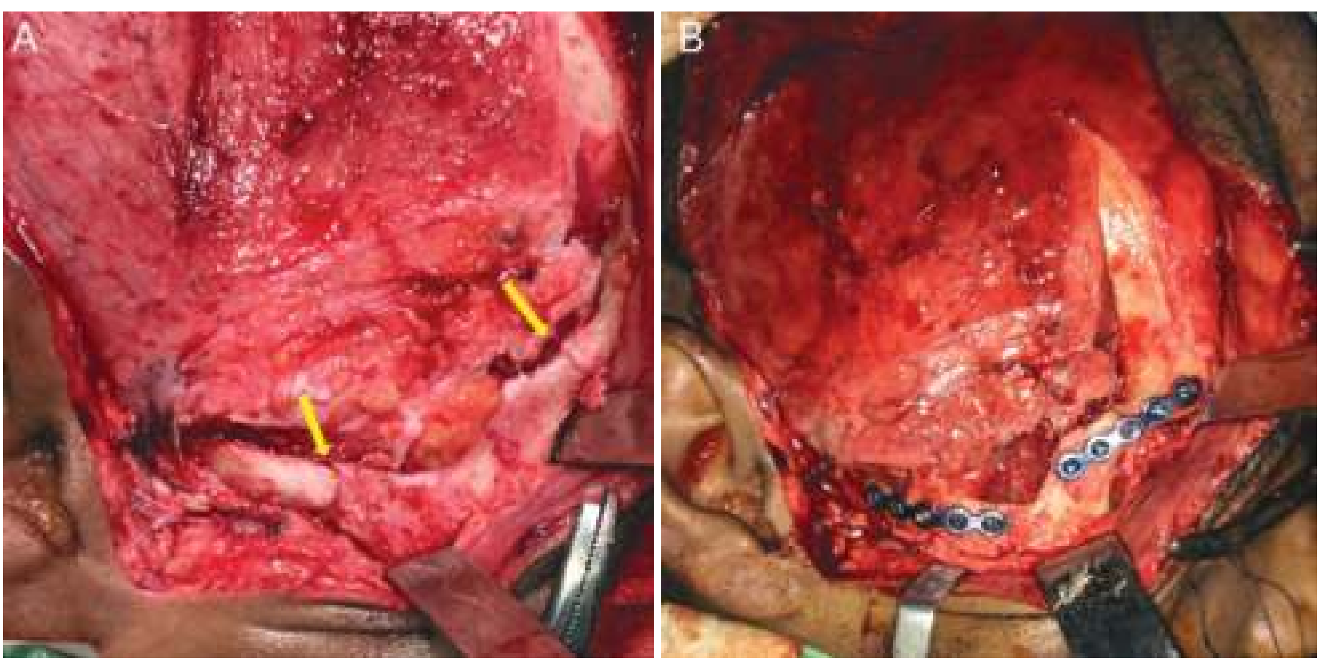

Fig. 56.52 Coronal approach, intra-operative. (**a**) Exposure of arch demonstrating fractured zygomatic arch and FZ region (yellow arrows). (**b**) Arch after reduction and fixation at ZT and FZ region

Table 56.1 Fixation methods for ZMC fractures

	Temporary support	Indirect fixation	Direct fixation
Access to fracture	Fracture is not visualized	Fracture is not visualized	Fracture is visualized by surgical exposure
Fixation technique	Provide support to reduced fragments	Indirectly fixed using anchorage from a distant site	Directly fixed
Modalities	• Antral pack • Antral balloon • Silicone wedge • Percutaneous wire with splint (arch)	• Trans-osseous pins (K wire, Steinmann pins) • External fixatorsCranio-zygomaticFronto-zygomatic	• Trans-osseous wiring • Miniplates and screws • Microcompressive screws
Advantages	Less surgical morbidity	Less hardware Less invasive	• Functionally stable/semi rigid/rigid (lag screw) • Anatomic reduction possible
Limitations	• Nonrigid • Not precise • Chances of infection • Poor patient compliance	• Poor patient compliance • Non-precise • Chances of pin track infection • Requires second intervention for removal	• Wiring is nonrigid • Surgical morbidity
Indications	When the surgery must be delayed (eg. compromised systemic status)	• Comminuted fractures • Inability to visualise fracture site (Please add bullets for both these points)	For most fractures, unless contraindicated

miniplates and compressive screws. However, some of the nonrigid fixation modalities are still applicable in certain clinical situations. A brief description of all fixation methods is provided below along with their indications and limitations.

- ***Trans-osseous wiring*** using stainless steel wires is rarely used in current practice due to its nonrigid mode of fixation that compromises post-reduction stability. However, it still remains a useful technique for fracture reduction by traction, especially at the FZ and IOR. The advantages include minimal periosteal stripping and lesser hardware as compared to use of miniplates and screws.
- **Antral packing** [89] with gauze or balloon/Foley's catheter is used in special scenarios where the ZMC is comminuted. But it is an inaccurate technique with high relapse potential and increased possibility of infection.

  Antral packing may be done either with a roller gauze pack or balloon. The technique followed for both is similar. The anterolateral wall of the maxilla is exposed by a Caldwell-Luc incision in the vestibule through which the fracture is inspected and manipulated to achieve reduction of the fragments. A trans-nasal antrostomy port is created in the inferior meatus. (refer Sect. 24.10, Fig. 24.24)
  - The *medicated ribbon gauze* pack is introduced into the antrum through trans-nasal antrostomy, and one end of the gauze is packed tight in the antrum under direct visualization through the vestibular incision. The oral layer is closed, once the desired level of packing is achieved. The other end which is free is pulled out through the nostril and taped to the cheek. This is later used to retrieve the pack once the healing phase is complete.
  - The *inflatable balloon* is positioned within the sinus cavity in a similar manner and verified through the vestibular approach. The balloon is then inflated with about 20cc of saline till adequate support is obtained for the reduced fragments. The vestibular approach is then closed meticulously without damaging the balloon. The balloon is left in situ for the fracture to heal. Removal is accomplished by deflating the balloon and pulling it out through the antrostomy port.
- **Kirchner or K wires and Steinmann pins** [1, 90] (Fig. 56.53a–c) are still popular in some units as they serve as tools of reduction as well as fixation. But these techniques are associated with cutaneous scars and poor patience compliance due to the transcutaneous presence of pins. The noteworthy advantages of external pin fixation are the reduced cost and the possibility of adjusting the fixation in the immediate postoperative period.
- K wires and Steinmann pins constitute an indirect method of fixation whereby the fractured zygomatic bone is fixed in a secure fashion to another stable point in the craniofacial skeleton. Such indirect anchorage may be obtained by using pins (1) to secure the fractured fragment to other stable bones or (2) to provide anchorage for connectors of an external fixator. The different techniques of indirect fixation that have been advocated for management of ZMC fractures include (Fig. 56.54):

  (A) ***Trans-zygomatic***—by this technique, the zygoma is first reduced through an intraoral approach to

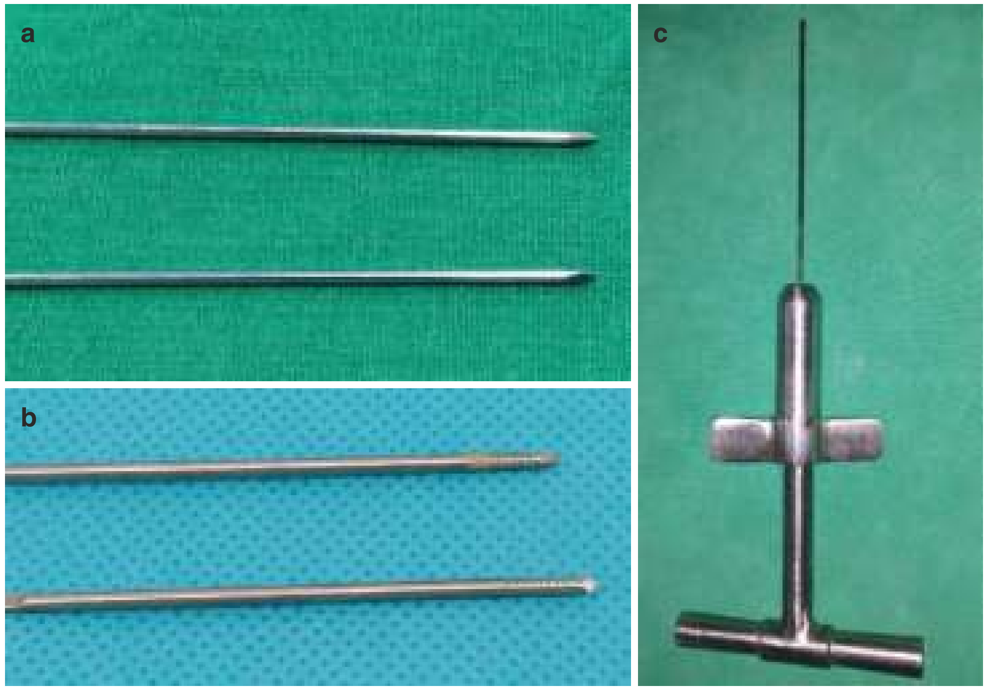

Fig. 56.53 Armamentarium for indirect fixation. (**a**) K wire. (**b**) Steinmann pin. (**c**) Manual K-wire driver

enable adequate visualization of the entry of K wire/pin thorough the vestibular incision. The reduced ZMC is then stabilized by transfixing it to the contralateral zygoma using a K wire. The K wire is passed from the body of the reduced zygoma in a trans-facial fashion to engage the stable cortex of the contralateral zygoma by the use of a K-wire driver.

(B) ***Naso-zygomatic***—this method involves the use of a K wire to stabilize the reduced ZMC to the frontal process of the maxilla on the contralateral side. The wire is driven from the frontal process of the maxilla in a forward and downward direction to engage the antral surface of the zygomatic body. This must be done with care to prevent any inadvertent damage to the nasolacrimal duct which lies adjacent to the path of pin.

(C) ***Zygomatico-palatal***—this procedure involves fixation of the reduced ZMC to the palatal surface of the contralateral maxilla, by passing a K wire through the reduced ZMC in a downward and oblique direction.

Indirect fixation may also be performed by the use of external fixators or a halo frame that can be attached to pins for anchorage. This may include the techniques described below.

(D) ***Fronto-zygomatic fixation***: This technique involves the use of a Steinmann pin for anchorage onto the reduced ZMC fragment. The pin is then anchored to another pin which is fixed on the stable orbital process of the frontal bone by the use of an external fixator device.

(E) ***Cranio-zygomatic fixation:*** This method is performed in the same fashion as the fronto-zygomatic method, except that the stable component for anchorage is from a halo frame that is cranially anchored, rather than a single pin on the frontal bone.

- **Lag screw**s [91] have been found to be an effective alternative at the FZ region because of the additional stability offered by interfragmentary compression. But this technique requires adequate bone stock for fixation.
- **Micro screws** [92]: Micro screws are 2 mm screws which are used to fix sagittal zygomatic fractures by using the lag screw technique. These screws also reduce hardware (Fig. 56.55a–c).
- **Miniplates** [3, 4]: The principal method of fixation is miniplate osteosynthesis. Miniplates are chosen based on

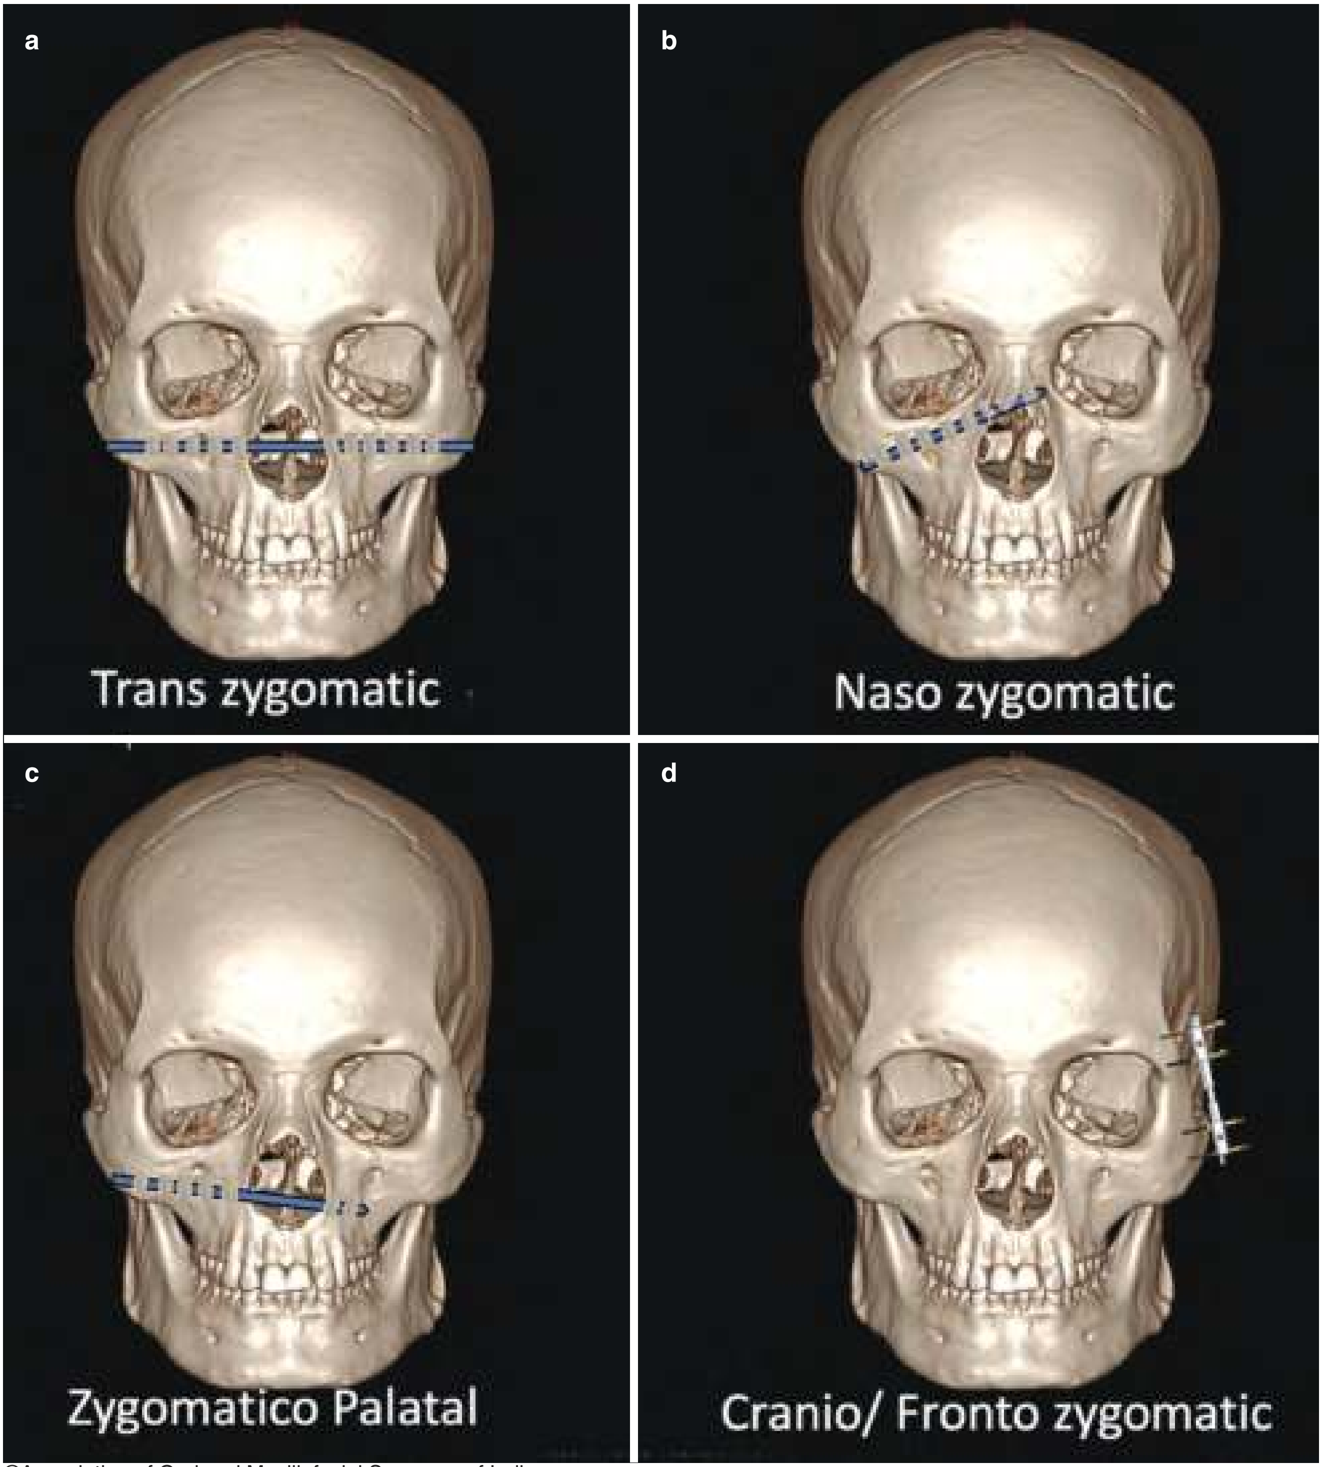

Fig. 56.54 Techniques for indirect fixation

rigidity requirements, anatomical site involved, presence of bone deficits, and biological considerations pertaining to protection of adjacent vital structures.

Shape of plates: The plates are chosen according to the contour of the bone that needs to be fixed; L plate for the ZM suture and a curved plate for the IOR.

Presence of bone loss: Comminuted fractures or bone loss may result in sagging of overlying soft tissues, especially in the ZM buttress region. This may be negated by using a broad mesh that bridges defects.

Biological considerations: Care must be taken to protect the roots, infra-orbital nerve and eye during fixation. In regions where the skin is thin, low-profile plates are preferred, 2 mm system for the ZM buttresses and 1.5 mm at the FZ, IOR, arch, and SZ suture [72].

Stability requirements: For ideal stability, screws of 6 mm length with a minimum of two screws on either side of fracture are essential. The only exception being the SZ suture where one screw on either side of the fracture line is adequate.

- *Fixation points:* The number of fixation points is directly proportional to the requirements of stability. Five different possibilities exist (Fig. 56.56a–f):
  – One-point fixation [92] refers to fixation at either the FZ or ZM suture. This has been found to be adequate in resisting post-reduction in-stability in simple tripod fractures while reducing hardware and surgical exposure.

  Comparative studies have shown that one-point fixation at the ZM buttress has been found to more advantageous due to many reasons: (1) absence of external scarring; (2) ease of surgical access; (3) unlike the FZ region, adequate soft tissue cover is present; and there are no issues of plate palpability; (4) easier to remove the plate, when needed; and most importantly (5) ZM buttress is a better indicator of zygoma alignment than the FZ region due to the wider area of articulation. However, FZ may be used in fractures with comminuted ZM buttress.
  – Two-point fixation indicates fixation at ZM and FZ/IOR [93, 94].
  – Three-point fixation/tripoding includes fixation at the FZ, IOR, and the ZM. A recent meta-analysis indicates that three-point fixation is the most effective in ensuring absolute clinical stability against displacing forces after reduction [94].
  – Four-point fixation/tetrapoding [95] involves fixation at the FZ, IOR, arch, and the ZM. This may be indicated in panfacial fractures requiring fixation of the arch to restore the anteroposterior projection of the face (case scenarios 1 and 2).
  – Five-point fixation/pentapoding [4] is used to manage severely comminuted or dislocated ZMC fractures wherein the SZ suture is also fixed, in addition to the other four sites of fixation. The SZ fixation may be performed either through a temporal or an intra-orbital approach

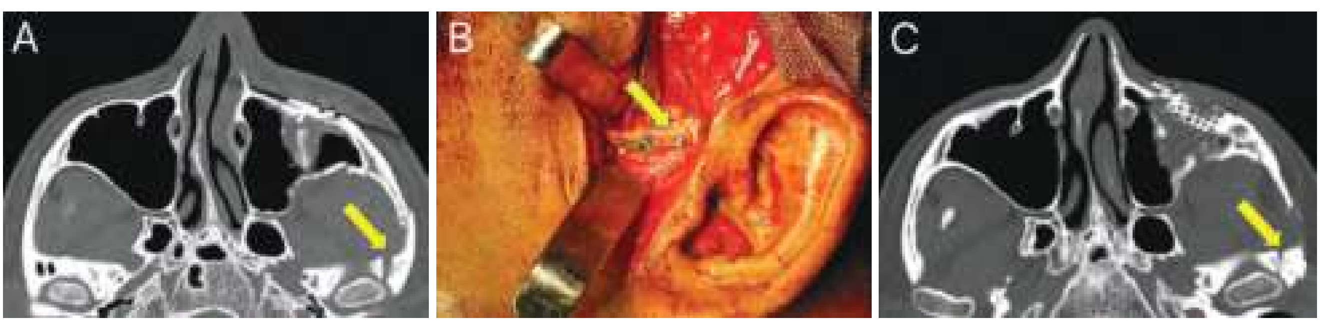

Fig. 56.55 Fixation of zygomatic arch fracture with microcompressive screws a, b, and c. (**a**) Preoperative CT showing diastasis at the zygomatic root. (**b**) Intra-operative picture showing arch fixation with screw. (**c**) Postoperative CT showing adequate fracture reduction and screw fixation

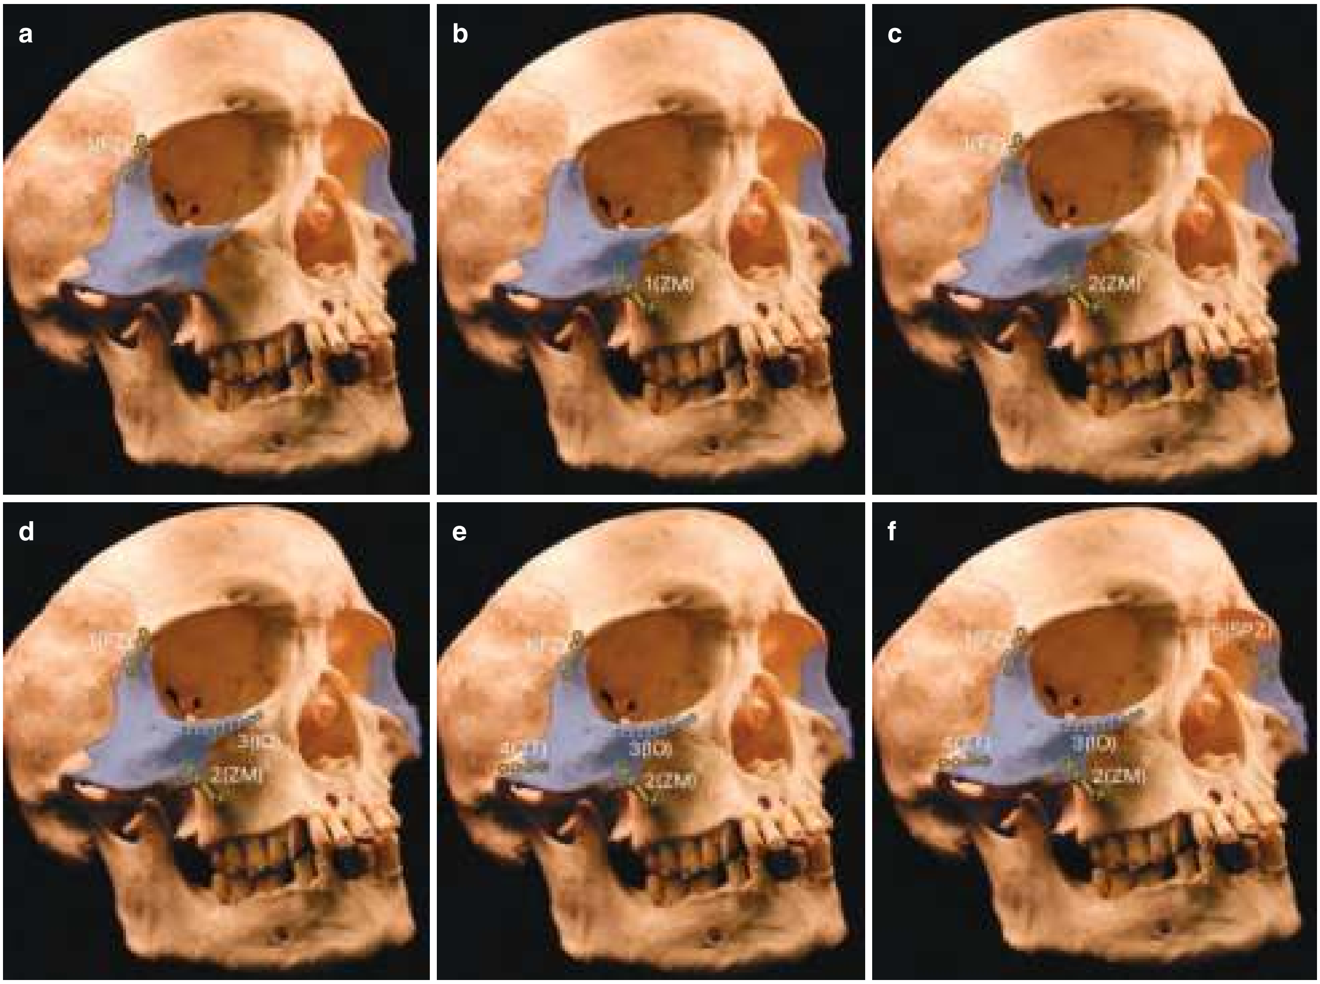

Fig. 56.56 Types of fixation using miniplates. (**a**) One-point fixation at FZ suture; (**b**) one-point fixation at ZM buttress; (**c**) two-point fixation; (**d**) three-point fixation; (**e**) four-point fixation; and (**f**) five-point fixation (the 5th articulation (SPZ) of the right is unseen and hence is depicted on the contralateral side for better understanding)

  – ZMC fractures requiring orbital reconstruction [59]: irrespective of the type of fixation, when ZMC fracture is associated with orbit, the orbital rims are fixed first. This is important because it is safer and easier to gauge the depth of orbital dissection from the restored infra-orbital rim and also to facilitate floor reconstruction [66] (case scenario 2). Also, the size of the orbital defect is better assessed when the rims are aligned.

- **Bio-resorbable plates** [96, 97]

  Though titanium miniplates are more commonly used to fix ZMC fractures, substantial clinical success has been obtained with use of bio-resorbable plates. They offer comparable post-reduction stability along with the added advantages of preventing thermal sensitivity and avoiding the need for second surgery to remove plates. Limitations associated with bio-resorbable plates are its technique sensitivity and increased operating time.

56.9.5 Fixation of Zygomatic Arch

The ORIF of arch fracture is indicated when the fragments are unstable after closed reduction and in cases where re-establishment of sagittal projection of face is needed. Fixation may be performed by one of the three methods, based on the fracture pattern (Fig. 56.57a, b, c): (1) a mini-plate for an arch demonstrating a single fracture line (Fig. 56.52b), (2) a spanning adaptation plate (Fig. 56.62b) when the arch is multi-fragmented [98], and (3) a micro screw for an outfractured root or sagittal fracture of the arch [99] (Fig. 56.55). Kim et al. proposed plating on the superior surface of the upper border as an alternate line of arch fixation which negated the drawbacks associated with the conventional fixation [100] (Fig. 56.57).

56.10 Soft Tissue Resuspension [101, 102]

Accurate reduction and fixation of ZMC fractures frequently necessitates the use of multiple incisions on the midface which deglove the entire periosteum-muscle-fat complex of the midface and zygoma. Failure to re-approximate the dissected tissues may lead to undesirable changes in the soft tissue projection and form.

The various changes that may be a sequel to wide subperiosteal dissection of the midface include (1) cheek ptosis, (2) descent of the lower eyelid skin and infraorbital hollowness, (3) loss of malar prominence due to inferior displacement of the malar fat pad, and (4) exaggeration of the nasolabial fold [101].

Over the years many authors have documented these undesirable changes and proposed soft tissue resuspension methods to minimize them. This can be achieved by various methods (Fig. 56.58a): (1) re-approximating the incised periosteum using absorbable sutures, (2) by suspending the periosteum using heavy absorbable or nonabsorbable sutures to a drill hole placed in a superiorly positioned bony landmark

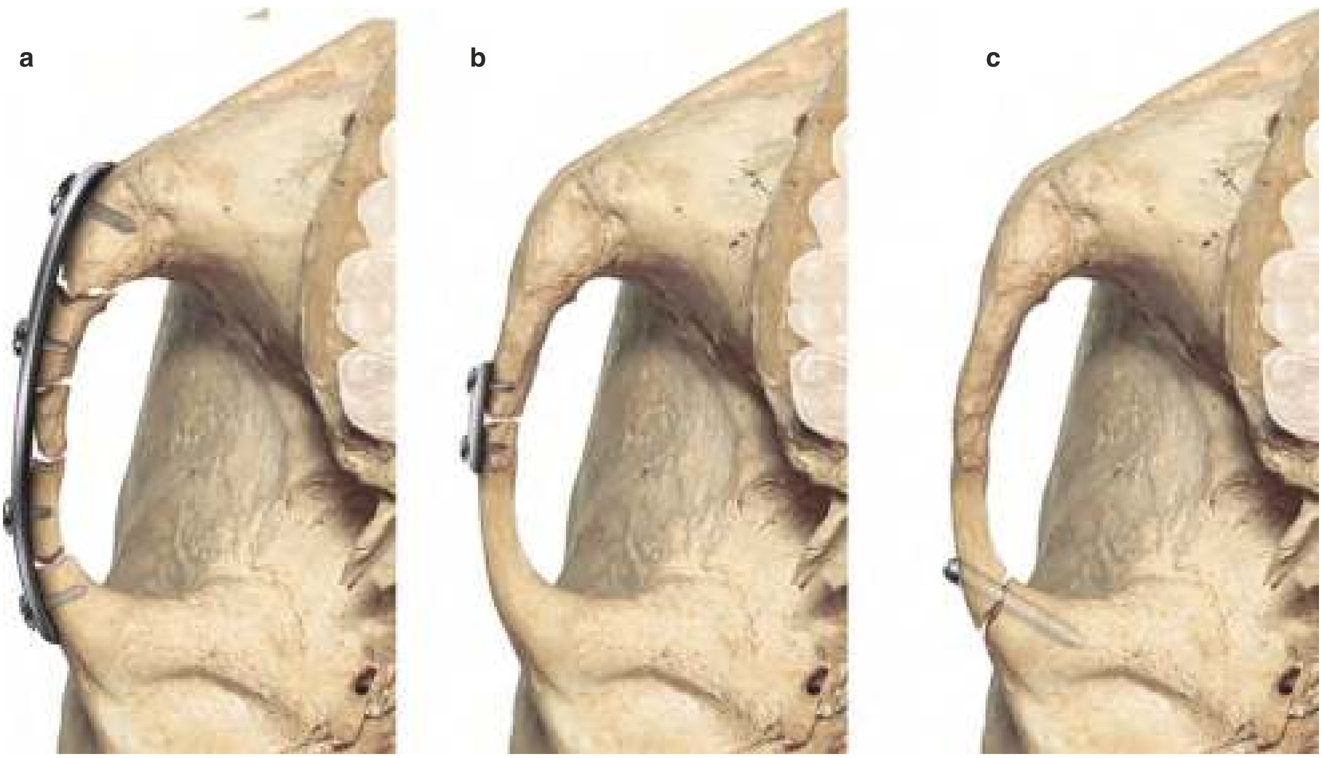

Fig. 56.57 Different fixation options for zygomatic arch fractures. (**a**) Adaptation plate. (**b**) Miniplate. (**c**) Compressive screw

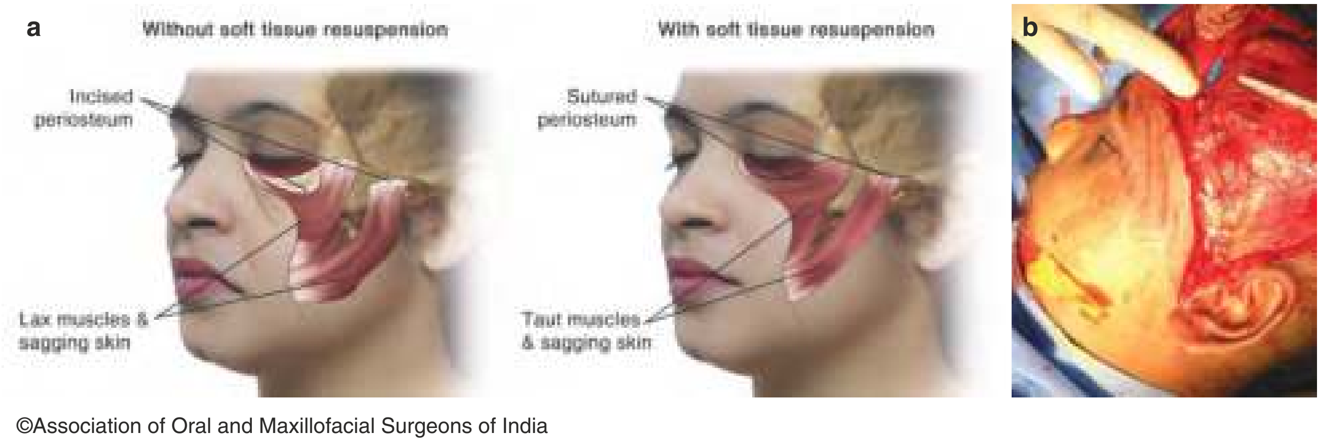

Fig. 56.58 Soft tissue resuspension. (**a**) Graphical representation. (**b**) Resuspension of temporal soft tissues to deep temporal fascia (blue arrow)

such as the orbital rim [103], (3) resuspension of lateral facial and temporal soft tissues to the deep temporal fascia in the temporal region [104] (Fig. 56.58b), and (4) prophylactic endoscopic midface lift [101].

56.11 Postoperative Care

Following reduction of ZMC fractures, with or without fixation, the following measures are taken to maintain post-surgical stability and prevent soft tissue complications (Box 56.12):

Box 56.12: Postsurgical Care

- Soft diet
- Protection of surgical site and eye
- Frost suture
- Post-op sinus regimen
- Periodic assessment of vision
- Anti-edema measures
- Anti-emphysema measures
- Physiotherapy (eye and mouth opening)

- Soft diet: Patients managed with conservative methods are advised soft diet for a period of 2 weeks.
- Protection of surgical site: The reduced zygoma or the arch must be protected with a tape labelled "do not touch" to provide cognitive input to the patient and people around.
- Frost suture: This temporary suspension suture is maintained for 3–5 days in any patient undergoing an inferior eyelid approach for the prevention of ectropion.
- Post-op sinus regimen [105]: A sinus regimen including prophylactic antibiotics for sinus coverage and decongestants is advocated by some authors.
- Periodic assessment of vision [66]: Periodic ophthalmic examination for the first 2 postoperative weeks is mandatory, in an awake patient. In an unconscious patient, it is achieved by swinging flashlight test or VEP (visual evoked potential).
- Anti-edema measures: Head end elevation must be maintained to prevent facial edema.
- Anti-emphysema measures, such as avoiding nose blowing [106].
- Protection of eye with ophthalmic ointments.
- Physiotherapy to prevent postoperative trismus: Postoperative trismus is a common phenomenon following ORIF of ZMC fractures due to hematoma, reflex muscle spasms, and fibrosis. Measures such as physiotherapy, forced mouth opening using gag [107], and kinesiologic tapes [108] may be used to improve mouth opening.
- Eye movement exercises are encouraged to facilitate resolution of edema and expedite restitution of movements [66].

56.12 Pediatric Considerations

56.12.1 Nonsurgical vs. Surgical Intervention [109]

The incidence of ZMC fractures is high in pediatric population due to its prominence [109]. In children, most authors favor a "nonsurgical" management or "reduction without fixation" of ZMC fractures due to concerns regarding "surgery/implant-induced" growth disturbances of facial skeleton and injury to teeth. However, literature supports ORIF of zygoma fractures which are grossly displaced or unstable after reduction. This is very important in pediatric population to (1) correct the facial asymmetry which may cause psychological impact, (2) restitute normal mouth opening to permit mastication, and (3) restitute globe position and function to enable normal vision and prevent development of phthisical eye or hypoplasia of zygoma, in the future.

56.12.2 Approaches and Fixation Principles

The preferred approaches include vestibular and lateral brow with minimal soft tissue dissection. Literature suggests one-point fixation at FZ region as adequate for pediatric ZMC fractures because of the short lever arm forces between the FZ and IOR [110]. But current studies have demonstrated that two-point fixations provide adequate stability and are associated with the least complication rates when compared with one and three-point fixations. Similarly, fixation at the zygomaticomaxillary buttress had the least complications when compared against the fronto-zygomatic and infra-orbital fixations [111]. In contrast, Defazio et al. proposed that plating at the FZ and IOR may be done conveniently in children below 6 years without any risk of damage to tooth buds [112].

56.12.3 Osteosynthesis Methods

Fixation techniques prior to year 2000 advocated titanium miniplates for pediatric midface. However they must be removed after 2 months to prevent any growth disturbances, plate migration, or burying of plate due to bone apposition. Microplates and self-drilling screws are also reported to give adequate stability and fixation in this age group without compromising vital structures [110]. Alternatively, bio-resorbable plates may be used which became popular after year 2004 to negate the need for re-surgery for plate removal [113]. Figure 56.59a–f shows a case of displaced zygoma fracture in a 5-year-old boy managed by ORIF. The plates were removed after 2 months.

56.13 Malunited ZMC Fractures [114]

Malunion of the zygoma may be a sequel to two clinical scenarios, (1) a neglected ZMC fracture which was never treated and (2) an improperly treated fracture. The protocol for the management of the malunited zygoma is based on the type of deformity which may be either cosmetic or functional. The protocol followed by the author is demonstrated in Fig. 56.60.

Deformities producing aesthetic concerns may again be subdivided into those demonstrating facial asymmetry or those showing altered globe positions.

Fig. 56.59 ZMC fracture management in a pediatric patient. (**a**) Frontal view of patient with left-sided ZMC fracture. (**b**) Basal view demonstrating loss of facial projection and enophthalmos of left side. (**c**) Preoperative 3D CT image demonstrating en bloc displacement of ZMC. (**d**) Preoperative coronal section demonstrating separation at FZ suture and lateral displacement of the body of zygoma. (**e**) Postoperative frontal view. (**f**) Postoperative basal view demonstrating restoration of facial projection and enophthalmos correction. (**g**) Postoperative 3D CT. (**h**) Post-operative coronal section

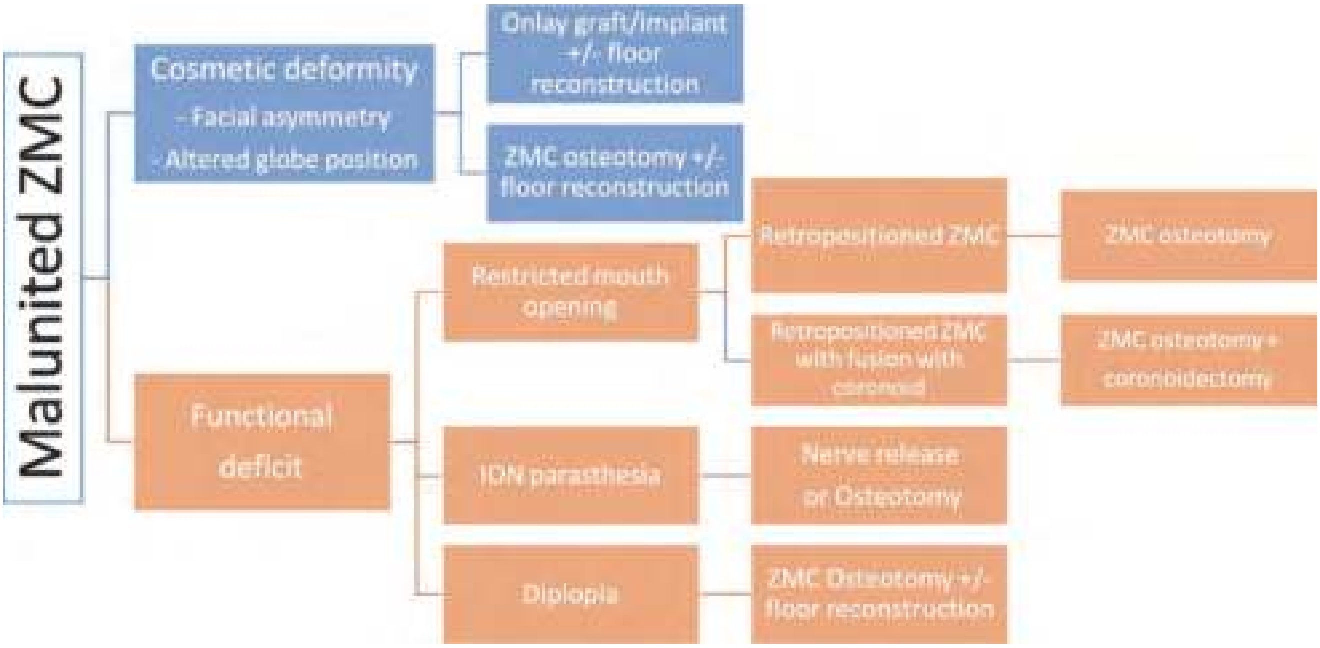

Fig. 56.60 Management of malunited ZMC fracture—algorithm

- The patients with asymmetries involving only the malar or infra-orbital regions with no functional deficits can be treated with onlay grafts which may either be autogenous in nature (rib, iliac crest, calvarium) or alloplastic (Medpore, PEEK (polyether ether ketone), etc.) (Fig. 56.61).
- Patients demonstrating gross facial asymmetry along with orbital dystopia and/or anti-mongoloid slant of the palpebral fissure may not be amenable to treatment with onlay augmentations. In such cases, a conventional osteotomy (re-fracture) and repositioning of the zygomatic complex is advocated (case scenario 2).
- When either of the deformities are associated with large floor defects, they require concomitant orbital floor reconstructions.

Functional deficits secondary to malunited ZMC fractures essentially fall into three categories; Restricted mouth opening, parasthesia and diplopia.

- Restricted mouth opening due to retropositioned zygoma/arch which either (1) forms a mechanical obstacle to mandibular translation or (2) fuses to the coronoid process of the mandible (extra-articular ankylosis) (Fig. 56.62a, b). The choice of treatment in these patients is dictated by the presence or absence of fusion (bony/fibrous); ZMC osteotomy, and repositioning alone are indicated in the absence of fusion, while presence of fusion mandates additional coronoidectomy [8, 115].
- Paresthesia over the infra-orbital nerve (ION) distribution: The entrapment of the ION or constriction of the infra-orbital foramen is not an uncommon finding. The first line of management in these patients is to perform a nerve release by an ostectomy around the infra-orbital foramen or by repositioning of the ZMC when it is compressing the nerve.
- Diplopia: The major cause for diplopia in ZMC fractures may either be gross displacement of the ZMC or mechanical restriction due to entrapment of orbital soft tissues (muscle, orbital septum, or fat) with resultant fibrosis or adhesions. Correction in these instances is achieved only by an osteotomy along with release of the entrapped tissues. These patients may also require orbital floor reconstructions if they present with floor defects that are large (>2 cm^2 in area). Non-resolving diplopia may be subjected to management with prism glasses and/or strabismus surgery.

56.14 Bilateral ZMC Fractures

Bilateral fractures of the ZMC are a rare occurrence and present more difficulty in achieving adequate reduction. In contrast to unilateral fractures where the normal side is used as a guide to achieve symmetry on the fractured side, bilateral ZMC fractures are complex in management. Two options exist: (1) reducing the less displaced or comminuted side first and using it as a reference for the more displaced side [116]. This may however result in compromised results, if three- or four-point fixation is not achieved, and (2) meticulous preoperative planning [43] by virtual surgical procedure to achieve the ideal facial width and projection. This involves a sequence of segmenting and virtually repositioning the fracture fragments to the "best possible fit" position. Once this is completed, the stents for intra-operative guidance can be generated.

Fig. 56.61 Use of Medpore onlay for malunited fracture

56.15 Complications of ZMC Fractures [3–5]

The incidence of postoperative complications increases with certain risk factors such as severe displacement, presence of sinus infection, and compound/comminuted ZMC fractures [37].

The various complications specific to surgeries of the ZMC may be categorized as intra-operative, immediate post-operative, and delayed postoperative complications.

- ***Intra-operative complications***: Commonly encountered intra-operative complications are bradycardia and bleeding. *Bradycardia due to oculocardiac/trigemino-cardiac* reflex occurs typically during elevation of the ZMC [117]. Manipulation of zygoma stimulates the trigeminal nerve which subsequently stimulates the vagus nerve, due to the neuronal interconnections between them. Vagal stimulation is cardioinhibitory and hence results in bradycardia of varying degrees. This complication can be prevented by identifying risk factors and administering prophylactic vagolytic agents or minimizing nerve stimulation by administering regional blocks. However, management of bradycardia after its onset involves temporary cessation of manipulation and or medical management with atropine or epinephrine [64].

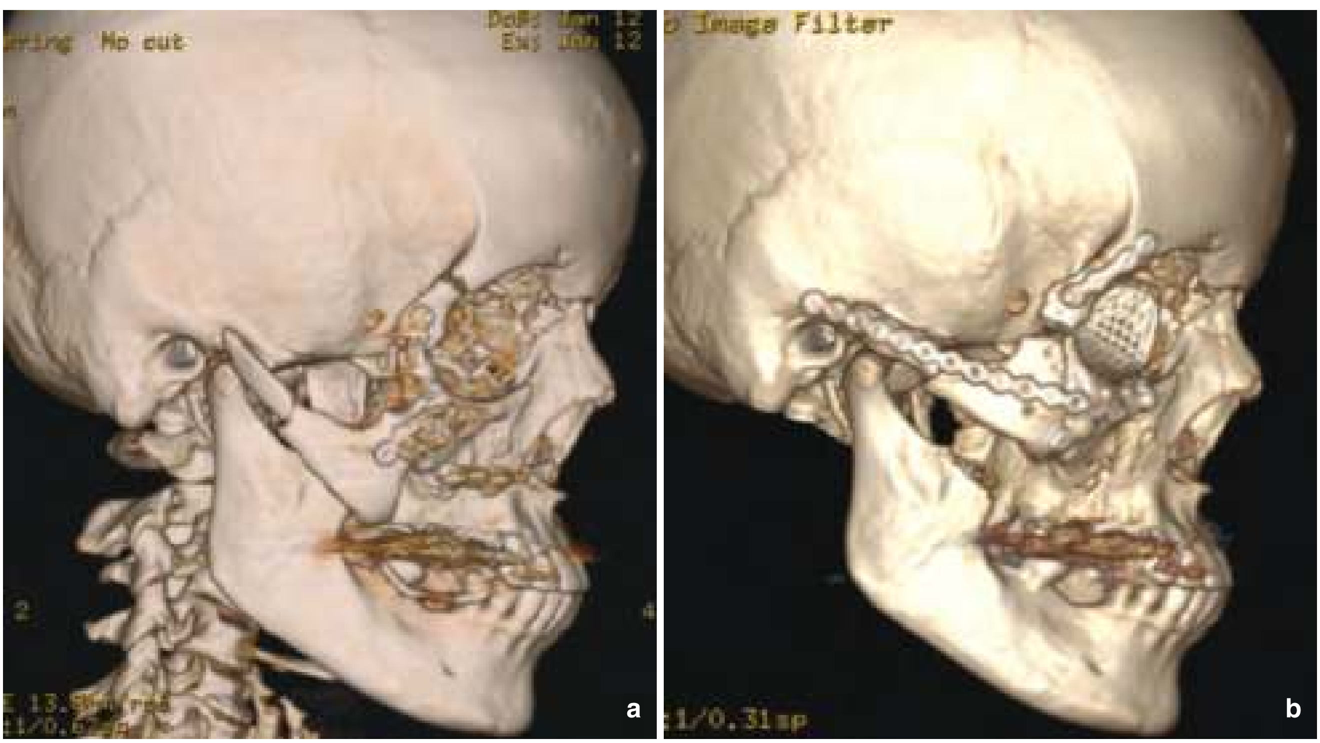

Fig. 56.62 Coronoidectomy for malunited ZMC fracture. (**a**) Pre-operative scan showing malunion of the right ZMC with fusion of the body of zygoma and coronoid process, and (**b**) post-operative scan demonstrating reduction and fixation of the right zmc with ipsilateral coronoidectomy.

Brisk intra-op bleeding can occur due to the sudden rupture of vessels (mainly infra-orbital artery) during reduction.

- **Immediate postoperative complications:** In the immediate postoperative phase, the adverse effects range from maxillary sinusitis, meteorosensitivity [3] (discomfort arising due to change in weather conditions) to infra-orbital nerve paresthesia, diplopia, blindness, and SOF syndrome. The incidence of postoperative infra-orbital nerve paresthesia is higher with ZMC fractures which demonstrate more rotation, displacement, and comminution [118]. Interestingly, recovery from post-trauma ION paresthesia shows better prognosis with reduction and fixation due to de-compression on the nerve. Blindness following surgery may arise either due to direct injury to optic nerve by impingement of fracture fragments or hemorrhage into the optic sheath/retro-bulbar hemorrhage (Refer Fig. 56.16) producing nerve compression [119].
- **Delayed post-op complications** commonly witnessed include enophthalmos and hypophthalmos due to inadequate reduction or inadequate fixation. Oroantral fistula [120], TMJ dysfunction [121], and ankylosis of zygoma to coronoid process, referred to as Jacob's disease [1, 122], are also recorded in literature.

56.16 Recent Trends

Fractures of the ZMC are notorious for their sub-optimal outcomes due to over or under reductions. This may be attributed to difficulty in simultaneous visualization of its multiple articulations without increasing surgical morbidity due to additional exposures.

Technological advancements in the recent years have added ease as well as predictability to the reduction and fixation of these fractures while minimizing surgical morbidity. The most popular methods in contemporary surgical management are discussed below.

1. ***Intra-operative reduction and fixation templates*** [123]
   This has been discussed earlier under the section for preoperative planning.
2. ***Computer-assisted patient-specific implants (PSI)*** [42]: Another method for improving intra-operative accuracy is the use of virtual surgery to plan for reduction of the fracture and design patient-specific implants (PSI). These PSI designs are then printed using a 3D printer which can double up as intra-operative reduction guides also. Refer to section 57.13.2 in Chap. 57 for additional information
3. ***Intra-operative navigation*** [124]: Intra-operative navigation is an excellent method for obtaining intra-operative guidance for precise reduction. Refer to Chap. 41. "Computer-assisted navigation surgery in oral and maxillofacial surgery" for additional information. The margin of error with use of intra-operative navigation is less than 1.2 mm with accurate restoration of facial symmetry. A case of deformity secondary to ZMC fracture treated using intra-operative navigation is illustrated in Fig. 56.63.
4. ***Intra-operative imaging*: **Intra-operative imaging greatly improves the accuracy of intra-operative fracture reduction. The various imaging modalities that are available include ultrasound, conventional C-arm (videofluoroscopy), and intra-operative CT. The quality of imaging with videofluoroscopy is not accurate in reflecting the complex anatomy of the cranio-facial skeleton. This makes intra-operative CT a more accurate and reliable tool. However, the associated radiation doses may be a concern. This has been surmounted with the advent of the intra-operative CBCT devices [125]. This device has the significant advantages of portability, ease of use, increased accuracy, and reduced radiation exposure.
5. **Transbuccal Arch Fixation:** A technique involving intra oral reduction of zygomatic arch and its fixation by transbuccal instrumentation has been described by Panneerselvam et al for fractures of the zygomatic arch which are displaced at the zygomatico temporal articulation. This technique minimises the potential morbidity associated with the coronal approach which is commonly used for ORIF of zygomatic arch [126].

56.17 Conclusion

The ZMC fracture is one of the most complex fractures to reduce and fix, because of its propensity to undergo displacements in all three planes of orientation, along its five articulations. Accurate reduction is challenging due to the difficulty in intra-operative assessment of reduction, inability to predict the rotation of the zygoma during reduction, and complexity involved in concomitant orbital fractures.

> The surgical objectives must include (1) choice of incisions which provide maximal exposure with minimal morbidity, (2) increase in number of fixation points with increase in severity of fracture displacement, (3) achieving three-dimensional stability of ZMC complex and minimizing post-reduction complications, and (4) resuspension of overlying soft tissues to prevent sagging.

Preoperative planning and intra-operative imaging play a great role in improving accuracy of fracture reduction while minimizing surgical exposure and post-reduction complications.

56.18 Case Scenarios

Case Scenario 1: Fracture of right ZMC (Fig. 56.64)

Patient: 21-Year-Old Male, with History of RTA

Preoperative CT (Fig. 56.64a, c) showing right-sided fracture of the ZMC and arch with undisplaced frontal bone.

The sections demonstrate:

- Medial displacement with reduction of the transverse dimension of the face
- Diastasis at the FZ and ZM sutures
- Overriding of fragments at the IOR and SZ suture
- Medial displacement of the right zygomatic arch

Surgical plan: Reduction of ZMC fracture with four-point fixation

Surgical procedure:

- The exposure of fracture sites was done by:
  1. Trans-conjunctival incision with extended lateral approach
  2. Intraoral buccal sulcus approach
- Reduction of ZMC fracture and arch fracture by Balasubramaniam's approach
- Four-point fixation of fracture was performed at FZ, IOR, ZM, and SZ (Fig. 56.64f) regions with miniplates

Postoperative CT (Fig. 56.64b, d, e):

CT demonstrating optimal reduction of fractured ZMC and arch. The successful surgical outcome may be appreciated by the approximation and fixation at the SZ suture, which is the most reliable indicator of accurate ZMC reduction.

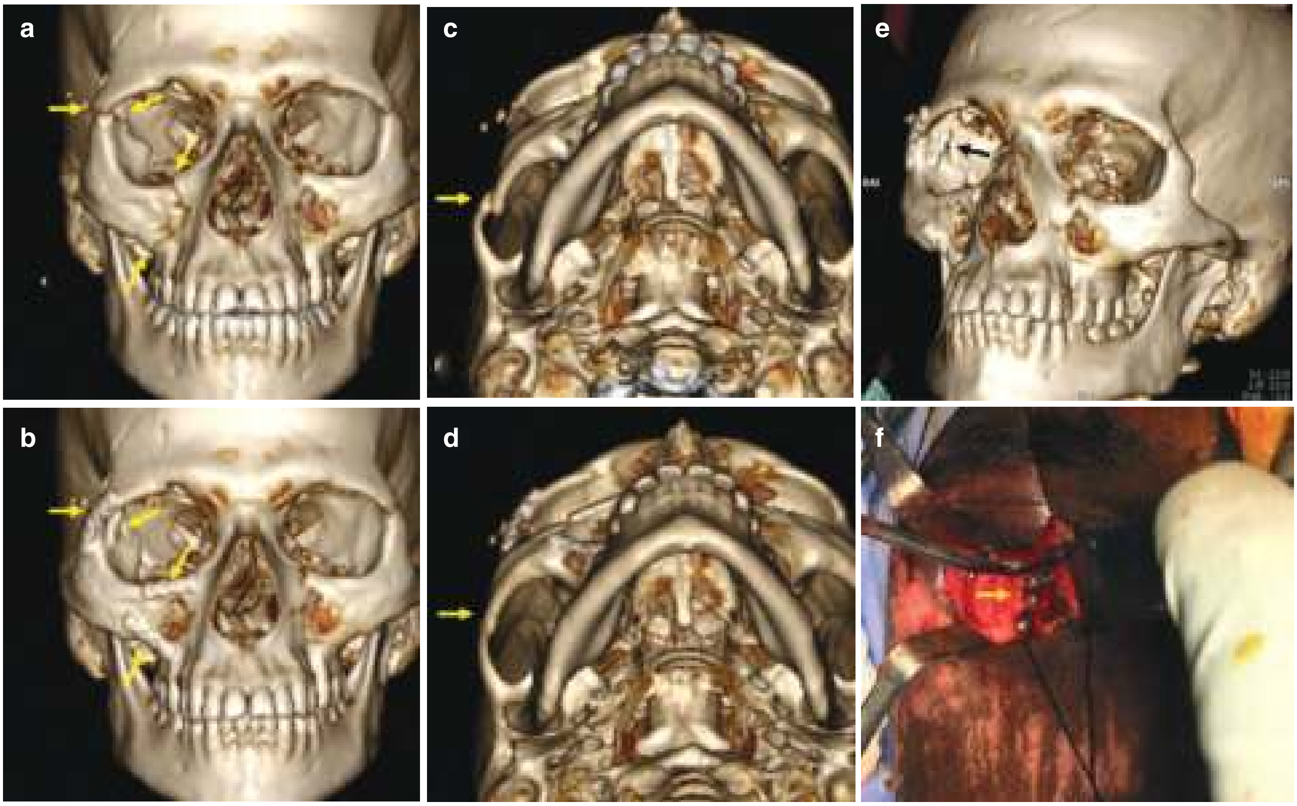

Fig. 56.64 Case scenario 1. (**a**) Preoperative 3D CT-frontal view demonstrating fractures. (**b**) Postoperative 3D CT-frontal view demonstrating fixation. (**c**) Preoperative 3D CT-basal view demonstrating arch fracture. (**d**) Postoperative 3D CT-basal view demonstrating arch reduction. (**e**) Postoperative 3D CT demonstrating fixation at SZ suture. (**f**) Intra-operative fixation at SZ suture

Case Scenario 2: Fracture of left ZMC and orbital floor (Fig. 56.65 a–h)

Patient: 27-Year-Old Male with History of RTA and delayed presentation after 2 months

Preoperative CT findings (Fig. 56.65a, b):

- En bloc fracture of the left ZMC with diastasis at the left infra-orbital rim, zygomatic arch, and FZ and SZ sutures.
- The fracture shows posterior, inferior, and lateral displacement and comminution at the infra-orbital rim, zygomaticomaxillary buttress, and the arch.
- The CT also demonstrates a concomitant left orbital floor fracture with resultant enophthalmos and hypo-ophthalmos (Fig. 56.65g).

Surgical plan: ZMC osteotomy, repositioning, and internal fixation

Surgical procedure:

- Virtual surgical planning to generate a mirrored STL model for pre-contouring of implants (Fig. 56.65c, d)
- Surgical exposure of the fracture through a transconjunctival (infra-orbital rim and floor), upper lid blepharoplasty (FZ and SZ sutures), vestibular for the ZM buttress, and preauricular approaches for the zygomatic arch.
- Mobilization of the malunited ZMC after osteotomy and ORIF with pre-contoured implants
- Fixation of the fracture performed at the FZ, infra-orbital rim, and the zygomatic arch regions
- Orbital exploration and reconstruction with pre-contoured left-sided anatomical titanium orbital implant

Postoperative features (Fig. 56.65e, f and h):

The postoperative CT demonstrates optimal reduction and fixation of the left ZMC with reconstruction of the left orbital floor defect with titanium implant.

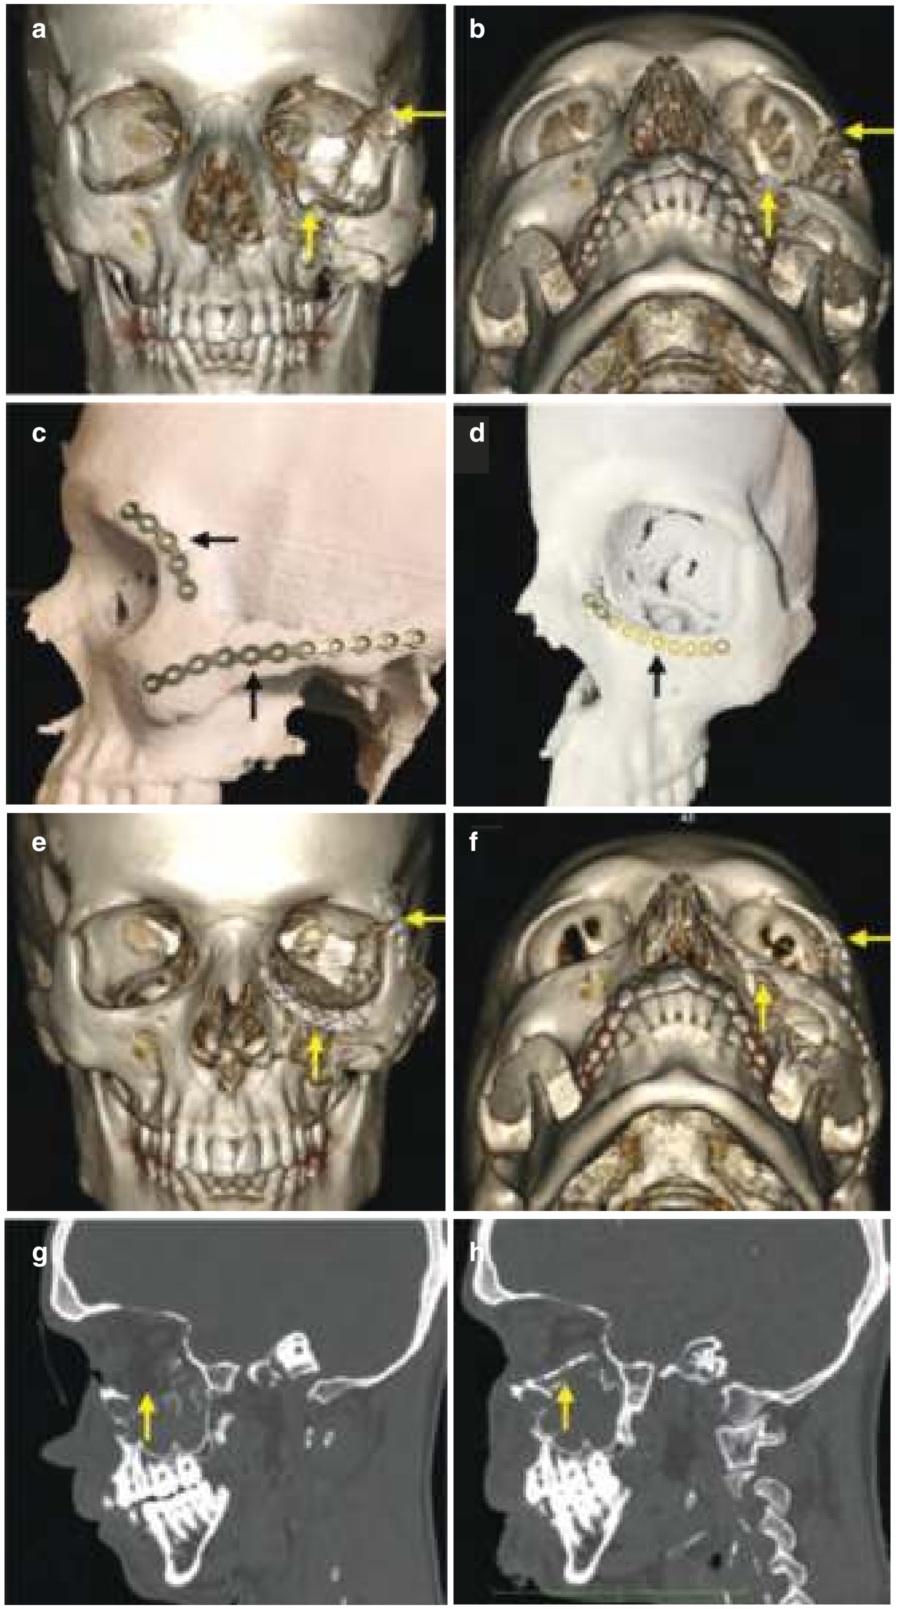

Fig. 56.65 Case scenario 2. (**a**) Preoperative 3D CT-frontal view demonstrating fractures. (**b**) Preoperative 3D CT-basal view. (**c**) STL model surgery with pre-contoured plate. (**d**) STL model demonstrating mirroring of normal side and plate adaptation. (**e**) Postoperative 3D CT-frontal view demonstrating fixation. (**f**) Postoperative 3D CT-basal view demonstrating fixation. (**g**) Preoperative CT-sagittal view demonstrating floor fracture. (**h**) Postoperative CT-sagittal view demonstrating reconstruction of floor with orbital mesh

57 Orbital Fractures

Ananthanarayanan Parameswaran, Madhulaxmi Marimuthu, Shreya Panwar, and Beat Hammer

57.1 Introduction

Orbital fractures are unique among cranio-maxillofacial (CMF) fractures. They have functional, cosmetic, and psychological implications. Most importantly they are among the few true emergencies in the realm of CMF trauma. Management of orbital fractures poses a challenge to every surgeon because of its complex anatomy, relationship to vital structures such as the globe and the brain, and its direct influence on the most precious of senses, *Vision.*

The orbit is a small bony cone filled with numerous vital and delicate structures, which require absolute precaution while handling and immense precision in its reconstruction. The principles of managing orbital trauma differ significantly from rest of the CMF fractures, which mandate a thorough understanding of its morphology and biodynamics. Choosing the appropriate indication for intervention and management protocol is critical in achieving the desired surgical outcome. This chapter aims to answer the questions of the *When*, *Why*, and *How* of managing orbital trauma.

57.2 Surgical Anatomy of the Orbit

The orbits are bilateral bony cavities which house the globes. Each orbit is made up of seven bones: the maxilla, frontal bone, zygomatic, sphenoid, ethmoid, lacrimal, and the palatine bones (Fig. 57.1). The orbital cavity is a pyramidal structure with a quadrilateral base anteriorly, forming the orbital aperture, and the apex posteriorly which ends at the optic foramen. The apex is superomedially placed, while the base is directed anterior and lateral. The orbit encases two fissures: (1) the inferior orbital fissure also called the sphenozygomatic fissure and (2) the superior orbital fissure otherwise called as the inter-sphenoidal fissure (Fig. 57.2). The major structures within the orbit are provided in Box 57.1.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_57) contains supplementary material, which is available to authorized users.

Box 57.1 The Major Structures that Occupy the Orbit

- Eye/globe
- Orbital fat
- Extraocular muscles
- Ciliary parasympathetic ganglion
- Nasolacrimal apparatus
- Optic nerve
- Oculomotor
- Trochlear
- Abducent nerves
- V1 and V2 of trigeminal nerve
- Ophthalmic vessels

The orbits have an average height of 35 mm and a mediolateral width of 40 mm [1–3]. The intra-orbital volume of an adult is approximately 30 cc, while the volume of the globe is 7 cc [4]. Generally, the orbital and globe volumes are bilaterally symmetrical at any stage of growth. The medial walls are parallel to each other and around 45–50 mm in length, while the lateral walls are around 90° to each other and 40–45 mm long (Fig. 57.3).

The orbital skeleton may essentially be divided into walls and rims. These include the orbital roof, floor, and medial and lateral walls. The rims include the inferior, superior, medial, and lateral orbital rims. A brief description of the structure of the orbital cavity is provided below.

57.2.1 Orbital Walls

The roof (Fig. 57.4a) is formed by a concave broad plate of the frontal bone which delineates the orbital contents from the cranial cavity. The posterior portion of the roof has a small contribution from the lesser wing of the sphenoid. The anterolateral portion has a shallow depression called the lacrimal fossa, while 5 mm behind the medial aspect of the supraorbital rim is the trochlear fossa which has the cartilaginous pulley of the superior oblique muscle. The roof is triangular in shape and ends in optic foramen, which is the entry of the optic nerve into the orbit.

In older patients there may be spots of resorption in the orbital roof which may cause the dura to adhere to the periorbita of the roof. The junction of the medial wall and the roof has a suture line which lies in close proximity to the cribriform of the ethmoid and is prone for fragmentation. This may be a major concern for CSF leak into the orbits or the nose or at times both.

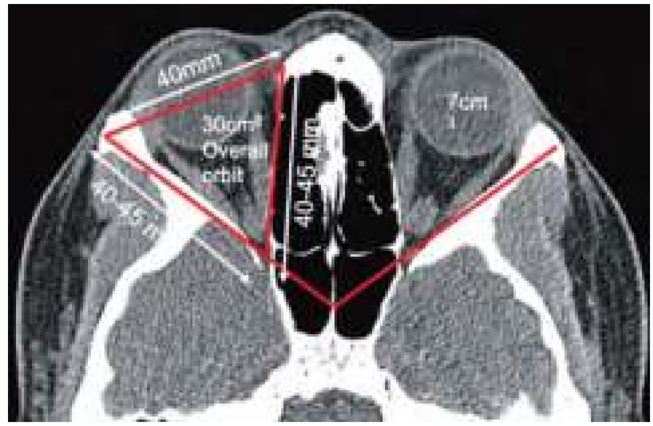

Fig. 57.3 Diagrammatic representation of the various measurements of the orbit and the globe

The roof is separated from the lateral orbital wall by the superior orbital fissure which serves as a passage of entry for the cranial nerves III, IV, V1, and VI into the orbit. The other structure coursing through the fissure is the ophthalmic vein. On the anterior aspect of the roof, at the junction between the medial 1/3rd and the lateral 2/3rd of the supraorbital rim is the supraorbital foramen which transmits the supraorbital neurovascular bundle [1–3, 5].

The medial wall (Fig. 57.4c) is quadrangular in shape and is constituted by the ethmoid bone in the center. The anterosuperior aspect is formed by the frontal bone, while the anteroinferior part is formed by the lacrimal bone. The sphenoid bone forms the posterior part of the medial wall. The infraorbital rim continues along the anterior aspect of the medial wall forming the anterior lacrimal crest which is a part of the frontal process of the maxilla, while the superomedial aspect of the supraorbital rim continues inferiorly as the posterior lacrimal crest which is formed by the lacrimal bone. Between these crests lie the fossa which houses the lacrimal sac. This is of importance during access planning for surgery of the medial wall and the anteromedial aspect of the infra-orbital rim.

The anterior and posterior ethmoidal foramen are located along the fronto-ethmoidal suture which signifies the height of the cribriform plate. The anterior ethmoidal foramen which transmits the anterior ethmoidal artery and nerve lies approximately 22–25 mm behind the medial orbital rim while the posterior ethmoidal foramen which transmits the posterior ethmoidal artery and the spheno-ethmoidal nerve is present about 12 mm posterior [6]. The optic foramen is in continuation of the medial wall and is approximately placed 45–50 mm behind the medial rim. The safe distances the sur-

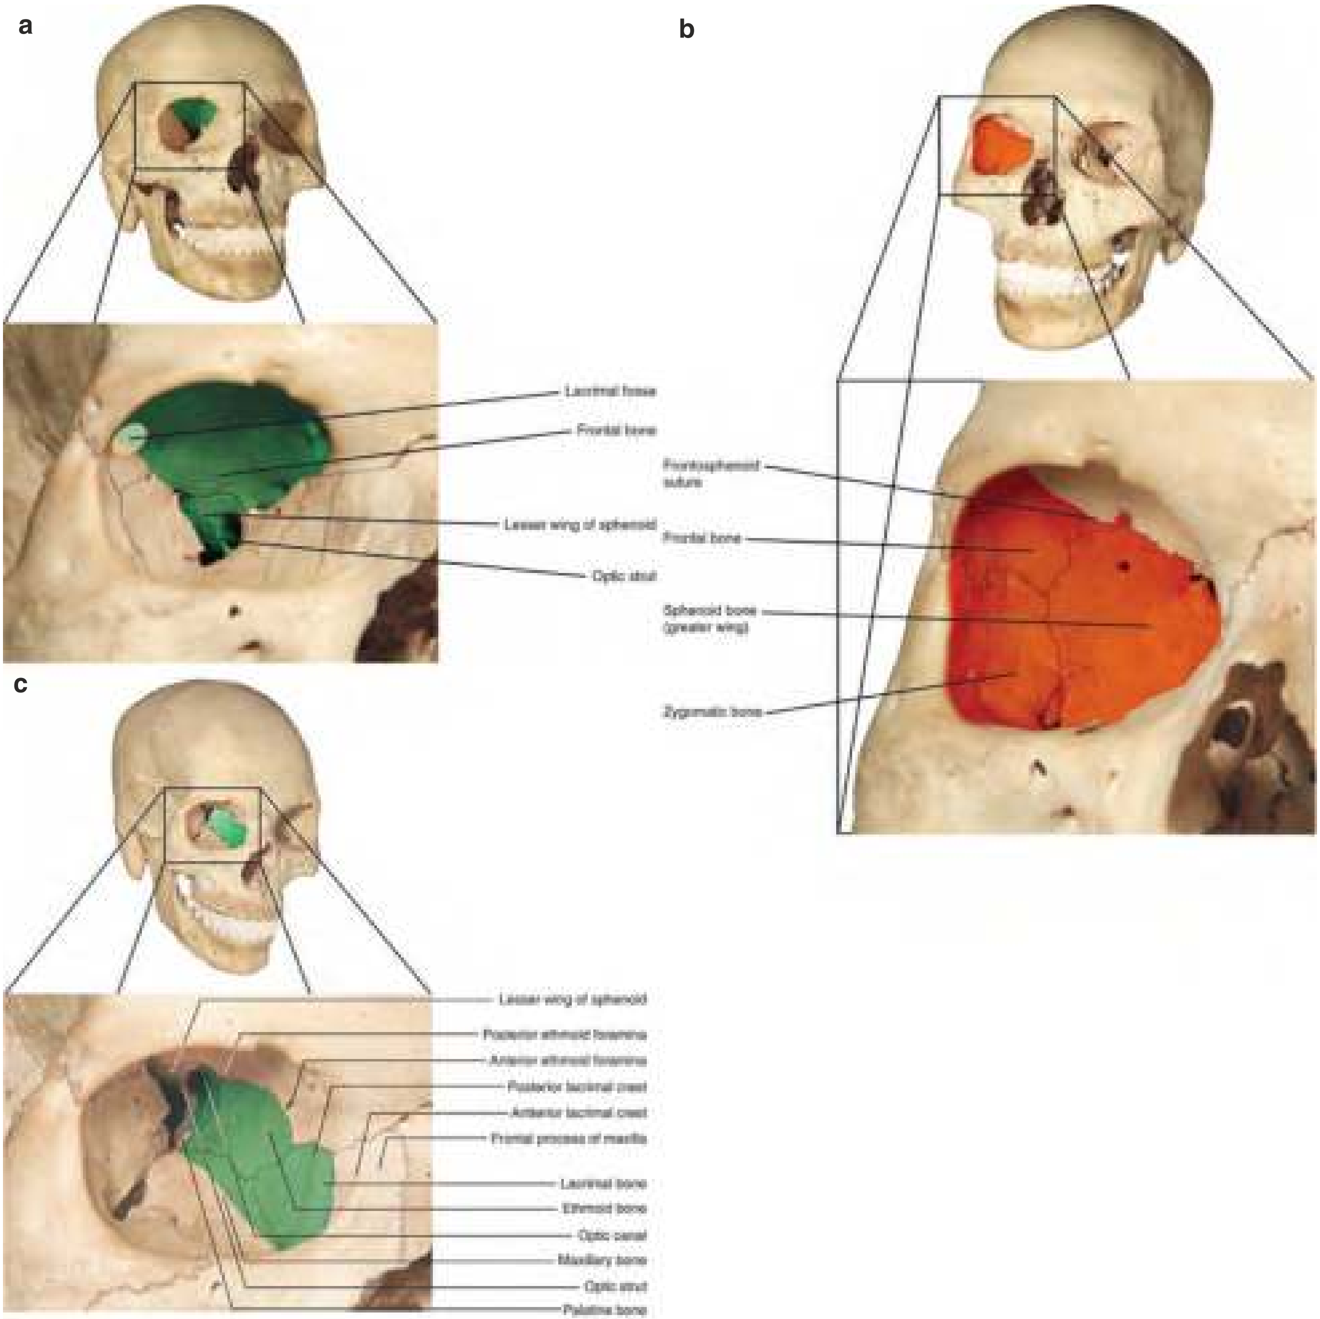

Fig. 57.4 (**a**) Roof, (**b**) lateral wall, and (**c**) medial wall of the orbit

geon needs to remember are 24 mm for the anterior ethmoidal artery, with an additional 12 mm for the posterior ethmoidal vessel and a further 6 mm as the limit to stay away from the optic foramen making it *24-12-6*, an easy formula to remember. One important structure which may be involved in medial wall trauma is the medial rectus muscle which can get entrapped causing ocular motility disturbances.

The lateral wall (Fig. 57.4b) is the thickest wall and is made primarily by the orbital surface of the zygomatic bone and the greater wing of the sphenoid. A small bony projection seen on the lateral wall is the Whitnall's tubercle which lies 11 mm below the fronto-zygomatic suture and 4 mm behind the rim (Fig. 57.7).

This tubercle forms the attachment of the 4L's:

1. The suspensory ligament of Lockwood
2. The lateral horn of the levator aponeurosis
3. The ligaments of the lateral rectus muscle
4. The lateral palpebral ligament

A small groove may be seen at the anterior end of the inferior orbital fissure which transmits the zygomatico-facial and zygomatico-temporal vessels. These course through the zygoma and exit through independent foramina to supply the face and the temporal regions.

The floor (Fig. 57.5a, b) follows a gentle slope from its medial to lateral side. The highest point lies in the posteromedial aspect of the floor forming a bulge called the "Hammer's key area" [7] (Fig. 57.5a), which influences the position of the globe in the anteroposterior axis. In the sagittal view, the floor follows a "lazy S" shape with the anterior part concave and the posterior convex. The reconstruction of this convexity is important to maintain the anterior position of the globe (Fig. 57.5b). The floor is separated from the lateral wall by the inferior orbital fissure. The fissure communicates with the pterygopalatine fossa extra-orbitally. The maxillary division of the V nerve and its branches, the infraorbital artery, and branches of the sphenopalatine ganglion are transmitted through the posteromedial aspect of the fissure, while the inferior ophthalmic veins pass through the lateral aspect to communicate with the pterygoid plexus. The floor is formed by the zygomatic bone and the maxilla with a small contribution from the orbital process of the palatine bone in the posteromedial aspect. A rough area at the anteromedial angle of the floor behind the infra orbital rim forms the attachment of the inferior oblique muscle. The infraorbital groove originates from the inferior orbital fissure and transmits the infra-orbital neurovascular bundle.

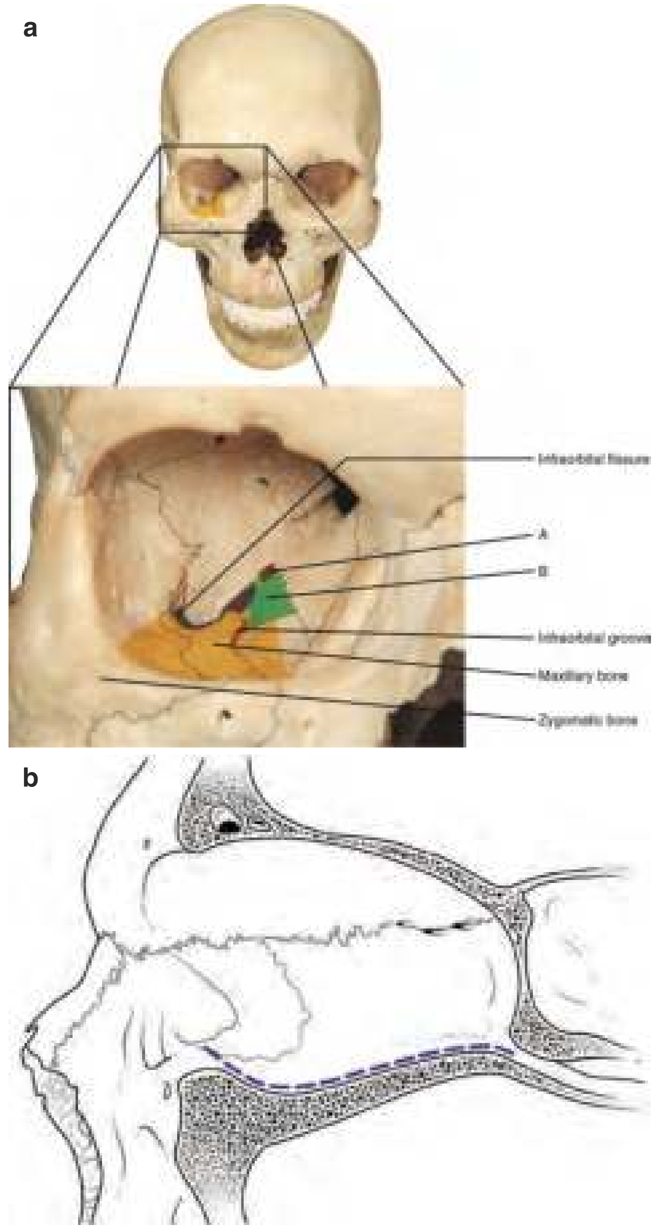

Fig. 57.5 The orbital floor in (**a**) frontal view demonstrating the (A) orbital process of palatine bone and (B) "Hammer's key area." (**b**) Sagittal view of the floor with the "lazy S" form

Orbital Rims:
The rims are superior, inferior, medial, and lateral. Three major bones—the maxilla, zygomatic bone, and frontal bone—make up the rims of the orbit. The width of the rims is greater than its height making it into a rectangular form. The presence of the maxillary sinus and the insertion of the inferior oblique muscle make the infra-orbital rim more prone for fracture and comminution.

57.2.2 Muscles of the Orbit (Fig. 57.6a)

Muscles in relation to the orbit can be divided into

- the muscles associated with the lids
- and the muscles associated with the globe.

The muscles of the lid are:

1. The orbicularis oculi which has a palpebral portion (upper and lower eyelids), the intervening orbital septum, and the inner layer connecting the tarsus
2. The levator palpebrae superioris which is the elevator of the upper eyelid
   The levator palpebrae superioris along with the four recti, and the two obliques form the seven extraocular muscles of the human eye.

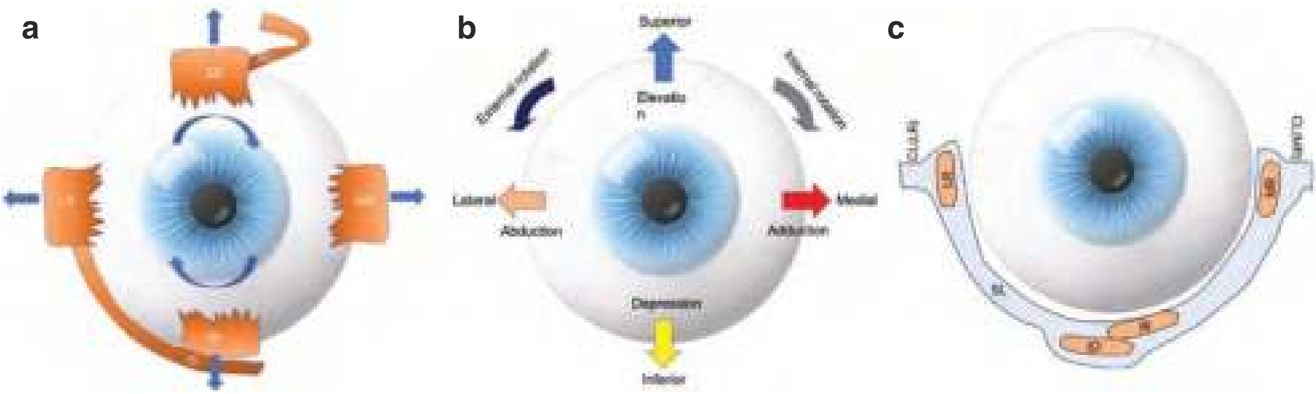

Fig. 57.6 Diagram of right eye demonstrating (**a**) the extraocular muscles and (**b**) the movements they cause. (**c**) The fascial sheath. (*SR* - Superior Rectus, *IR* - Inferior Rectus, *MR* - Medial Rectus, *LR* - Lateral Rectus, *SO* - Superior Oblique, *IO* - Inferior Oblique, *CL(MR)* - Check Ligament of Medial Rectus, *CL(LR)* - Check Ligament of Lateral Rectus, *SL* - Suspensory Ligament

The origin of the superior rectus is from the common tendinous ring superolateral to the optic canal, and its insertion is into the upper part of the sclera. Its function is to produce elevation of the eye and to move the cornea upward and medially helping in adduction and medial rotation.

The origin of the medial rectus is from the medial aspect of the tendinous ring and inserts into the medial surface of the sclera. The medial rectus helps in moving the eye medially (adduction), and bilateral action of the medial rectus helps in medial convergence of both the corneas. A suspensory attachment to the lacrimal crest is also seen on the medial orbital wall where it blends with the medial canthus and the check ligament (Fig. 57.6c) [2, 3, 6, 8]. The origin of the lateral rectus is from the lateral part of the common tendinous ring, and it inserts into the lateral surface of the sclera. Its primary function is to move the eye laterally (abduction).The inferior rectus arises from the common tendinous ring, below the optic canal, and inserts into sclera below the cornea. It is responsible for depression and lateral rotation of the eye.

The inferior rectus followed by the medial rectus are the most common muscles to be entrapped secondary to orbital trauma and may need to be explored and released surgically as indicated. Delayed release of the recti may cause significant necrosis and fibrosis of the muscles hampering return to normal function.

The superior oblique arises superomedial to the optic canal. It has a pulley action at the trochlea on the anteromedial aspect of the orbital roof and inserts into the sclera behind the equator of the globe. The contraction of the muscle produces depression of the cornea and movement of the eye laterally with medial rotation (intorsion).

The inferior oblique muscle arises from the orbital surface of the maxilla lateral to the nasolacrimal groove and inserts into the lateral part of the sclera behind the equator between the inferior and lateral recti muscle. It produces elevation of the cornea and helps in moving the eye laterally with lateral rotation (extorsion).

57.2.3 Movements of the Eye and Their Innervation

Box 57.2 The Movements of the Eye

- Elevation
- Depression
- Adduction
- Abduction
- Intorsion
- Extorsion (Fig. 57.6b)

The different movements of the eye are enumerated in Box 57.2. These are facilitated by the extraocular muscles described above and are contained by the check ligaments. The inferior oblique and inferior rectus muscles which course the floor of the orbit serve as the inferior check ligaments. The fascia of the levator palpebrae superioris, which is anchored to the Whitnall's tubercle laterally and the trochlea medially, acts as the superior check ligament [8].

The contraction of the orbicularis oculi innervated by the facial nerve dictates the closure of the upper eyelid. The movements of the globe within the orbit are however dictated by the synchronous movements of the extraocular muscles of the orbit. The oculomotor nerve innervates all the extraocular muscles other than the lateral rectus which is supplied by the abducent nerve and the superior oblique supplied by the trochlear nerve. Reflex closure of the eyelids occurs via the sympathetic pathways traveling to the smooth muscles of the upper and lower eyelids.

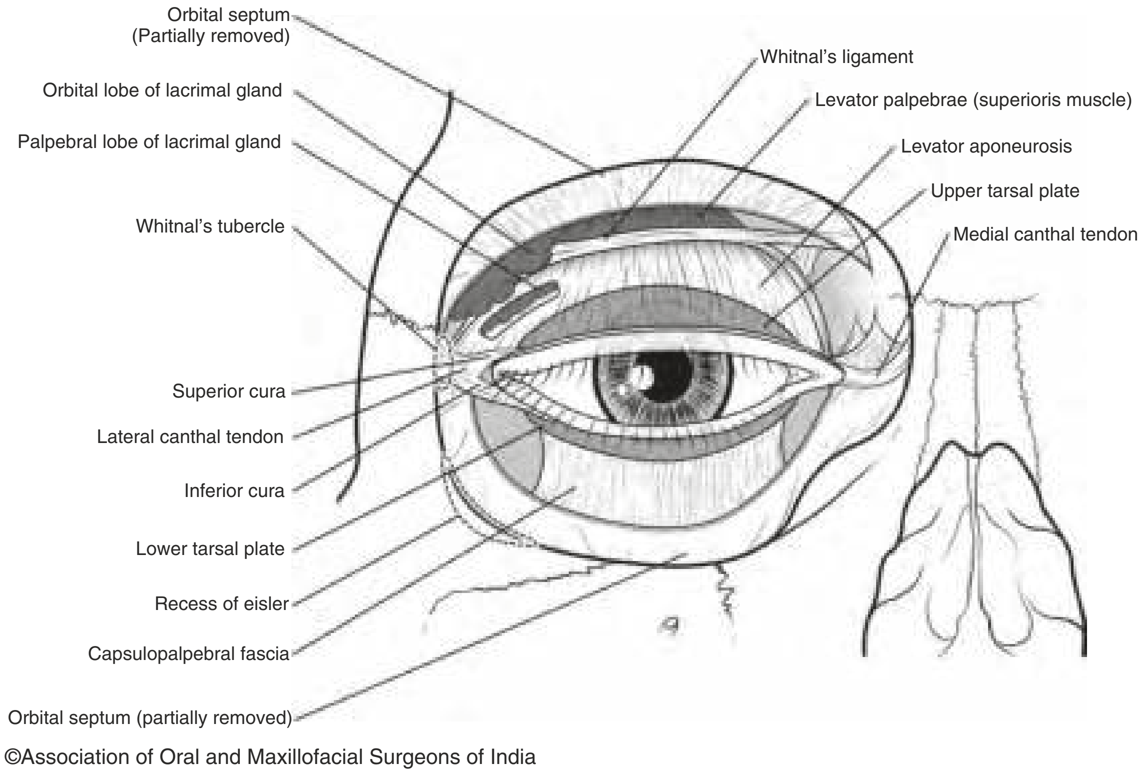

Fig. 57.7 The tarsal apparatus and the orbital septum

57.2.4 Orbital Septum and Tarsal Plates (Fig. 57.7)

The supporting framework for the eyelid is formed by a dense fibrous tissue called the orbital septum which condenses at the lids as the tarsal plates. The orbital septum which separates the orbital and lid contents attaches to the bone and becomes the periorbita inside the orbit and periosteum outside the orbit. The septum of the lower eyelid attaches to the orbital rims, while the septum of the upper eyelid is attached intra-orbitally behind the equator of the globe. The tarsal plates add rigidity to the lids and also serve attachments of multiple muscles and membranes [1, 3].

57.2.5 Conjunctiva

The conjunctiva is the transparent mucous membrane that covers the front surface of the globe and the inner surface of the eyelids.

This has two segments:

1. The bulbar conjunctiva that covers the anterior part of the sclera (the "white" of the eye)
2. The palpebral conjunctiva otherwise known as tarsal conjunctiva which covers the inner aspect of the eyelids

57.2.6 Fascial Sheath of the Eyeball (Fig. 57.6c)

The fascial sheath of the eyeball is called the Tenon's capsule [8]. It extends from the optic foramen to the sclerocorneal junction enveloping the eyeball on the inferior aspect. It attaches to the sclera on the anterior and posterior surfaces of the eyeball and becomes continuous with the fascia of the muscles posteriorly and around the inferior oblique muscle. The fascial sheath of all muscles blend together and form a continuous fascial band called the suspensory ligament of the eye that provides support for the eyeball [8, 9].

57.2.7 Orbital Fat

The orbital fat is present both intra- and extra-conally. They cushion the globe and muscles of the orbit. The extra-conal fat determines and influences the position of the globe. This may be altered either due to herniation or atrophy secondary to fractures of the orbit resulting in enophthalmos.

57.3 Classification System

Manson [10] and colleagues classified the fractures based on the energy of impact, the degree, and extent of comminution and displacement observed on CT:

(a) Trap door fractures—low-velocity injuries
(b) Medial blowout fractures—intermediate-velocity injuries
(c) Lateral blowout fractures—high-velocity fractures

Converse and Smith [11] termed them "pure" or "impure" based on the involvement of orbital rims (Fig. 57.8):

(a) Pure (blow-in or blowout fractures)—fracture of the internal walls with intact rims
(b) Impure (complex with involvement of one or more rims)—associated fractures of the rims

Hammer [7] described four classes of orbital fractures based on their occurrence with other fractures of the face (Fig. 57.9):

(a) *Type I*: Orbito-zygomatic fractures—These involve the fractures of the walls of the orbit along with the zygomatic complex.
(b) *Type II*: Internal orbital fractures—These involve isolated fractures of any of the walls, roof, and floor.
(c) *Type III*: Naso-orbito-ethmoid-type fractures—These involve fractures of the naso-orbito-ethmoid complex which involve the orbit.
(d) *Type IV*: Complex fractures of the face—This type involve fractures of the orbit with concomitant fractures of the face other than the ones mentioned above [7].

57.4 Blowout and Blow-In Fractures

Smith and Converse in 1960 recognized the phenomenon of blowout fractures (Fig. 57.10a). These fractures may involve entrapment or herniation of periorbital tissues resulting in restricted eye movements and/or enophthalmos due to reduction in the volume of intra-orbital contents [3, 11].

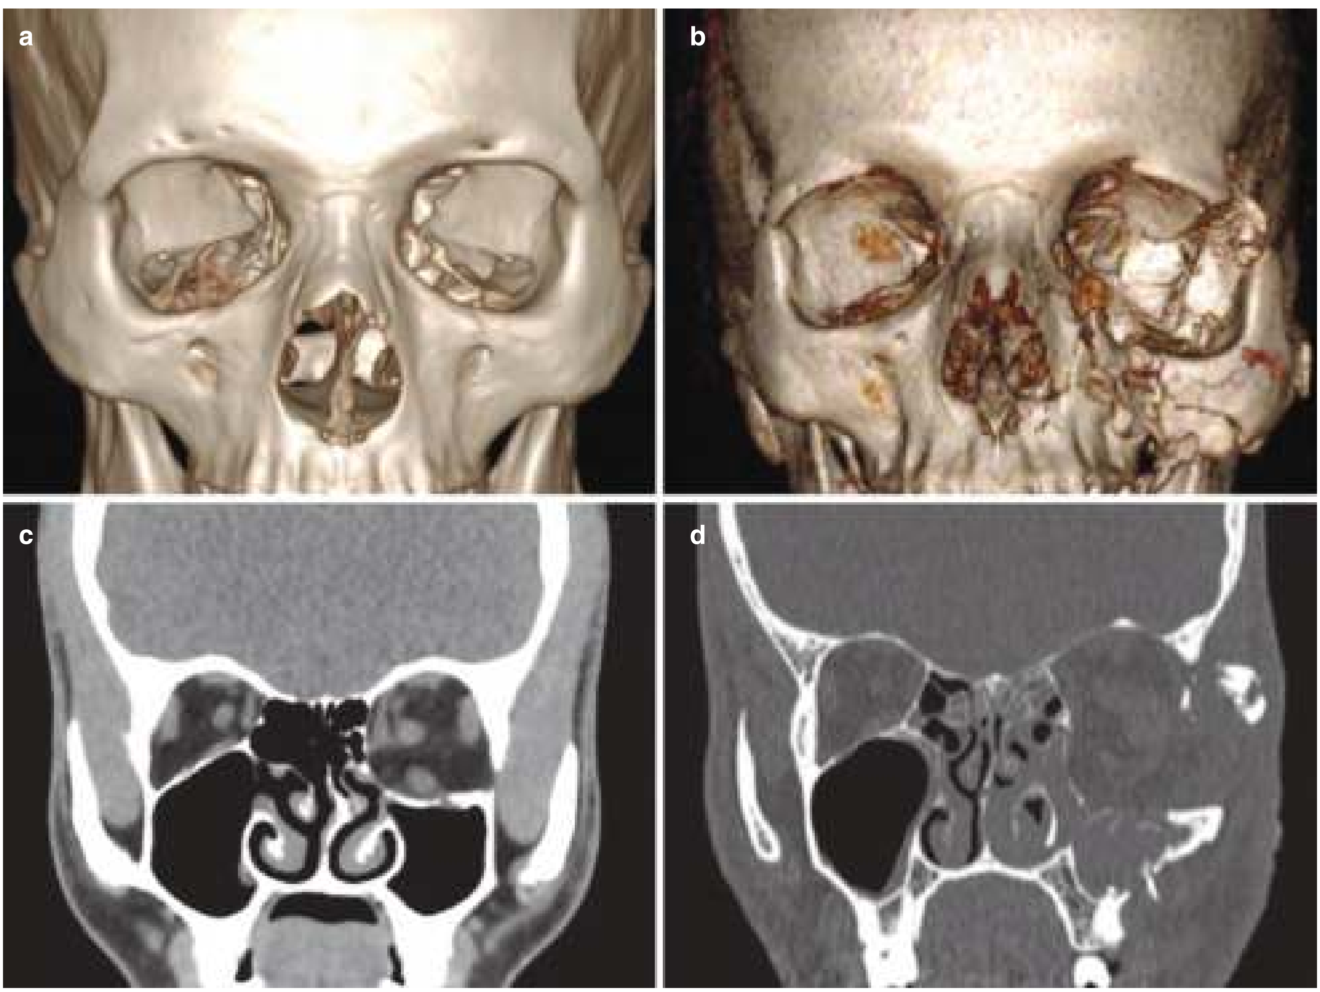

Fig. 57.8 CT scans showing Pure (**a** and **c**) and impure (**b** and **d**) blowout fractures of the orbit

"Blow-in" type of orbital fractures was described by Dingman and Natvig [3, 12] in 1964 wherein the intra-orbital space is reduced by an internally displaced bony fragment (Fig. 57.10b). Such types of fractures are usually accompanied with proptosis on the affected side [13].

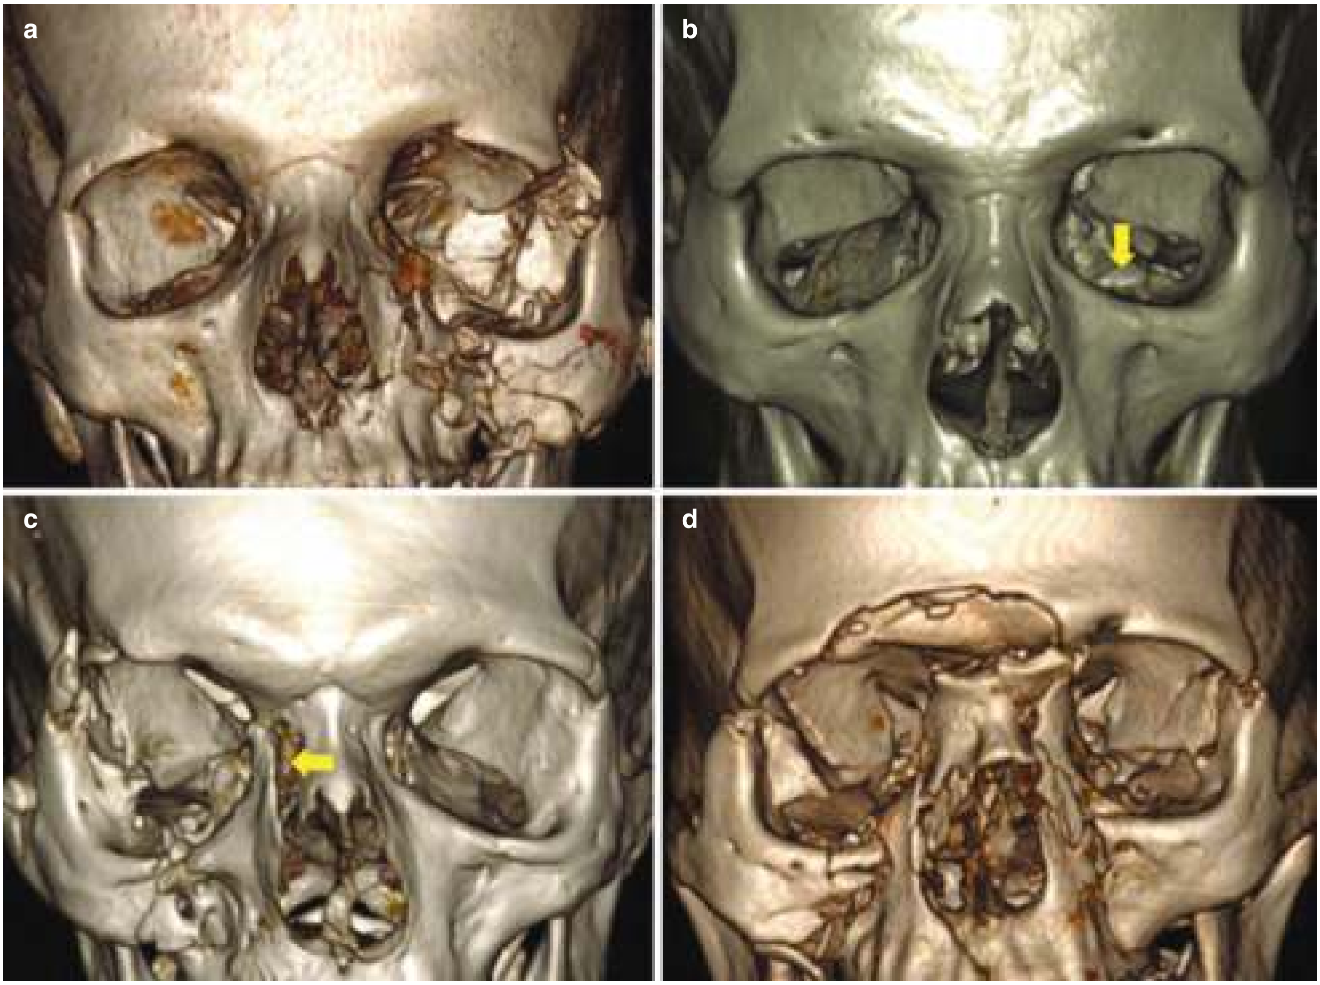

Fig. 57.9 CT scan images showing types of orbital fractures: (**a**) orbito-zygomatic, (**b**) internal orbital, (**c**) naso-orbito-ethmoid type, and (**d**) orbit with complex facial fractures

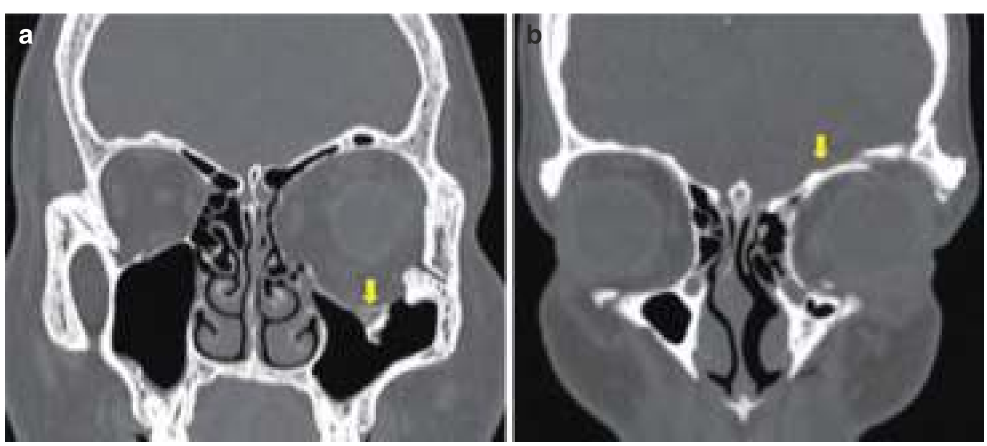
Fig. 57.10 CT scans demonstrating a blowout of the medial orbital wall and floor (**a**) and a blow-in fracture of the orbital roof (**b**)



57.5 Biomechanics of Injury

One of the first mechanisms of orbital wall fractures was suggested by Pfeiffer [14] in 1943, called *globe-to-wall theory or hydraulic theory* (Fig. 57.11a), wherein posterior displacement of the globe after sustaining a direct hit was propounded to transmit force along the walls resulting in fracture of the thinner walls. There are two more widely accepted mechanisms of orbital wall fractures, namely, the:

(i) *Retropulsion theory* (Fig. 57.11b)
(ii) *Buckling mechanism* [15] (Fig. 57.11c)

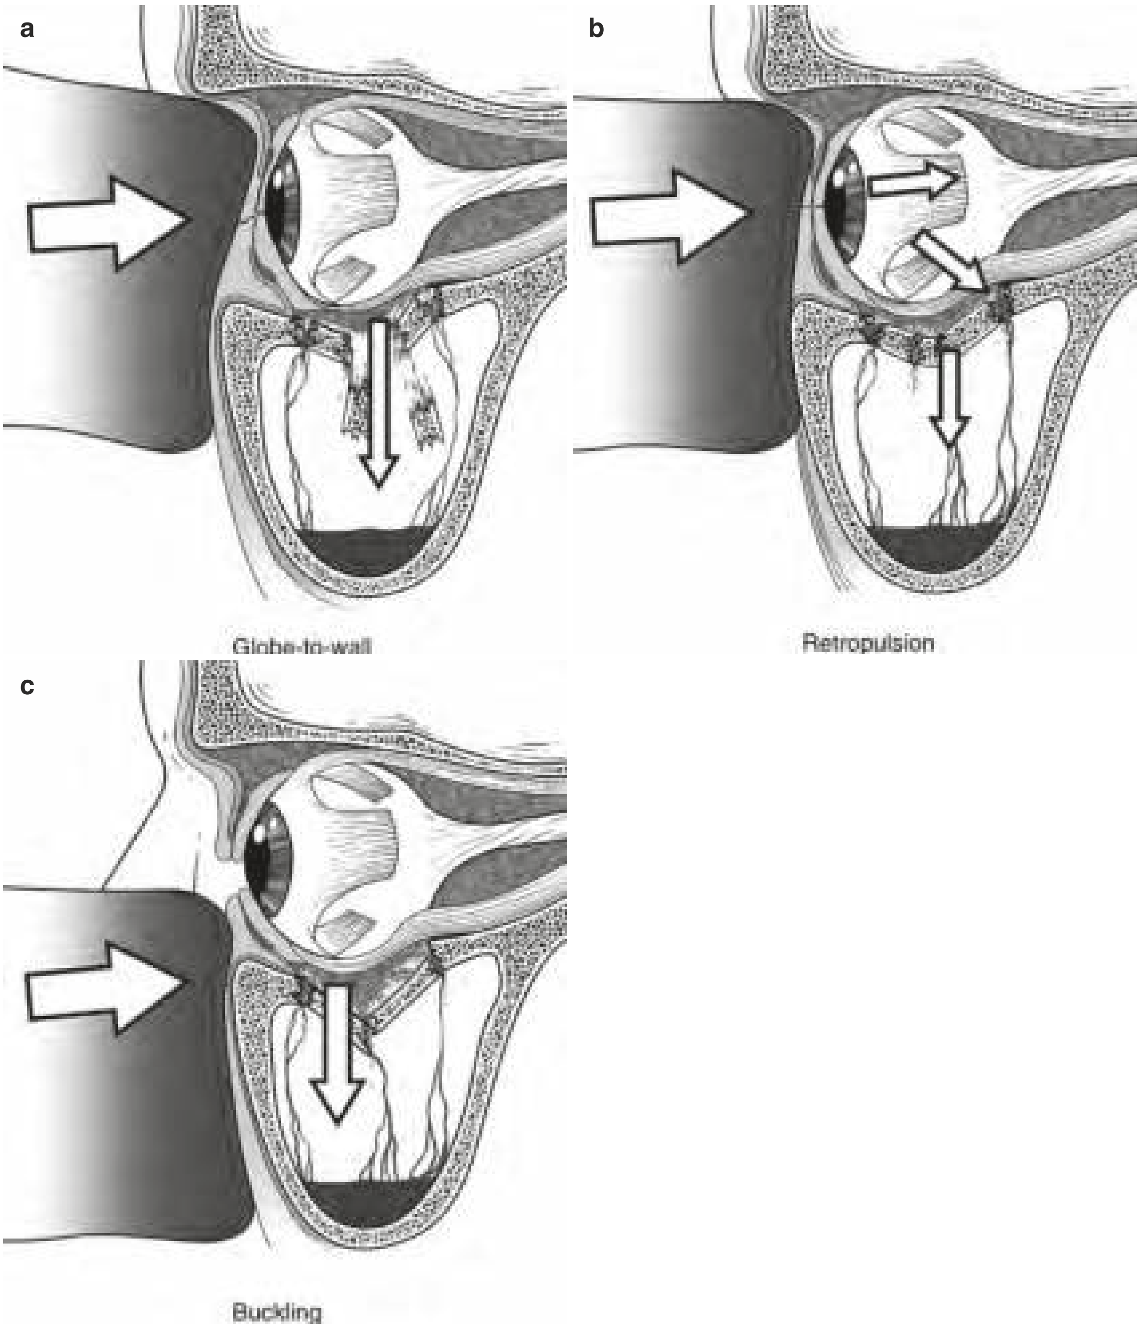


Fig. 57.11 Diagrammatic representation of (**a**) hydraulic theory, (**b**) retropulsion theory, and (**c**) buckling mechanism

First proposed by King [16] in 1944, retropulsion theory suggests that sudden increase in intra-orbital pressure caused by direct hit from a large object creates stresses along the orbital walls resulting in fractures at the areas of least thickness. The buckling theory or transmission theory explains the injury through a ripple effect created in the floor. The ripple thus created causes compression in an anteroposterior direction and resultant fracture at the posteromedial part of the orbital floor commonly [17, 18].

57.6 Initial Assessment

After initial stabilization of the patient, a thorough facial examination is performed in a way similar to any facial fracture. Special consideration is given to a detailed ophthalmic evaluation followed by eliciting signs and symptoms significant for periorbital trauma which are discussed below. The frontal area and supraorbital rim are examined first, with a logical progression downward, including the lateral and infra-orbital rims, although extensive edema in this area may obscure any steps making the palpatory examination difficult [3, 7, 19–22].

57.6.1 Ophthalmologic Examination

The American Association of Ophthalmology [23] advocates an 8-point ophthalmological examination which includes the following (Box 57.3):

1. *Visual acuity*: Visual acuity test for each eye is recorded using a Snellen chart (Fig. 57.12a) and includes ability to read letters, count fingers, perceive hand movements, and light perception. If visual acuity is extremely poor and recording of a chart test fails, the patient is subjected to a finger counting test or at times even assessed for primary light perception alone.
2. *Pupillary examination*: Pupillary examination is done to note the
   (a) size,
   (b) shape,
   (c) symmetry,
   (d) and direct/indirect reflex to light.
   Glaucoma, previous history of surgery, and/or injury to ocular system may also account for anisocoria or irregular pupils. Peaked or irregular pupils may also be indicative of perforation of the globe. The swinging flashlight test is performed for relative afferent pupillary defect (RAPD) (Fig. 57.12b).
3. *Extraocular motility and alignment*: The patient is first screened for all the six cardinal gazes (Fig. 57.12c). First checked binocularly for versions of both sides and then checked monocular for ductions. A thorough heterotropia check is also performed. Diplopia and restrictions in gazes are noted. Clinically, a forced duction test under topical anesthesia is done to elicit mechanical impediment to movement of the globe. This may also be performed under general anesthesia intraoperatively (Figs. 56.21, 57.13). A Hess chart examination is a part of the orthoptic assessment protocol for evaluation of ocular motility.
4. *Intraocular pressure*: Tonometry should be performed to evaluate intraocular pressure either in a clinic setting using a Goldmann applanation method or outside using a mobile/portable device. This examination is skipped if there is a suspicion of ruptured globe. The normal IOC

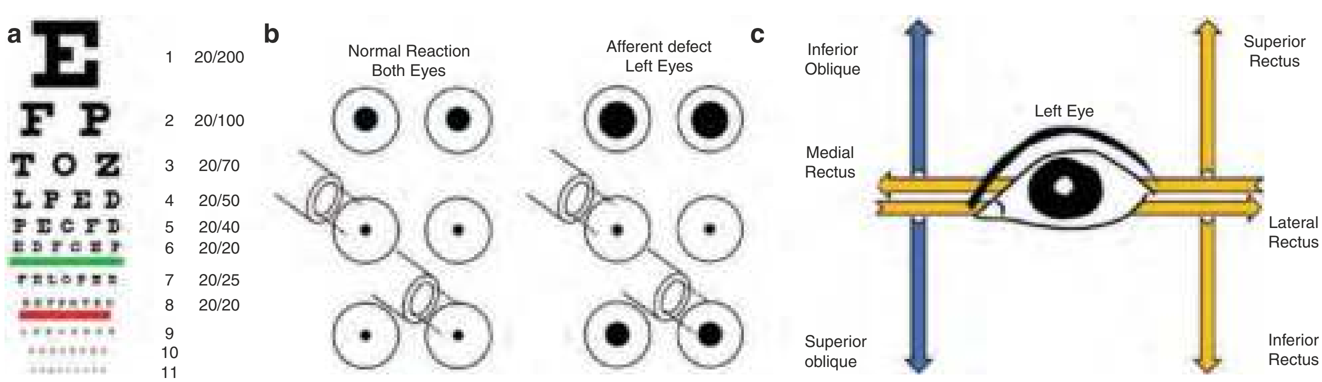

Fig. 57.12 Picture showing (**a**) the Snellen chart, (**b**) swinging flash light test, and (**c**) the six cardinal signs of gazes

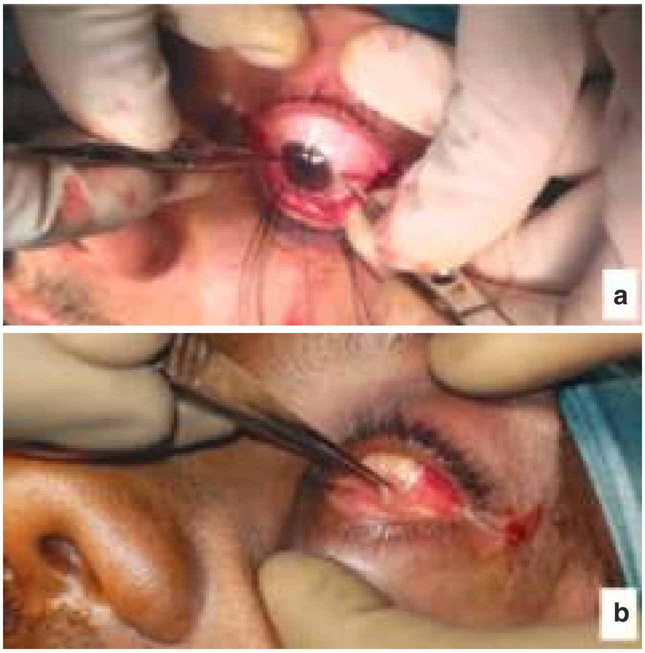

Fig. 57.13 Demonstration of the method of performing intraoperative forced duction test (**a**) by grasping the limbus (sclero-corneal junction) and (**b**) by grasping the inferior rectus muslce

is a range between 10 and 21 mmHg with the mean being around 15 mmHg. Low IOP may be suggestive of a ruptured globe or detached retina, while increased IOP may indicate hyphema, glaucoma, or an orbital compartment syndrome like "retrobulbar hemorrhage." A pressure of more than 30 mmHg is an ophthalmological emergency.

5. *Visual fields*: Visual fields for each eye are checked by asking the patient to determine movements at the periphery of the examiner's own visual field, while at a distance of about 2 ft from each other. Loss of field may be suggestive of compressive or ischemic injuries to the optic nerve with or without damage to the visual pathway. Goldmann visual field test can also be employed to objectively chart binocular visual field loss wherein patient is asked to look at a center of the chart and is required to track a point source of light.
6. *External examination/periorbital screening*: A thorough clinical evaluation is performed to note down all clinical features detailed below. Orbital trauma is generally associated with possible adnexal injuries which also need to be assessed for intervention and management.
7. *Slit-lamp examination*: A formal slit lamp test is performed if it may be allowed. This provides information about the lids, lashes, lacrimal system, conjunctiva, sclera, anterior chamber, iris, the lens, and the anterior vitreous.
8. *Fundoscopic examination*: A fundoscopic examination is performed to assess the retina, optic nerve head, and the vessels. This is done by the use of an ophthalmoscope. It also provides information about presence of intraocular hemorrhages and foreign bodies.
9. *Globe position*: An important feature in examination of orbital trauma from a cranio-maxillofacial perspective includes the examination of globe positions. This is performed both clinically and by using an exophthalmometer. The Hertel's exophthalmometer is used in common settings for the evaluation of proptosis or enophthalmos. In case of injuries involving the lateral face, like a fracture of the ZMC, the Naugle's exophthalmometer is used.

57.6.2 Clinical Features

A good evaluation of the skeletal and soft tissue components of the orbit as well its associated adnexa (eyelids, lacrimal apparatus, etc.) is mandated. The common clinical features that are presented with in orbital trauma are provided in Box 57.4.

Box 57.4 Common Clinical Features in Orbital Trauma Are Enumerated Below

- Periorbital edema (Fig. 57.14a)
- Periorbital ecchymosis and subconjunctival hemorrhage (Fig. 57.14b)
- Contusions and hematomas
- Subcutaneous emphysema with crepitus
- Lacerations involving the eyelids (Fig. 57.14c)
- Injuries to the canthal apparatus (medial and lateral)
- Neurological deficits of the infra-orbital and facial nerves

Fig. 57.14 Clinical pictures demonstrating (**a**) edema of the left periorbital region, (**b**) left-sided periorbital ecchymosis and subconjunctival hemorrhage, and (**c**) soft tissue injury of the left eyelid and supraorbital region

Clinical signs and symptoms that are more exclusive to orbital trauma are discussed further in more detail.

57.6.2.1 Enophthalmos/Hypophthalmos (Fig. 57.15a, b)

Any change in the orbital volume directly impacts the position of the globe and its anteroposterior projection and supero-inferior position [24]. Clinically enophthalmos can be detected by an exaggerated suprapalpebral fold and reduced projection on viewing from an inferior view or worm's view. Hertel's or Naugle's exophthalmometer can also be used to quantify and measure the discrepancy. Other causes of enophthalmos implicated are traumatic atrophy of intra-orbital fat, infections causing cicatricial contraction of retrobulbar tissues, and dislocation of trochlear attachment of superior oblique muscle due to trauma [25, 26]. Hypophthalmos is noted as a change in the horizontal pupillary levels.

57.6.2.2 Retrobulbar Hemorrhage (Fig. 57.16)

Retrobulbar hemorrhage is a vision threatening emergency which occurs due to accumulation of blood in the retrobulbar space. This causes increased intra-orbital pressure resulting in compression or stretching of the optic nerve and reduced perfusion to the eye. Orbital trauma especially blunt injury may be associated with retrobulbar hemorrhage which warrants immediate attention. However this may also occur as a complication following surgery to the orbit or pathologies like an aneurysm. Acute post-septal hemorrhage limited anteriorly by the orbital septum and posteriorly by bone may cause permanent loss of vision by creating a compartment syndrome [27]. It presents as reduced ocular motility, elevated intraocular pressure, proptosis, and diminishing vision. In unconscious patients, pupillary assessment, increased pressure, and presence of relative afferent pupillary defect or RAPD are usually diagnostic.

57.6.2.3 Lacrimal System Injuries

Due to its close topographical location to the orbital complex, nasolacrimal system especially the duct may be involved in traumatic injuries to the orbit. Injury to the canaliculi or the nasolacrimal ducts in naso-orbito-ethmoidal injuries may present as epiphora [28]. Patency of

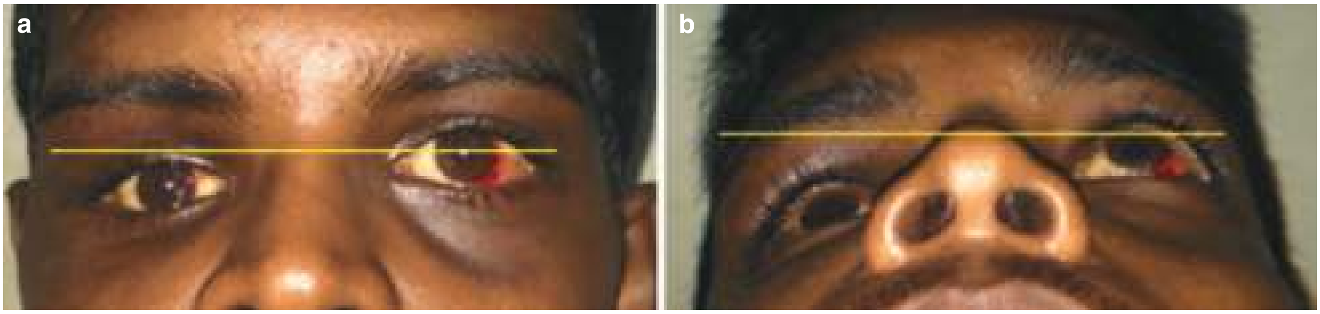

Fig. 57.15 Clinical photograph of a patient with both (**a**) hypophthalmos and (**b**) enophthalmos of the right globe

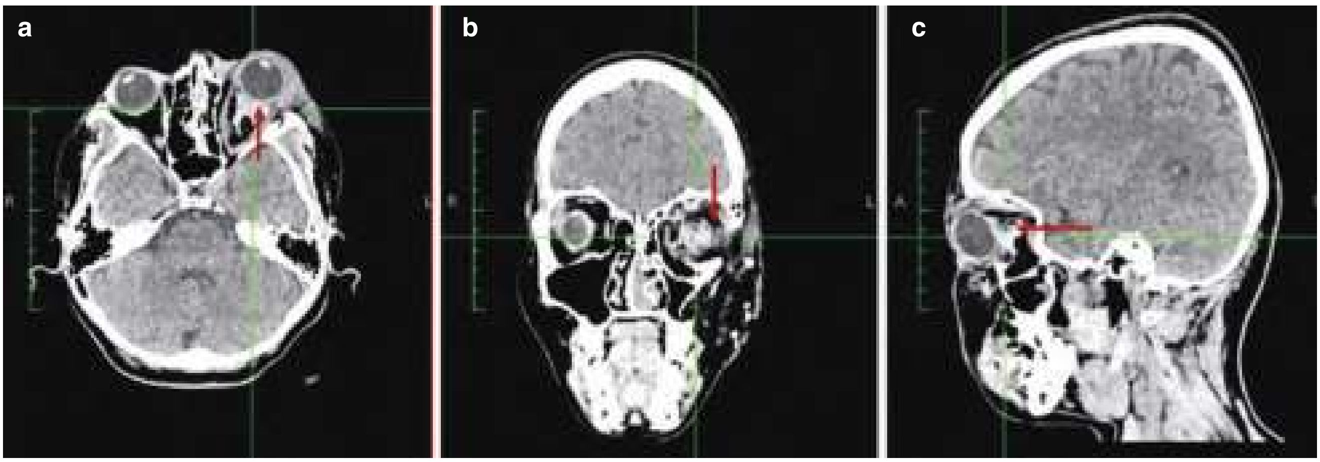

Fig. 57.16 (**a**) Axial, (**b**) coronal, and (**c**) sagittal section CT scan images demonstrating left-sided retrobulbar hemorrhage

the naso-lacrimal duct and sac can be verified by the Jones tests 1 and 2 or by a simple lacrimal probing test with insertion of a Crawford silicone intubation tubes though the canaliculi and visualization of the same at the distal end of the disruption. ROPLAS test or regurgitation on pressure over lacrimal sac may be performed clinically to elicit post-traumatic blockage of the nasolacrimal duct (Fig. 57.17c). Confirmation however is obtained with a CT dacryocystogram or CT-DCG (Fig. 57.17a, b). Reconstruction of the lacrimal drainage system is achieved by simple intubations or a formal dacryocystorhinostomy as indicated by the clinical scenario.

57.6.2.4 Oculocardiac Reflex (Trigeminocardiac Reflex)

First described by Dagnini and Aschner in 1908, oculocardiac reflex is bradycardia on manual compression of the eyes. The most common traumatic etiology is the incarceration of inferior rectus muscle in trap-door fractures of the orbital floor [29, 30]. Other causes that may present with oculocardiac reflex are retrobulbar hemorrhage, white-eyed blowout fractures and orbital surgery.

57.6.2.5 Superior Orbital Fissure Syndrome (Box 57.5)

Post-traumatic superior orbital fissure syndrome may be attributed to pressure exerted on the contents of the superior orbital fissure due to hemorrhage or impingement by fractured fragments.

Superior orbital fissure syndrome was first described by Hirschfield in 1858 [31, 32] and symptoms include:

(i) Ophthalmoplegia due to involvement of III, IV, and VI cranial nerves.
(ii) Paresthesia over the forehead due to involvement frontal nerve of first division of trigeminal nerve.
(iii) Ptosis due to impeded action of levator palpebrae superioris and Muller's muscle.
(iv) Pupillary dilatation due to paresis of circular sphincter muscle and unrestricted action of dilator pupillae.
(v) Impairment of direct pupillary reflex due to blocked ipsilateral efferent arc, whereas consensual reflex is preserved due to intact ipsilateral efferent and contralateral efferent arcs.

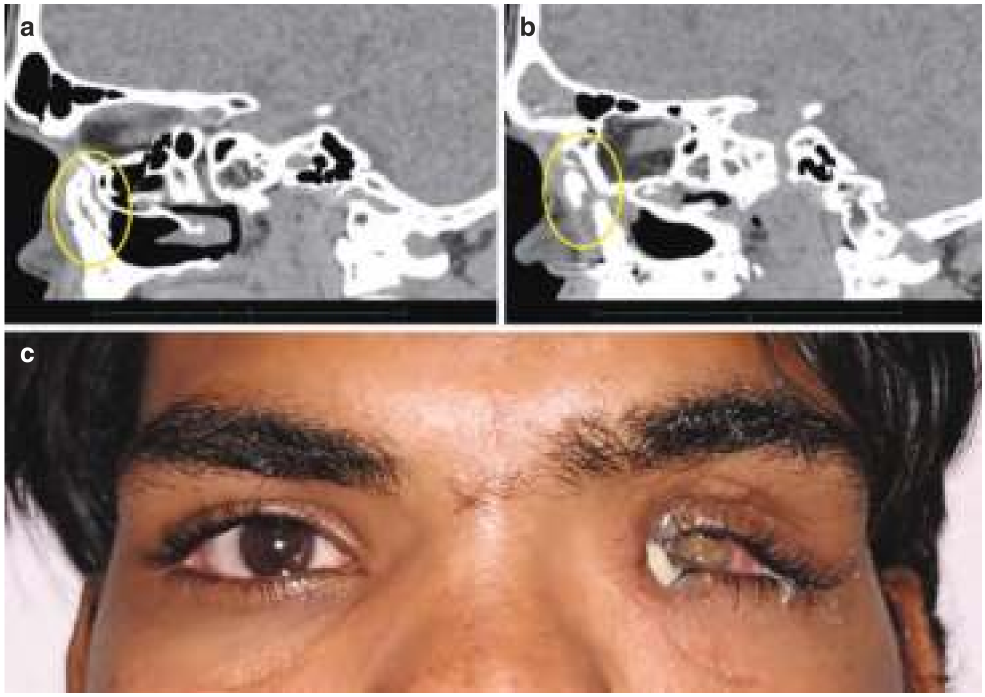

Fig. 57.17 (**a**) Sagittal section CT DCG demonstrating patent NLD with draining dye and (**b**) blocked NLD with no drainage of the dye. (**c**) Clinical photograph of patient with left-sided NOE fracture demonstrating regurgitation of contents due to blocked left naso-lacrimal duct ROPLAS positive

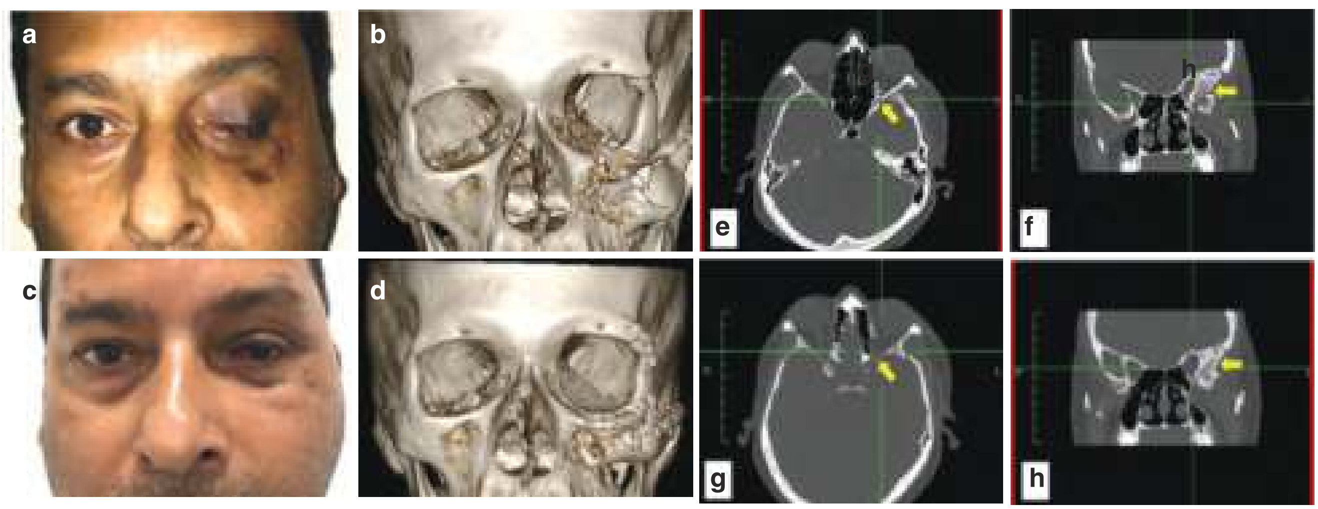

Fig. 57.18 Clinical pictures and CT scans of patient with orbital apex syndrome. (**a**) Clinical picture demonstrating left-sided orbito-zygomatic trauma with clinically evident ptosis, (**b**) 3D CT demonstrating comminuted zygomatico-orbital fracture with medial displacement of the greater wing of sphenoid, (**c**) clinical picture of patient 2 weeks post-surgery with resolution of ptosis, (**d**) post-operative 3D CT showing ORIF, (**e**) pre-operative axial CT demonstrating total compression of the left optic canal (yellow arrow), (**f**) pre-operative coronal CT demonstrating compression of the left superior orbital fissure (yellow arrow), (**g**) post-operative CT showing decompressed left optic canal (yellow arrow) and (**h**) post-operative coronal CT showing decompresison of the left superior orbital fissure (yellow arrow)

(vi) Impaired accommodation is because of impaired parasympathetic pathway to the ciliary ganglion.
(vii) Loss of corneal reflex due to lack of transmission via the nasociliary branch of ophthalmic nerve.
(viii) Proptosis either due to presence of hemorrhage or paresis and laxity of extraocular muscles which normally aid in globe retraction.

Management may be conservative or exploratory surgery of the orbit including surgical decompression [33].

57.6.2.6 Orbital Apex Syndrome (Fig. 57.18) (Box 57.5)

In severe orbital trauma, optic nerve may also be implicated due its close proximity to the superior orbital fissure [31, 34]. The term orbital apex syndrome was first coined by Kjaer in 1945 [35], and the symptoms include all features

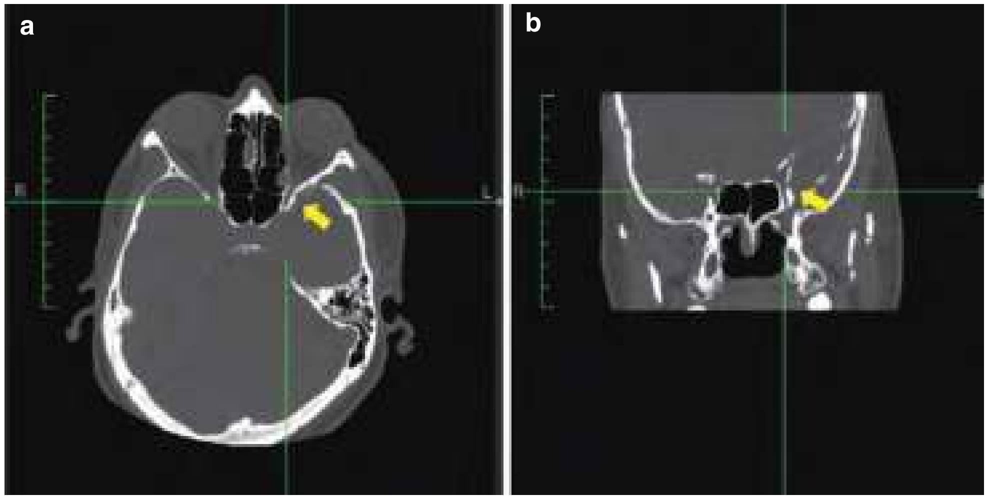

Fig. 57.19 (**a**, **b**) Axial CT scan of patient with direct traumatic optic neuropathy demonstrating a skull base fracture and bony spicule at the entry of the optic nerve into the canal

of superior orbital fissure syndrome along with partial or loss of vision.

57.6.2.7 Traumatic Optic Neuropathy (TON) (Box 57.5)

TON may be defined as an acute injury to the optic nerve with impairment of visual function. It may occur as a result of:

(i) Direct trauma to the optic nerve (Fig. 57.19) (physical damage or nerve sheath compression due to compartment syndromes)
(ii) An indirect insult due to diffuse axonal damage secondary to conduction of forces from blunt head trauma
The occurrence may be unilateral or bilateral.

Clinical features of TON include:

(i) Afferent pupillary defect
(ii) Diminished visual acuity
(iii) Diminished color perception
(iv) Varying reduction in visual fields

Management of TON is handled under the section of orbital emergencies.

Box 57.5 Comparison of Clinical Features of Traumatic Optic Neuropathy, Superior Orbital Fissure, and Orbital Apex Syndromes

Traumatic optic neuropathy (TON)	Superior orbital fissure syndrome	Orbital apex syndrome
Unilateral or bilateral	Ophthalmoplegia with involvement of cranial nerves III, IV, & VI	All features of superior orbital fissure syndrome
Relative afferent pupillary defect (RAPD) except in symmetrical bilateral cases	Forehead paresthesia	Partial or total loss of vison
Variable loss of visual acuity (from normal to no vision)	Ptosis	
Impaired color vision	Dilated pupil	
Variable visual field defects	Impaired direct but preserved consensual pupillary reflex. Impaired accommodation	
	Loss of corneal reflex	
	Proptosis	

57.6.3 Investigations

Conventional radiographs have a minimal role in the diagnosis and planning of orbital fractures. CT scans (Fig. 57.20a–c) have long been considered the "gold standard" in orbital trauma. The scans are usually ordered in fine cuts of 0.5 mm and taken in all the three planes. The coronal and the sagittal scans are important in the diagnosis

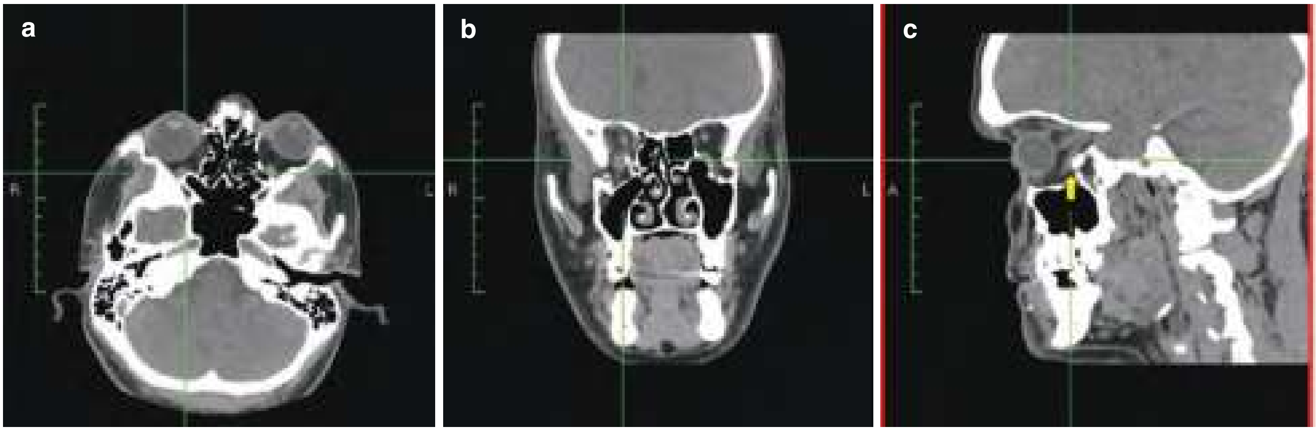

Fig. 57.20 CT scans showing (**a**) axial section with fracture of the medial wall of the right orbit, (**b**) coronal section showing fractures of the medial wall and floor, and (**c**) sagittal section showing fracture of the floor with fibrosis of the inferior rectus to the posterior ledge (yellow arrow)

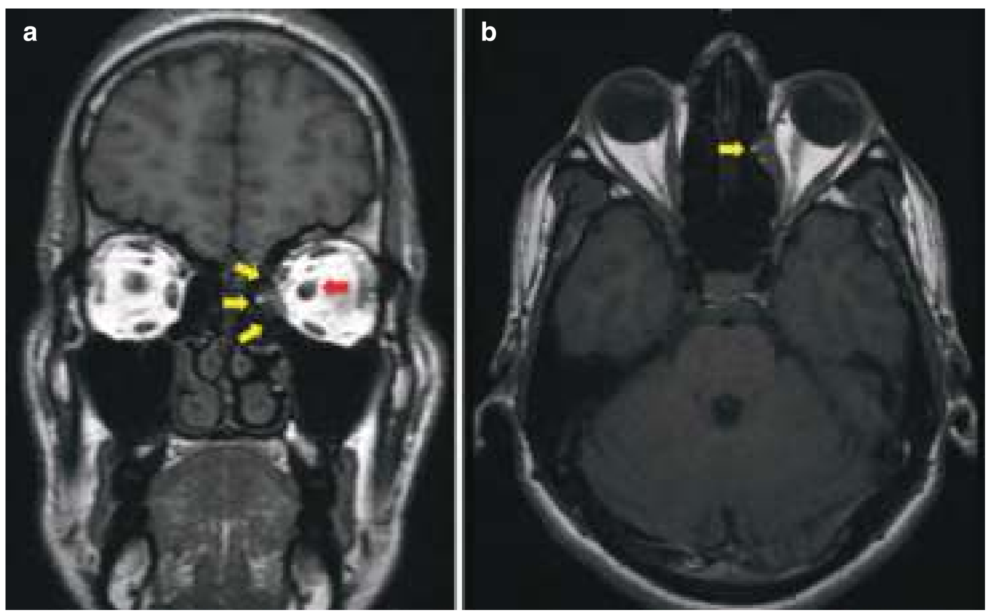
Fig. 57.21 MRI (**a**) coronal and (**b**) sagittal sections, demonstrating entrapment of the medial rectus (yellow arrows) and medial displacement of the optic nerve (left orbit)



of fractures of the floor and the roof, while the axial scans provide better information regarding the fractures of the medial and lateral walls. Axial sections are also important to study the optic canal integrity.

Indications for an MRI (Fig. 57.21a, b) scan are limited to determining soft tissue injuries and entrapment of muscles and to assessing damage to the optic nerve. It is also used to identify intra-orbital herniation of brain in the case of blow-in fractures.

57.7 Approaches to the Orbit

Box 57.6 Surgical Approaches to the Orbit

- Transcutaneous-medial and lateral
- Trans-caruncular
- Transconjunctival

57.7.1 Transcutaneous Approaches

1. Lynch
2. Extended glabellar approach
   (a). Lateral transcutaneous approaches
      (i) Lateral brow incision
      (ii) The upper lid blepharoplasty and the sub brow approaches
   (b). Lower eyelid approaches (Also refer Figs. 56.44, 56.45)
      (i) Sub-ciliary
      (ii) Sub-tarsal
      (iii) Infra-orbital (Video 57.1)

57.7.1.1 Lynch

This incision described by Lynch [36] in 1921 is a semilunar-shaped incision (Fig. 57.22a) placed between the nasal dorsum and the medial canthal ligament that provides direct access to the canthal apparatus and the medial orbital rim and wall. The major drawbacks of this particular incision are chances of developing a web and hence an unsightly scar. There may also be risk of damage to the medial canthal tendon and the lacrimal apparatus that is present infero-laterally. Recent modifications of the Lynch incision have accommodated options to reduce the scarring by the use of "Z" plasties (Fig. 57.22b, c) and other esthetic incision designs.

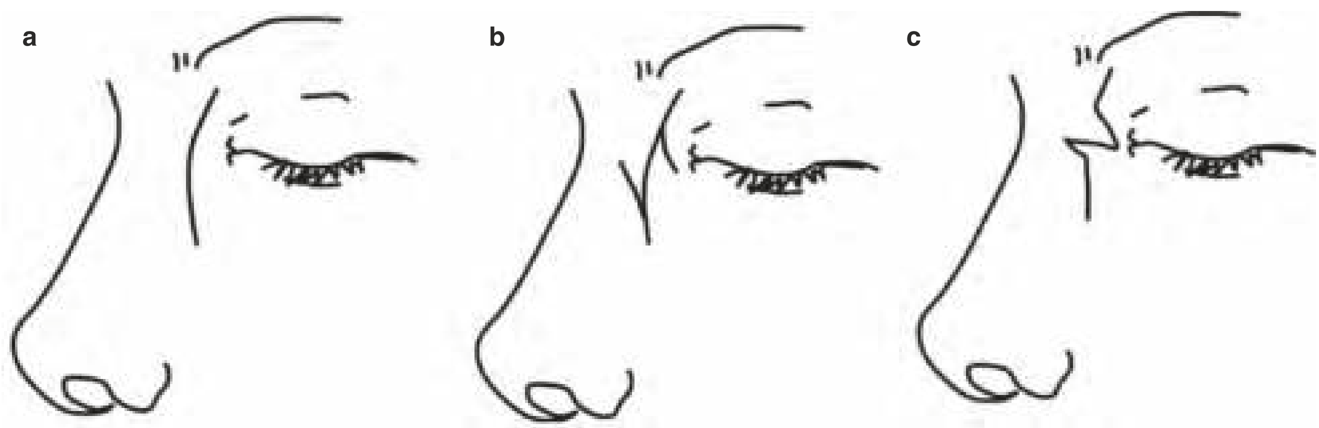


Fig. 57.22 Diagrammatic representation of the (**a**) classical Lynch incision and (**b, c**) modification with "Z" plasty

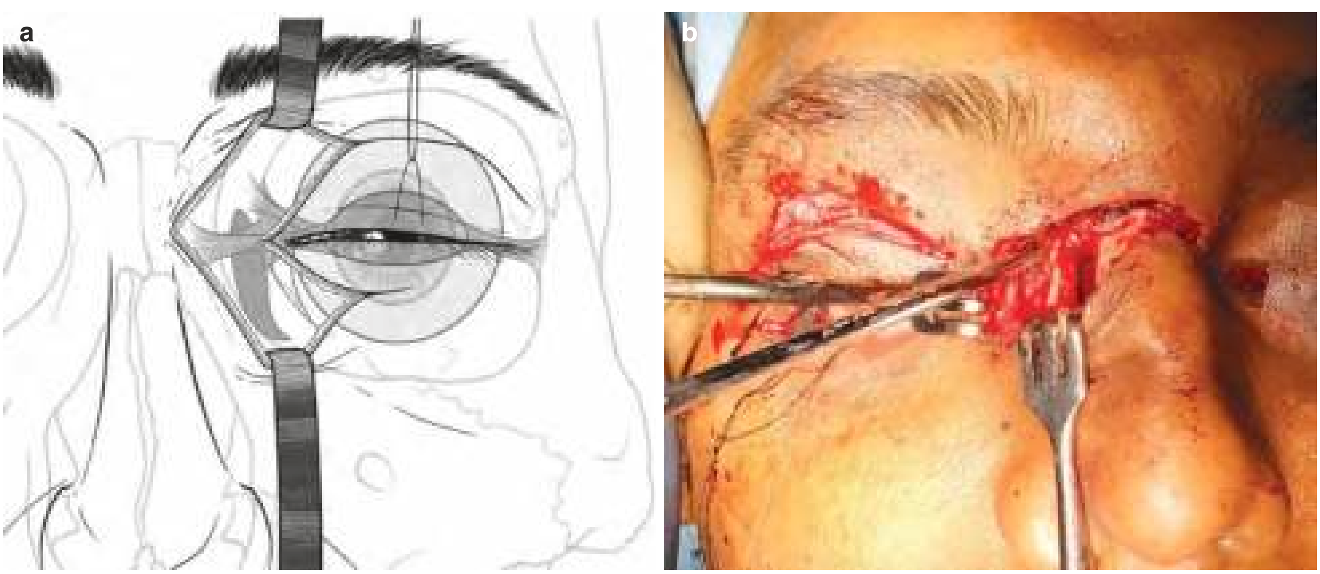

Fig. 57.23 Diagram and intraoperative picture showing extended glabellar approach to the medial orbit

57.7.1.2 Extended Glabellar Approach (Fig. 57.23)

The extended glabellar incision or a horizontal "Y" approach involves a small Y-shaped incision with the fork extending over the upper and lower lid crease with the long arm across the nasal dorsum over the glabellar region. This approach provides excellent access to the medial canthal tendon apparatus and also provides enough room for medial orbital wall exploration cephalad to the tendon.

57.7.2 Trans-caruncular Approach

The trans-caruncular route provides excellent exposure to the medial orbit without causing any esthetic concern. The caruncle is a papular structure seen medial to the plica semilunaris which is a fold of conjunctiva in medial canthal region. An avascular plane is located deep to the caruncle between the medial orbital septum and the Horner's muscle which on dissection exposes the medial wall of the orbit (Fig. 57.24a) [37].

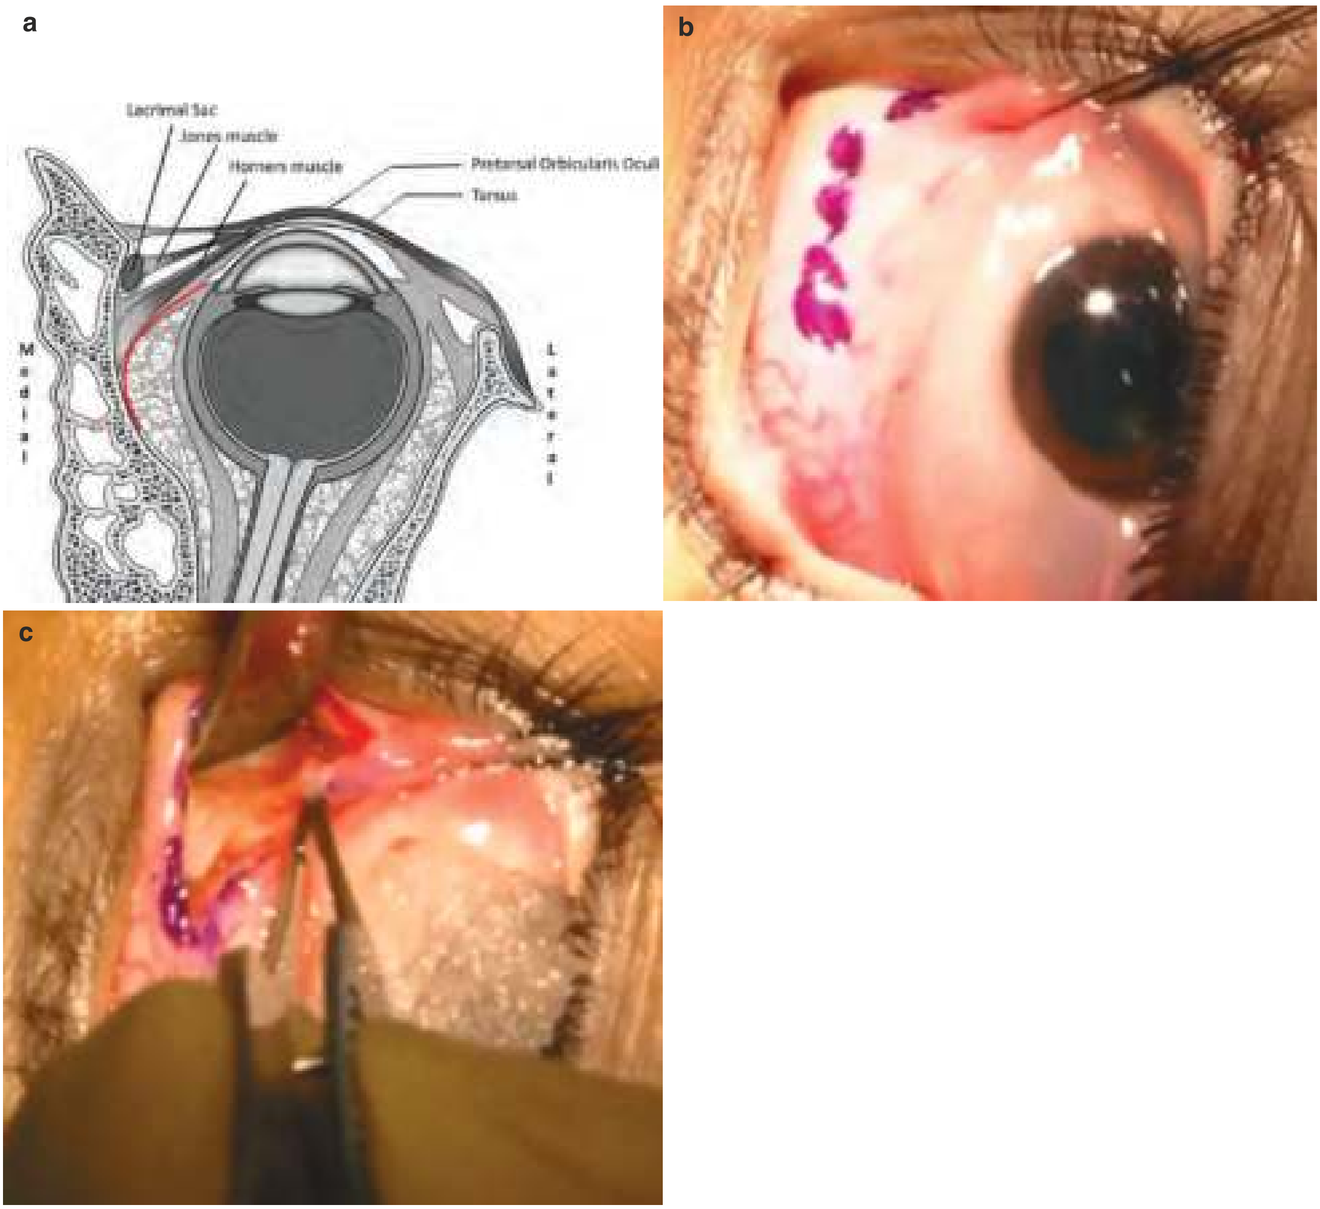

Fig. 57.24 (**a**) Diagram and (**b**) intraoperative pictures showing marking for trans-caruncular approach to the medial orbit and (**c**) exposure of the medial orbital wall. (Courtesy: Dept of Orbit & Oculoplasty, Shankara Nethralaya, Chennai)

After placing retraction sutures on upper and lower eyelids, gentle medial traction is applied over the skin of the nasal dorsum, and incision is placed lateral to the caruncle, while avoiding injury to the lacrimal puncta or canaliculi (Fig. 57.24b). The length of the incision is between 1.5 and 2.5 cm. Dissection through the fibers of the Muller's muscle exposes the medial wall just posterior to the posterior lacrimal crest (Fig. 57.24c). For additional exposure of associated orbital floor fractures, a C-shaped approach can be used including a transconjunctival incision with or without lateral canthotomy and inferior cantholysis in conjunction with the trans-caruncular approach.

As the lateral transcutaneous and lower lid approaches also find use in the management of fractures of the zygomatic complex fractures, they are discussed in detail in chapter on zygomatic complex fractures.

57.7.3 Transconjunctival Approach (Fig. 57.25)

The infra-orbital rim and orbital floor defects can be accessed through a transconjunctival incision (Video 57.2).

Its advantages include:

(i) Excellent cosmesis
(ii) Minimal incidence of ectropion
(iii) Extensive access up to 270° including the floor and medial and lateral walls, with the modifications to the conventional approach

A historical perspective of the description of the transconjunctival approach and its evolution into the most favored approach for access to the floor and medial wall of the orbit along with the infra-orbital rim is provided in Box 57.7.

Box 57.7 Evolution and Modifications of the Transconjunctival Approach

Author	Year	Description
Bourget J	1924	Conjunctival approach for blepharoplasty
Tenzel & Miller	1971	Post-septal approach
Tessier P	1973	Pre-septal approach
McCord & Moses	1979	"Swinging eyelid" with lateral canthotomy
Garcia GH	1998	Trans-caruncular approach

Pre-septal Approach (Fig. 57.26)

The incision is marked 2–3 mm posterior to the tarsal plate along the mediolateral length of the lower palpebral conjunctiva. Dissection is performed along the subconjunctival plane and is carried down toward the inferior orbital rim. This maintains the plane anterior to the orbital septum. Retraction sutures may be placed on the vestibular portion of the conjunctival flap with traction in superior direction, to provide additional protection to the globe. On reaching the facial surface of the infra-orbital rim, the periosteum is incised about

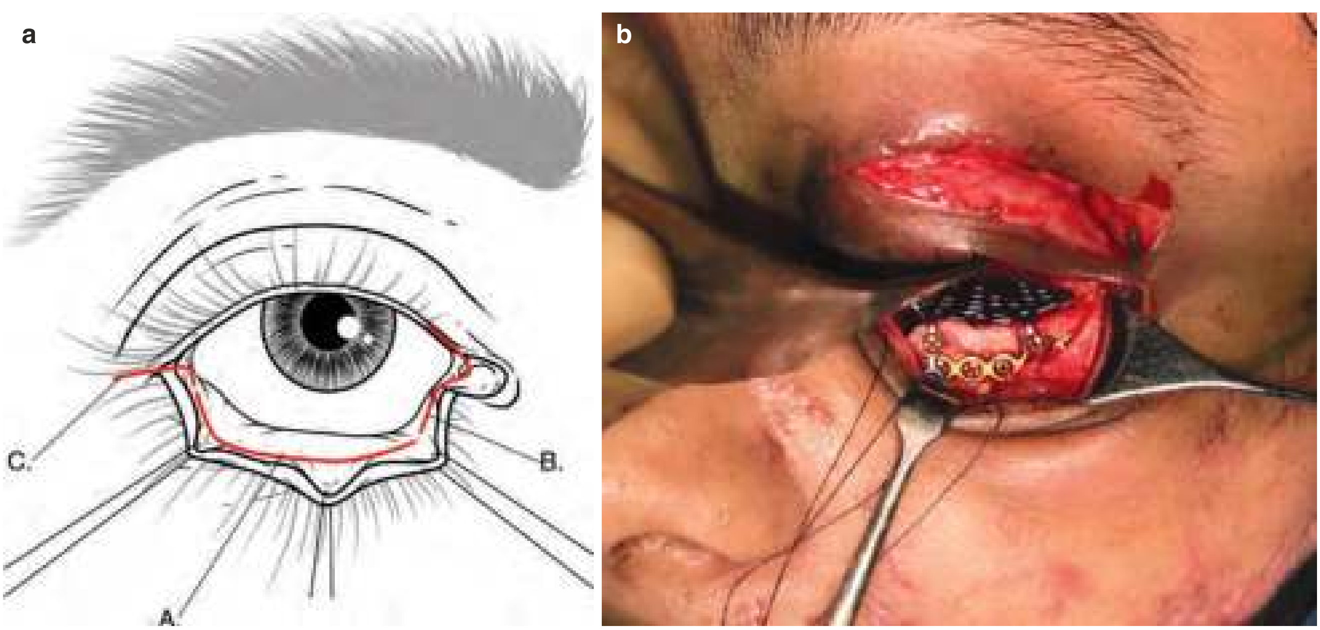

Fig. 57.25 (**a**) Diagram showing trans-conjunctival approach and its modifications - A. Transconjunctival, B. Trans-caruncular & C. Lateral canthotomy. (**b**) Intra-operative picture of trans-conjunctival with the lateral canthotomy modification. The picture also shows an upper lid blepharoplasty incision used to access the fronto-zygomatic suture

2 mm inferior to the rim. This is followed by subperiosteal dissection and exploration of the orbital floor by retracting the globe and orbital contents superiorly. Approximately 2–3 mm distance must be maintained from the lower end of the tarsal plates while making the initial conjunctival incision failing which there is vertical shortening of the lower eyelid and entropion post-operatively.

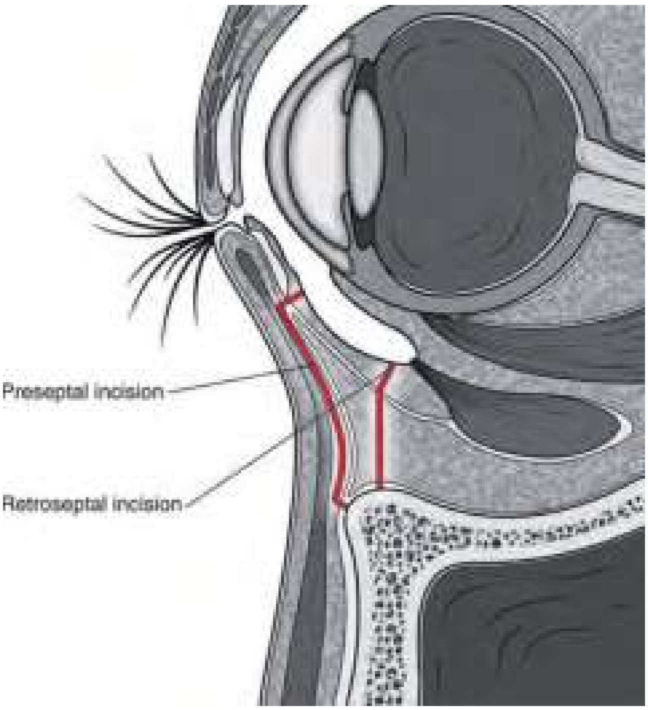

Fig. 57.26 Diagrammatic representation of the pre-septal and retro-septal modifications of the transconjunctival approach

Retroseptal Approach (Fig. 57.26)
In the retroseptal type, the conjunctival incision is made near the fornix spanning mediolaterally just short of the caruncle. Dissection is posterior to the orbital septum providing a fast and direct access to the floor when compared to the pre-septal type [38]. However, orbital fat is encountered before approaching the orbital floor, which may prove bothersome for dissection and manipulation. The periorbita is incised immediately posterior to the rim after superior retraction of the fat and globe with a malleable retractor. This is followed by subperiosteal dissection and exploration of the floor defect. Excessive manipulation of the orbital fat during orbital reconstruction increases the risk of enophthalmos due to fat disintegration [39, 40]. Placement of the incision too low into the fornix may damage the inferior oblique muscle and retractors of the lower eyelid, compromising esthetics post-operatively due to lower lid entropion.

57.7.4 Trans-antral Endoscopic-Assisted Approach (Fig. 57.27a, b)

The trans-antral approach was attempted by Converse and Smith [41] as early as the 1960s. Entry to the antrum is gained through a transoral Caldwell Luc procedure and a 0° or 30° endoscope may be used to visualize the orbital floor.

57.7.5 Coronal Approach

The coronal approach offers the most extensive exposure of the entire upper and middle third of the face including the orbit. A detailed description of the same is provided in Chap. 85 on access osteotomies.

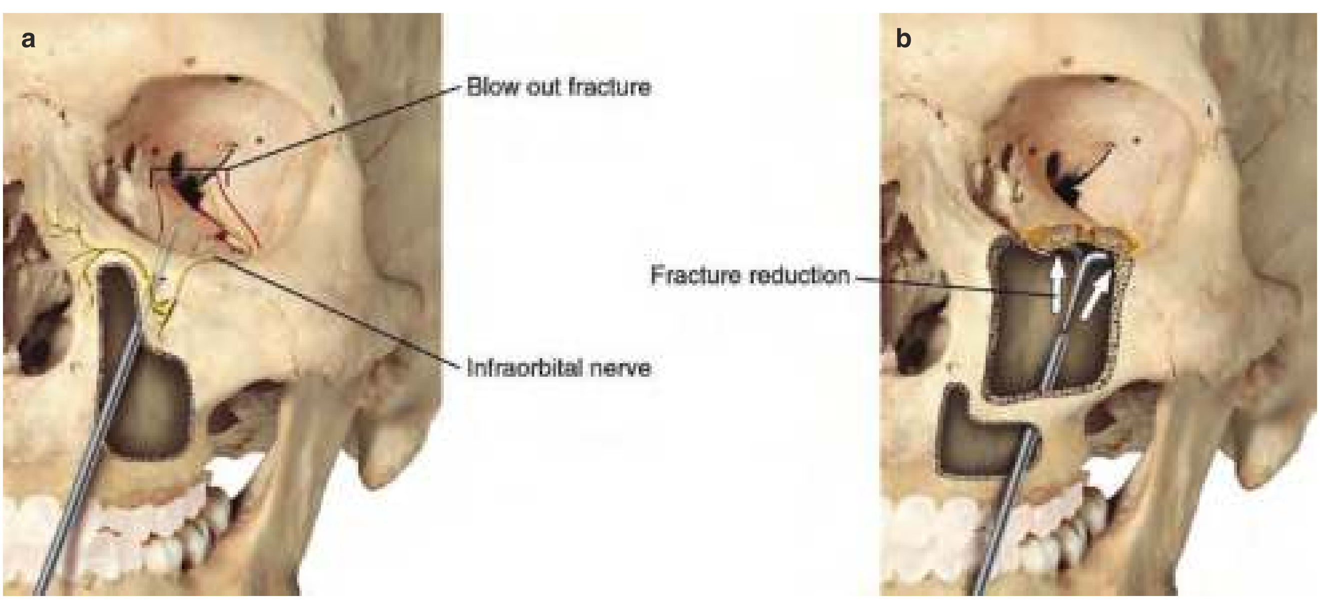

Fig. 57.27 (**a**, **b**) Diagram of the trans-antral endoscopy assisted approach to the orbital floor

57.8 A Clinical Sequence for Treatment Planning and Management of Orbital Fractures

A clear understanding of the various patterns of orbital fractures and their clinical implications is absolutely necessary to design and formulate a plan for their reconstruction. The basic management guidelines for the common variations in orbital fractures are detailed below (see Hammer [7] classification, Fig. 57.9).

57.8.1 Type I (Orbito-Zygomatic)

Concomitant fractures of the zygomatic complex and the orbit mandate ORIF of the zygomatic complex first, followed by internal orbital reconstruction. This sequence is favored because the orbital rims provide the most accurate guidance for restoration of the internal orbital architecture.

Box 57.8 The Surgical Objectives for Type I Fractures

- Restoration of transverse dimension of the face, malar prominence, and the arch anatomy
- Restoration of rim architecture
- Correction of orbital dystopia
- Correction of the axis of the palpebral fissure and
- Reconstruction of the internal orbit

Figures 57.28a–d and 57.29a–d demonstrate a type I fracture managed using the above principles.

Fig. 57.28 3D CT scans of patient with orbito-zygomatic fracture. (**a** and **b**) Pre-operative frontal and basal views demonstrating the fracture, (**c** and **d**) post-operative frontal and basal views demonstrating fixation of fractures

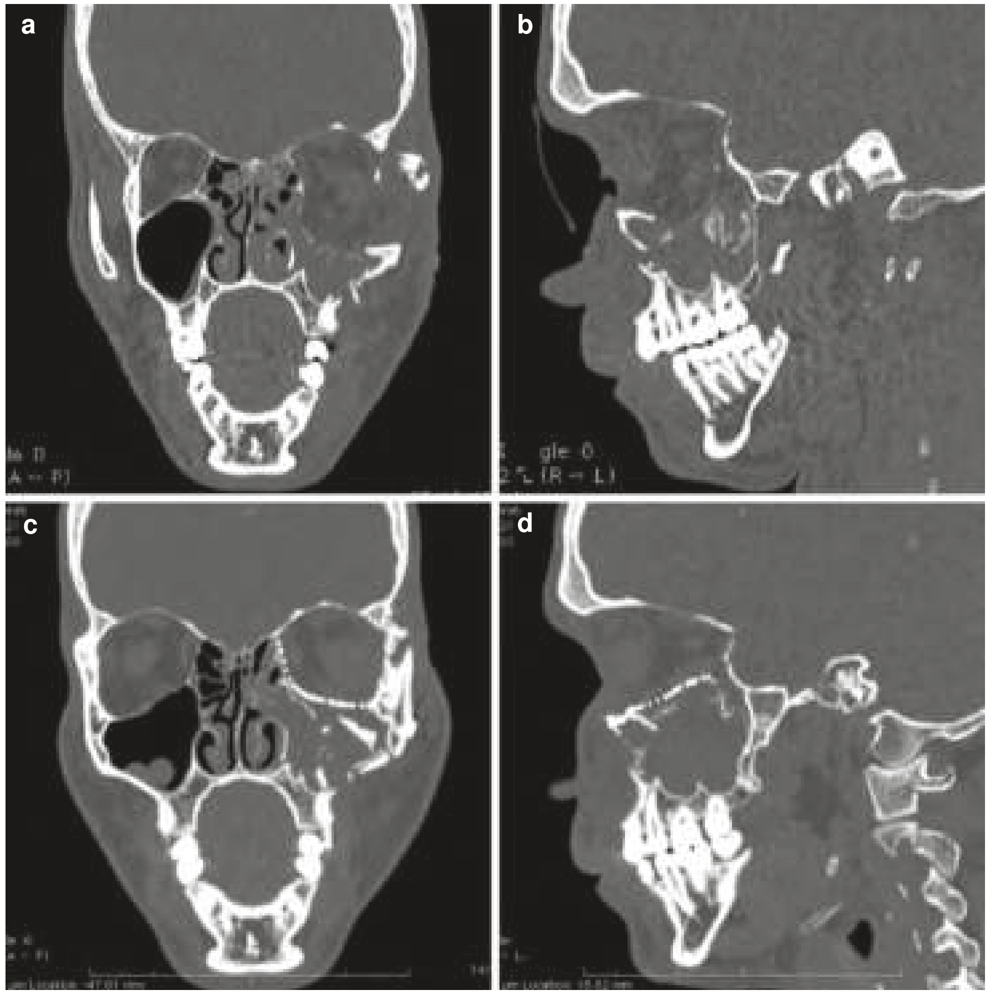

Fig. 57.29 Axial and sagittal scans of the patient in Fig 57.28, with orbito-zygomatic fracture. (**a** and **b**) Sections demonstrating fracture of the left zygomatic complex with a large defect of the orbital floor. (**c** and **d**) Post-operative sections revealing optimal reduction of the fracture and floor reconstruction with anatomical orbital floor implant

57.8.2 Type II (Internal Orbital)

Management of type II orbital fractures, which are essentially the internal fractures (both blow-in and blowout) of the orbit including (1) the roof, (2) the floor, and (3) the medial and (4) lateral walls are detailed below.

Box 57.9 The Management of All Internal Orbital Fractures Can Be Handled Essentially by Answering the Following Basic Questions *(Clinical Tip)*

(i) Is there a need for intervention?
(ii) When is the best time to intervene?
(iii) Is there a need for reconstruction?
(iv) What to use for reconstruction?

57.8.2.1 Fractures of the Orbital Roof

Isolated fractures of the orbital roof are extremely rare. They usually occur as a part of fronto-basilar fractures, fractures of the frontal sinus, or may occur concomitant with fractures of the supraorbital rim. Orbital roof fractures are present in approximately 5% of all orbital and cranial fractures, while incidence of isolated orbital roof fractures may be as low as 0.7% of all orbital and cranial fractures. The most common etiological factors include motor vehicle accidents, assaults, or falls.

Orbital roof fractures may be associated with more severe neurological symptoms including dural tears, CSF leak, tension pneumocephalus, diffuse cerebral edema, and contusions of the frontal lobe [42]. It is imperative for a neurological and ophthalmological consult prior to management.

In general, orbital roof fractures may be categorized into four types (Fig. 57.30).

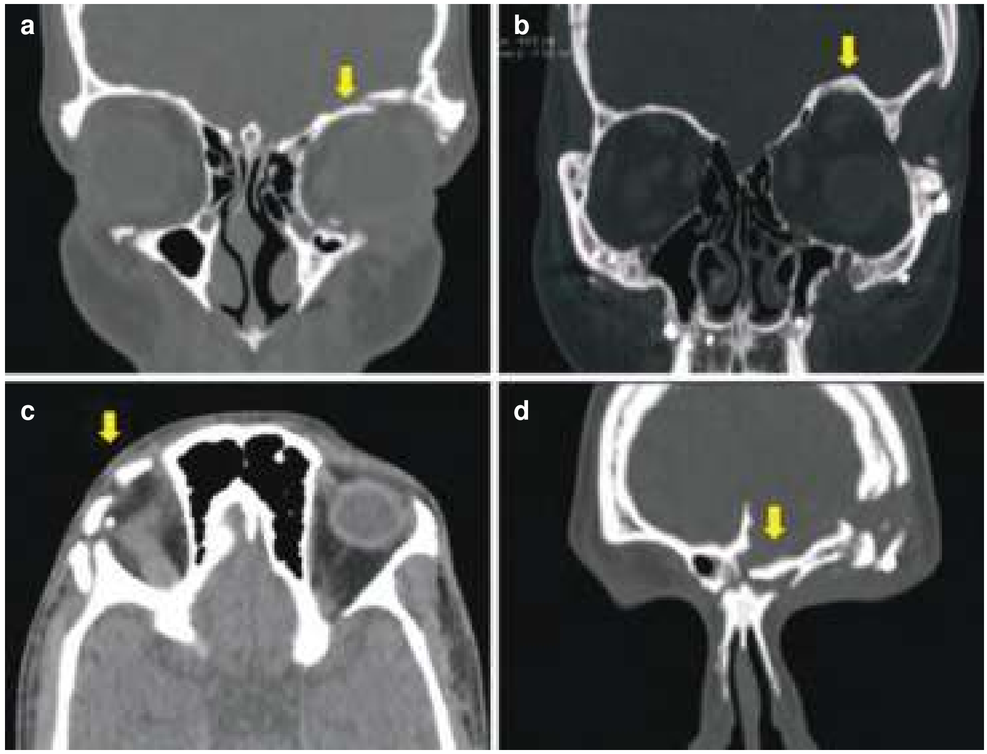

Fig. 57.30 CT scan images showing types of roof fractures (**a**) blow-in fracture, (**b**) blowout fracture, (**c**) fracture of the supraorbital rim, and (**d**) fronto-basilar fracture

- I—Blow-in fractures of the orbital roof where there is caudal displacement of the orbital roof with or without herniation of the brain. These may be undisplaced or displaced fractures. Comminuted fractures may leave fragments within the orbital cavity and may produce functional deficits with ophthalmic signs including restriction of extraocular muscle movement, diplopia, ptosis, and even blindness. These are generally caused due to increase in the intra-cranial pressure secondary to injuries.
- II—Blowout fractures of the orbital roof where there is cephalad displacement of the orbital roof into the cranial cavity due to increased intra-orbital pressure pushing the roof above. These injuries may be associated with neurological symptoms.
- III—Fractures involving the supraorbital rim. These may be seen as impure fractures of the orbital roof with an associated fracture of either a blow-in or a blowout nature.
- IV—Fractures involving the frontal sinus and the fronto-basilar complex. These fractures are more severe in nature and may often be associated with severe neurological implications.

Less than 10% of orbital roof fractures may need any form of surgical intervention [42]. Most are amenable to conservative management with observation and follow-up of neurological and ophthalmic status.

The need for management of fractures of the orbital roof may depend on:

(i) The presence of CSF leak which may need to be addressed
(ii) The necessity to retrieve displaced intra cranial fragments
(iii) Ophthalmic signs with compromise on vision
(iv) Large displacement of fragments which may act as mechanical impediments or significantly alter intra-orbital volume producing enophthalmos or exophthalmos.

Interventions may be indicated immediately or late primary depending on the indications mentioned above. Reconstruction of the roof of the orbit is not a procedure routinely indicated. However in cases where there is an absolute necessity for reconstruction like prevention of brain herniation or restoration of intra orbital volume which has been significantly altered, the choice may vary between the use of titanium meshes (Fig. 57.31) or porous polyethylene implants fixed with micro-screws to split calvarial grafts.

Figure 57.32a–f demonstrates the management of a malunited fronto-basilar fracture along with a blow-in fracture of the orbital roof compressing the eyeball producing restriction of movement.

57.8.2.2 Fractures of the Lateral Orbital Wall

Lateral orbital walls are the strongest of all the orbital walls [43]. The lateral wall generally shows diastasis and displacement in the case of fractures involving the zygomatico-orbital complex and is restored to its normal anatomy when the reduction of the zygomatic complex is achieved [44]. However this wall gets comminuted in high-velocity injuries [45] necessitating reconstruction in the primary intervention.

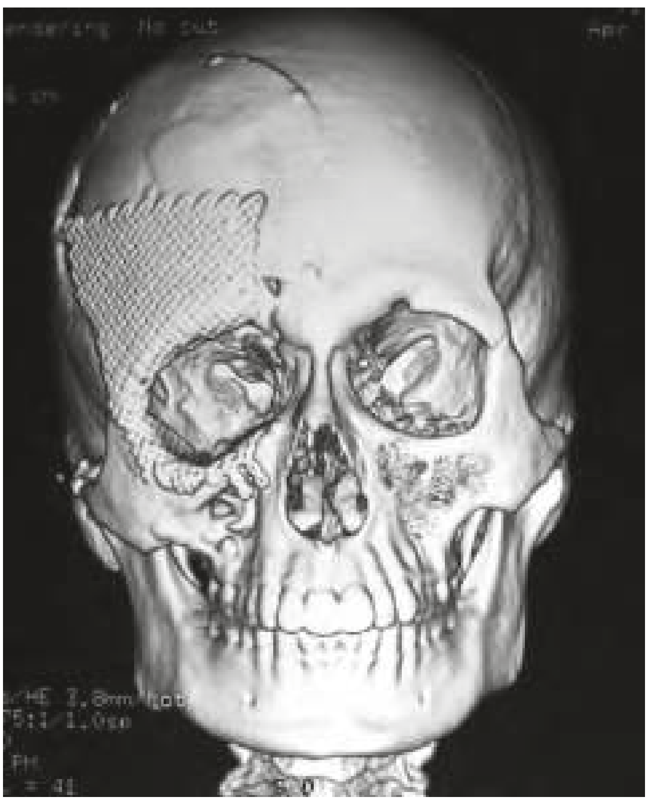

Fig. 57.31 Reconstruction of complex defect of the frontal bone, orbital roof, and supraorbital rim with a titanium mesh

The anatomy of the lateral wall plays an important role in the internal orbital volume as demonstrated by development of enophthalmos in unrestored lateral wall fractures [46]. Restoration of the architecture or augmentation of the same ensures correction of enophthalmos.

> Reconstruction of the lateral orbital walls is usually accomplished with the use of:
> (i) Alloplasts including titanium meshes, porous polyethylene sheets, and custom-made polyether ether ketone (PEEK) implants
> (ii) Bone grafts which may be harvested from either the calvarium or ilium

Figure 57.33a, b demonstrates the management of fracture of the lateral walls of the orbit in a patient with concomitant fracture of the zygomatic complex.

57.8.2.3 Medial Wall Fractures

The medial wall and the floor are the thinnest walls of the orbit and have the propensity to fracture the most [47, 48]. Though the incidence of concomitant fractures of the medial wall with that of the orbital floor have been reported over a wide range of 5–71%, its occurrence in isolation is very rare. Most fractures of the medial wall are incidental findings when CT scans are obtained to study other cranial, facial, or orbital fractures.

The most common type of clinical presentation would either involve a combination of the medial wall and floor (36%) or medial wall, floor, and zygomatic complex (28%) [49–51].

Fractures of the medial wall were managed conservatively in the past, but current literature proposes clear indications [49–51] for the exploration and reconstruction of the medial wall fractures and defects, which include:

1. Restriction of ocular motility
2. Diplopia
3. Clinically significant enophthalmos

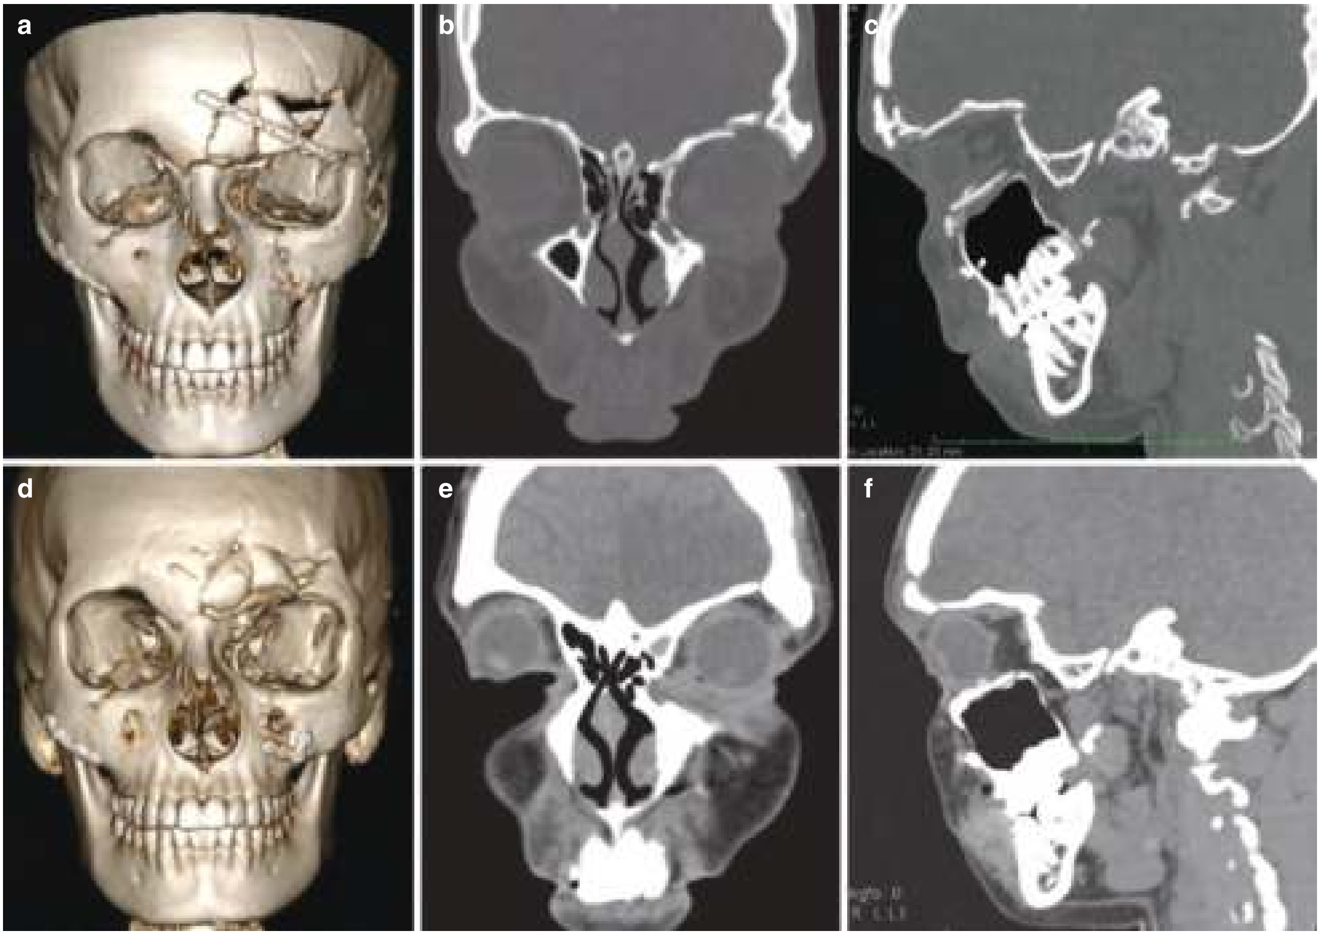

Fig. 57.32 CT images of patient with malunited fractures of the orbital roof. (**a**–**c**) Pre-operative images demonstrating malunited fracture of the frontal bone and orbital roof of the left side with decrease in intra-orbital volume and compression on the globe. (**d**–**f**) Post-operative images showing recontouring of the supraorbital rim and roof using ultrasonic aspirator system, with resultant expansion of the intra-orbital volume

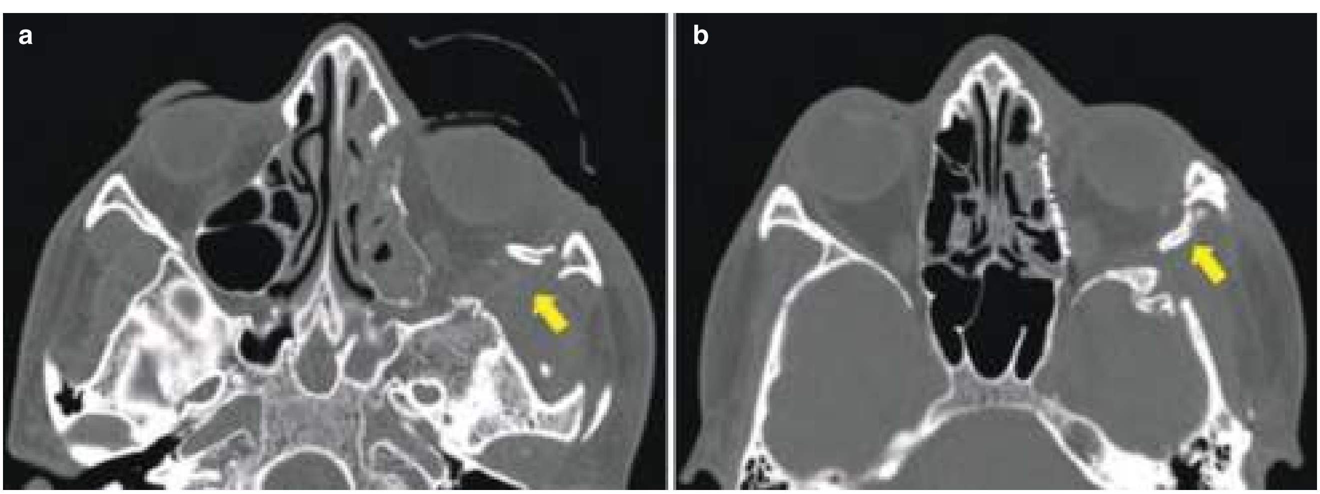

Fig. 57.33 CT scan images of lateral orbital wall with concomitant fracture of the zygomatic complex. (**a**) Pre-operative image showing fracture and displacement of the lateral wall and (**b**) post-operative image showing reduction of the lateral wall and re-establishment of the sphenozygomatic suture continuity

Box 57.10 A Clinically Useful Classification of Medial Wall Fractures Has Been Described by Nolasco et al. [47] in 1995 Based on CT Scan Findings

They describe four patterns of presentations (Fig. 57.34)

- Type I: Isolated medial wall fractures
- Type II: Fracture involving the medial wall and the orbital floor
- Type III: Fractures involving the medial wall, floor, and the zygomatic complex
- Type IV: Medial wall plus complex fractures of the face (maxillary, NOE, etc.)

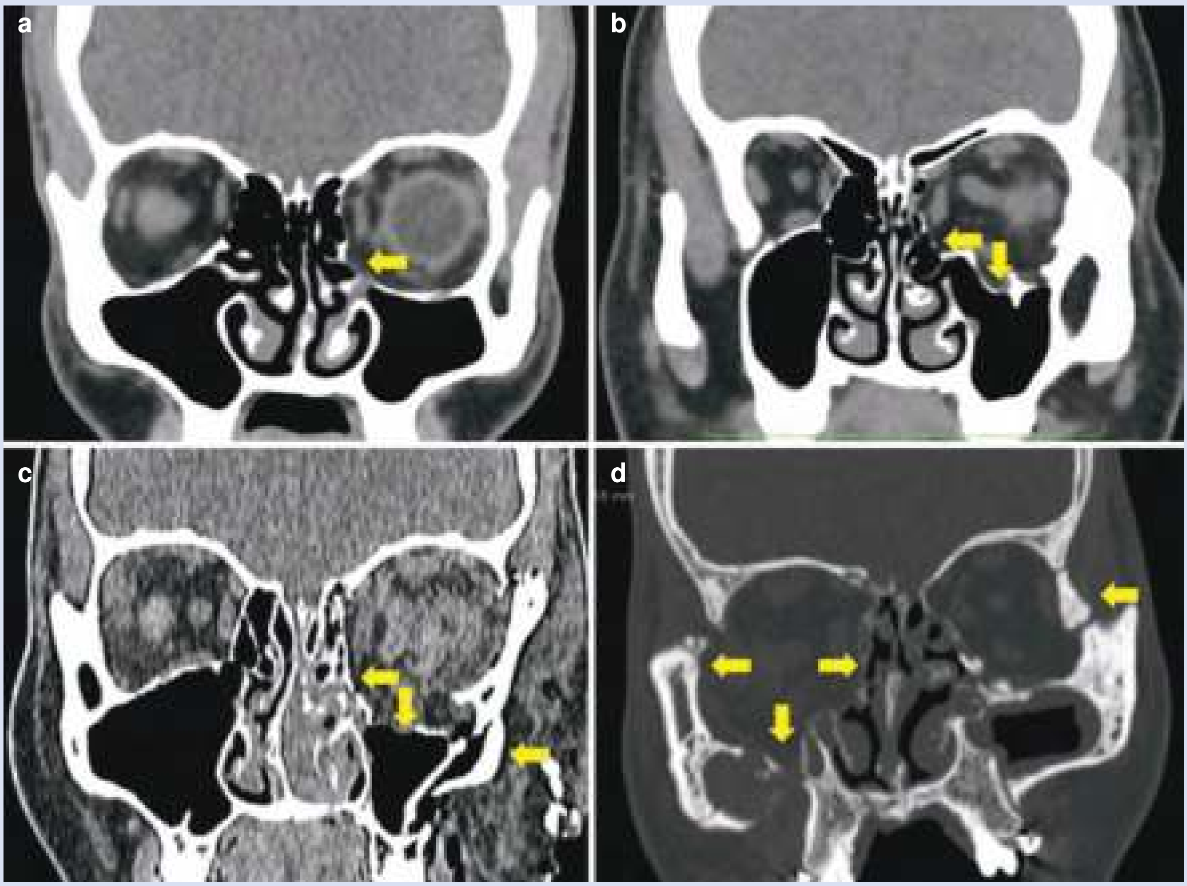

Fig. 57.34 CT scans showing types of medial wall fractures. (**a**) Isolated medial wall fracture; (**b**) fracture of medial wall with floor; (**c**) fracture involving medial wall, floor and zygomatic complex; and (**d**) concomitant fractures of the medial wall, floor, and midface at LeFort 3 level

Contrary to earlier belief the loss of medial wall integrity also significantly contributes to development of enophthalmos [49]—with any defect involving an area of more than 1.9 cm^2 or volume expansion of excess of 0.9 ml [50, 51] producing clinically significant enophthalmos (2 mm or more).

Approaches to the medial wall have already been described in detail earlier. The most favored being the transcaruncular/retro-caruncular approaches which give excellent exposure and access to the medial wall for both exploration and reconstruction [37, 52].

Options for reconstruction include a multitude of materials which may be autogenous or alloplastic as shown in Table 57.1. Bioactive resorbable sheets are also found to produce good outcomes [53].

Figure 57.35a, b demonstrates reconstruction of a medial wall fracture with a Titanium mesh.

57.8.2.4 Orbital Floor Fractures

The fractures involving the orbital floor are the most common fractures of the internal orbit either in isolation or concomitant with other facial fractures. A comprehensive classification of floor fractures with clinical guidelines for management is described by Jaquiery [54] et al. which lays emphasis on the morphology of the defect and the role of the infero-medial strut of the inferior orbital fissure.

The internal orbit is divided into three zones which helps in evaluating the difficulty of approach and exposure:

(i) Anterior third
(ii) Middle third
(iii) Dorsal third

Table 57.1 Commonly used biomaterials for orbital reconstructions

Material	Stability / fixation (S/F)	Contouring	Biological behavior	Permeability for inflammatory exudate	Donor site morbidity	Radio-opacity	Availability
Titanium	S+++ F++	++	++ (allows tissue in-growth)	+	+	+	+
Bone graft	S++ F+	-	+++	-	-	+	+/–
Porous polyethylene	S+/– F+/– (when thin)	+	++ (allows tissue in-growth)	–	+	-	+
Composite porous polyethylene/Ti	S++ F++	+	++ (allows tissue in-growth)	–	+	+	+
Resorbable (PLLA)	S+/– F+/–	+	+ (inflammatory response)	(non-perforated)	+	–	+
Pre-formed anatomical implant	S+++ F++	+++ (minimal contouring needed)	++ (allows tissue in-growth)	+	+	–	+

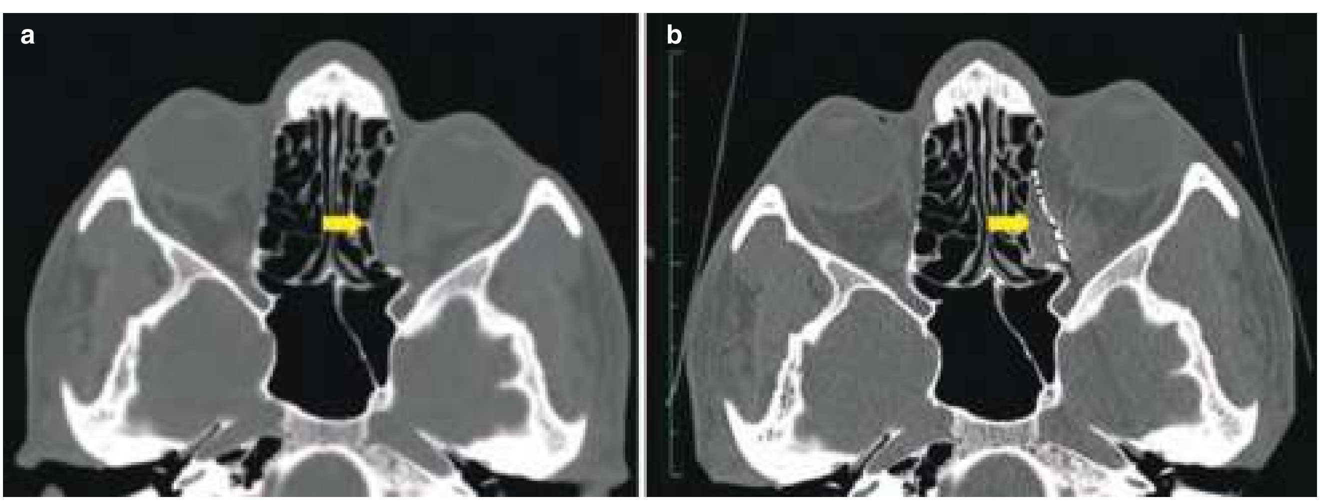

Fig. 57.35 CT images of patient with medial wall fracture. (**a**) Fracture of the medial orbital wall of the left orbit showing displaced medial rectus. (**b**) Post-operative image demonstrating medial orbital reconstruction with titanium mesh

Table 57.2 The classification of orbital wall defects (Jaquiery et al. modified by Dubois et al.) [53–55]

Category of fracture	Complexity of reconstruction	Defect description	Clinical finding
I	Low	Isolated defect of floor or medial wall, 10–20 mm^2 within zone 1 or 2	
II	Moderate	Defect of floor and/or medial wall >20 mm^2 within zone 1 and 2	Bony infero-medial strut of the inferior orbital fissure present
III	High	Defect of floor and/or medial wall >20 mm^2 within zone 1 and 2	Infero-medial strut of inferior orbital fissure absent
IV	High	Defect of the entire orbital floor with medial wall involving zone 3	Infero-medial strut of inferior orbital fissure absent. The posterior ledge of the floor also may be absent

The fractures themselves are then classified into four categories of defects (Table 57.2; Fig. 57.36a–d).

Which Fractures of the Orbital Floor Need Intervention?

Indications and contraindications for floor exploration and repair are well defined.

Absolute Indications

1. Acute injury to the orbit showing evidence of immediate clinical enophthalmos and/or hypophthalmos [55] (Fig. 57.15), necessitating a primary surgical intervention. Post-surgical outcome may get compromised with delay due to progressive atrophy of intra-orbital fat.
2. Severe restriction of ocular motility with CT or MRI evidenced muscle entrapment or incarceration of periorbital soft tissue.

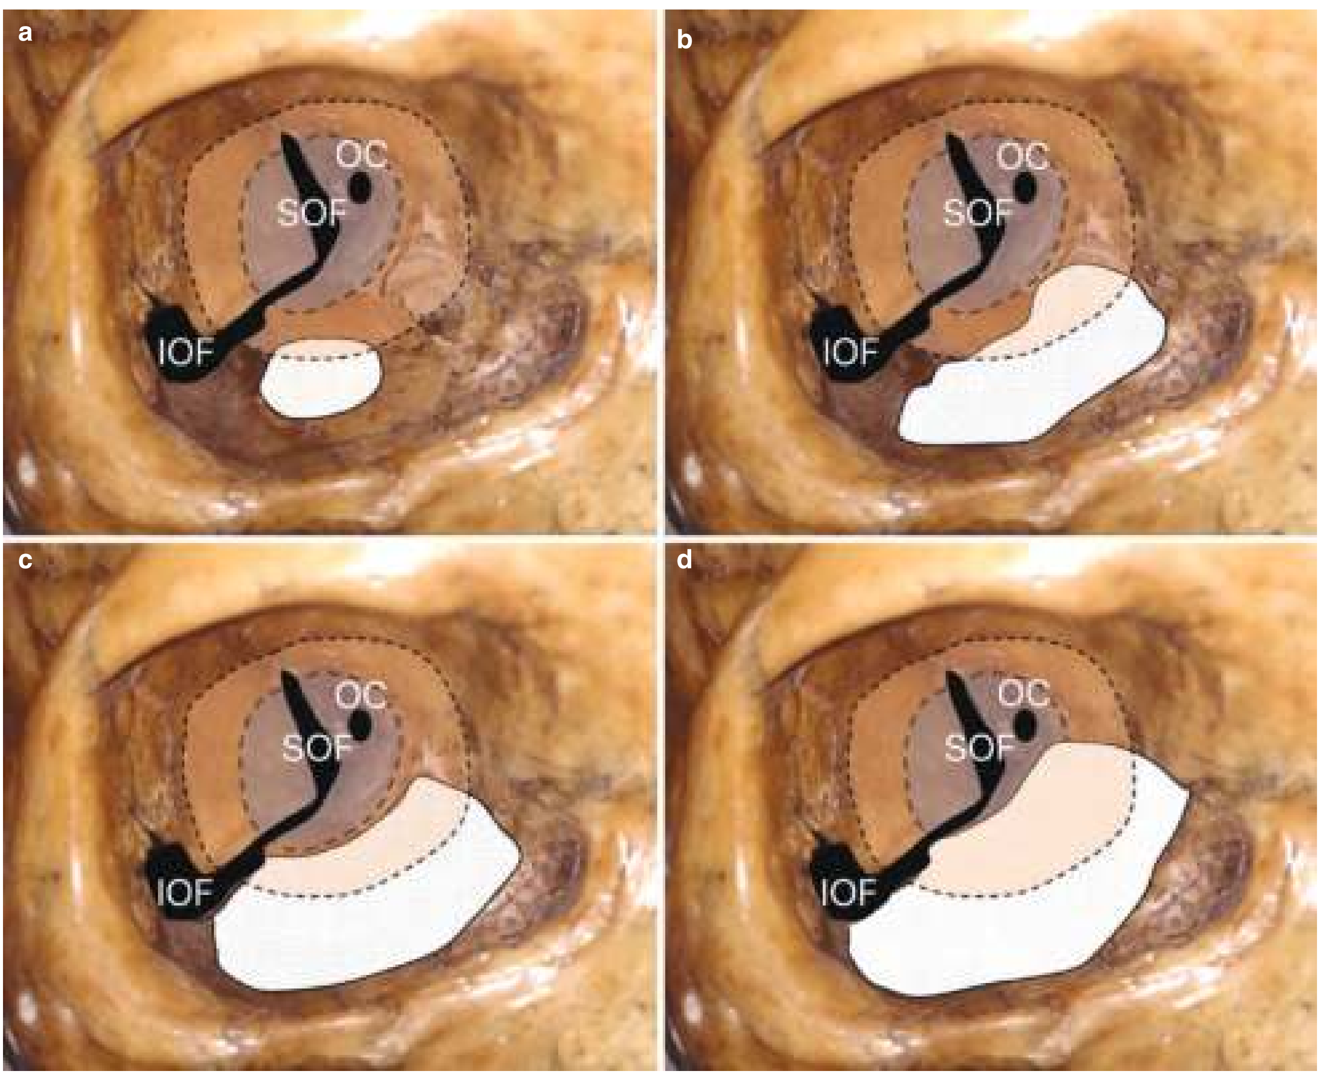

Fig. 57.36 Diagrammatic representation of the different types of defects of the orbital floor which indicate the grades of difficulty to reconstruct. (**a**) Type I, (**b**) Type II, (**c**) Type III and (**d**) Type IV

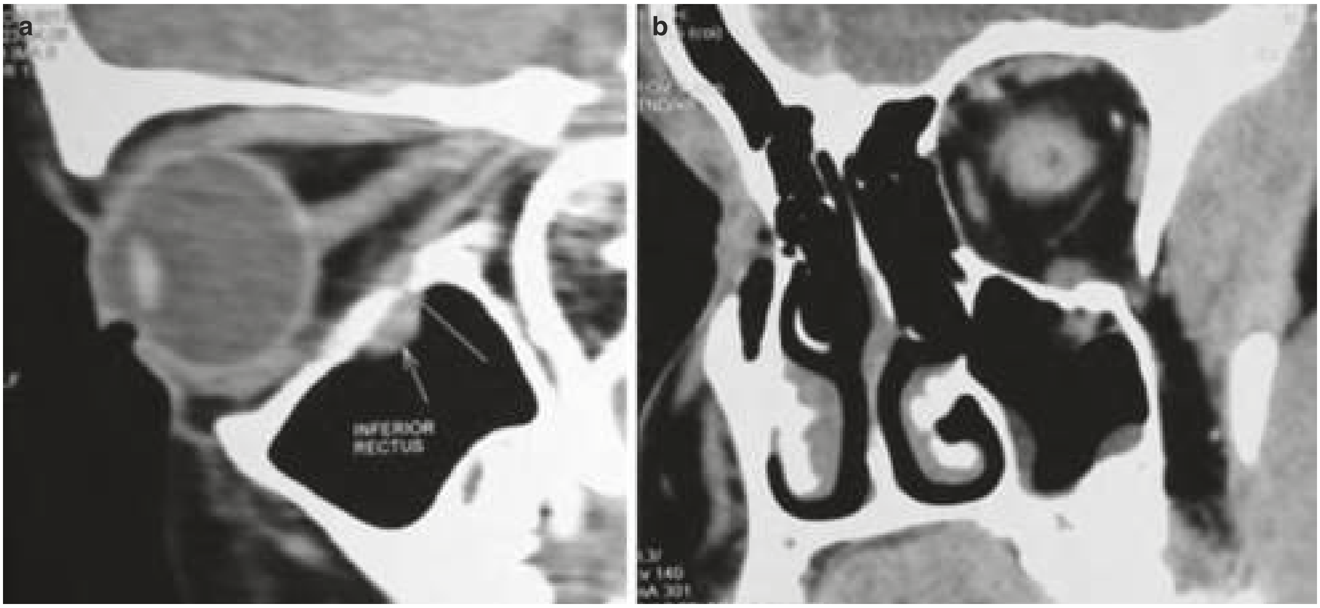

Fig. 57.37 CT scan images of a young boy with history of orbital trauma. (**a**) Sagittal and (**b**) coronal sections demonstrating a "springing trapdoor" fracture of the orbital floor on the left side with entrapped inferior rectus muscle. (Courtesy: Dept of Orbit & Oculoplasty, Shankara Nethralaya, Chennai)

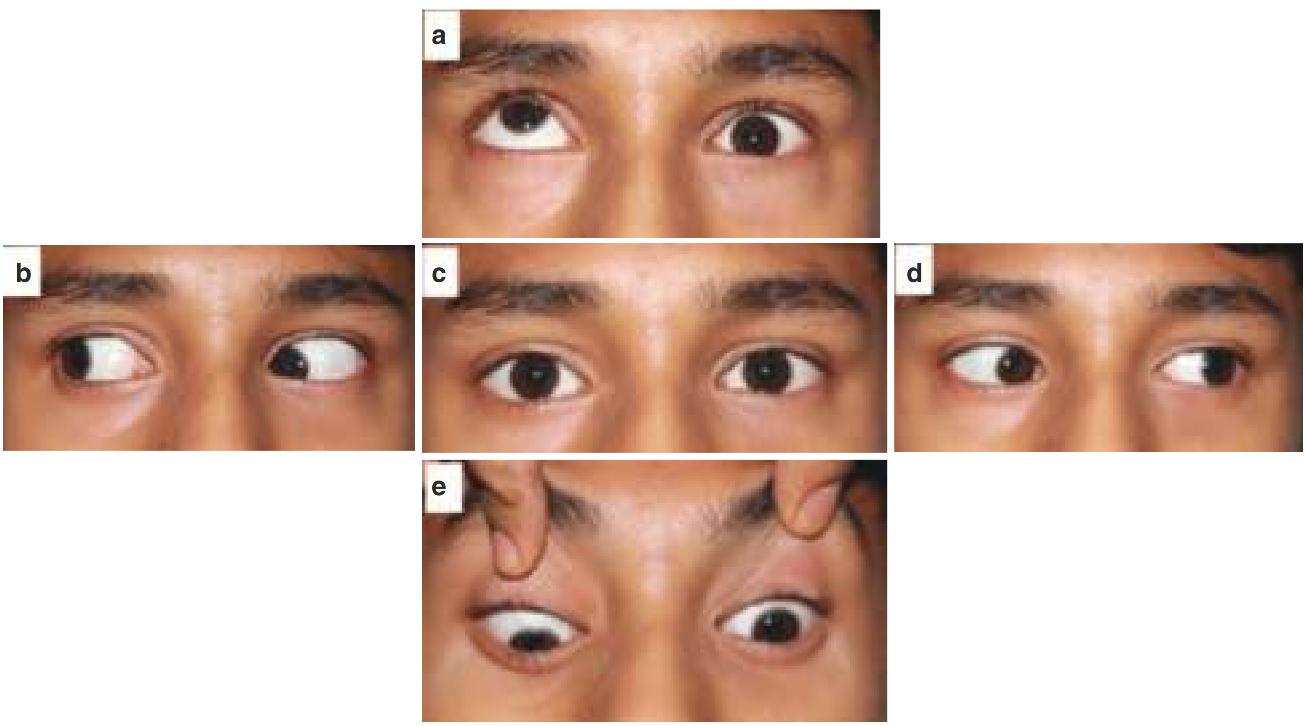

Fig. 57.38 Clinical photographs of a boy with "White eye blowout" fracture, showing restriction of ocular motility in the left eye in the superior (**a**) and inferior (**e**) gazes. The other gazes (**b**, **c** and **d**) show no abnormalities. (Courtesy: Dept of Orbit & Oculoplasty, Shankara Nethralaya, Chennai)

3. “White eye blowout” fracture in a child or young adult with severe restriction of ocular motility (Figs. 57.37a, b and 57.38) and vagal symptoms.

Relative Indications

1. Defects of the orbital floor often larger than 50% of the orbital floor area or greater than 20 × 20 mm of defect size especially in the zone between the floor and the medial wall (Fig. 57.39a).
2. Diplopia which is non-resolving and persistent for more than 2 weeks due to entrapment or fibrosis of orbital soft tissue (Fig. 57.39b) [56, 57].

Relative Contraindications

1. Associated ophthalmic injuries like retinal tears, hyphema, displacement of lens, ruptured globe, avulsion injuries of the globe, etc.
2. Loss of vision in one eye with the only seeing eye involved in a fracture

Figure 57.40a–f demonstrates the delayed management of a patient with an isolated fracture of the floor and medial walls. The CT scan shows fibrosis and adhesion of the inferior rectus muscle to the residual posterior ledge producing diplopia and restriction in superior gaze.

Surgery for Special Indications in Orbital Floor Fractures

Enophthalmos

Enophthalmos is the displacement of the eyeball in a posterior direction and is attributed to increase in the intra-orbital volume. Numerous studies have shown that there is a correlation between increase in intra-orbital volume and the presenting enophthalmos. It is proved that an increase in intra-orbital volume by 0.5–1 cc would produce posterior displacement of the globe by 1 mm. Enophthalmos of 2 mm or more may be clinically perceivable and warrant surgical intervention [58, 59]. An important aspect of orbital reconstruction lies in the fact that it is the only fracture in CMF region where the onus is not in recreating the anatomical form but rather in the restitution of the intra-orbital volume. Care should be taken to reconstruct the posteromedial aspect of the orbit (Hammer’s key area) to achieve anterior projection of the globe. It is imperative to understand that reconstruction of the floor posterior to the equator of the globe influences anterior projection of the globe, while reconstruction of the equatorial region of the floor influences only the supero-inferior position of the globe (Fig. 57.41).

Figure 57.42a–d shows a case of delayed correction of enophthalmos in a patient with an orbital floor fracture.

Hypophthalmos

This is otherwise called hypoglobus and signifies the downward displacement of the globe due to the interruption in the anatomical integrity of the orbital floor. The clinical presence of hypoglobus needs to be differentiated from orbital dystopia which essentially means that the entire bony orbit with its contents is displaced caudally, unlike hypophthalmos, where only the globe is displaced caudally.

However decision-making for surgical intervention based on both enophthalmos and hypophthalmos is challenging as they may or may not present immediately following trauma. (Refer to clinical scenario 1. Figs. 57.57, 57.58 and 57.59).

Diplopia

Clinically demonstrable double vision is termed diplopia. Generally post-traumatic diplopia due to edema and hemorrhage is self-limiting and shows spontaneous resolution.

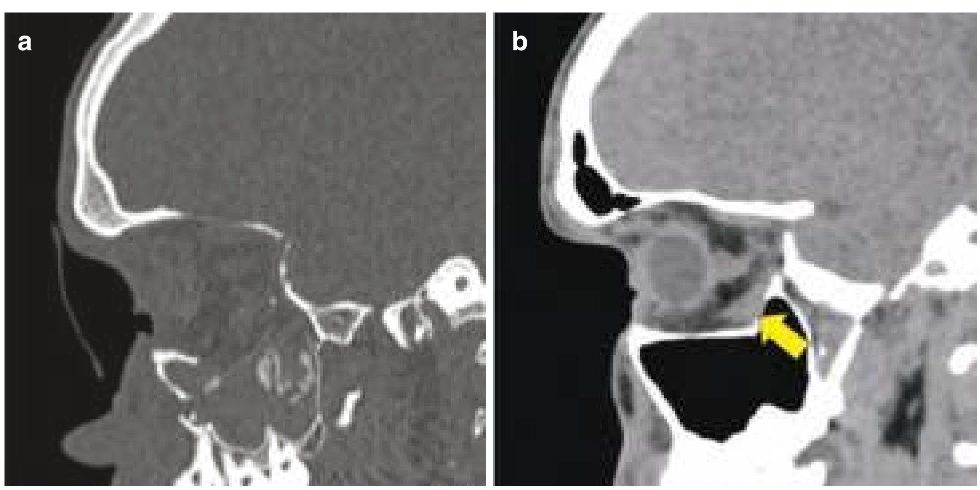

Fig. 57.39 (**a**) Sagittal section CT demonstrating large defect of the orbital floor. (**b**) Sagittal section CT demonstrating fibrosis and adhesion of the inferior rectus (yellow arrow) to the posterior ledge of the orbital defect

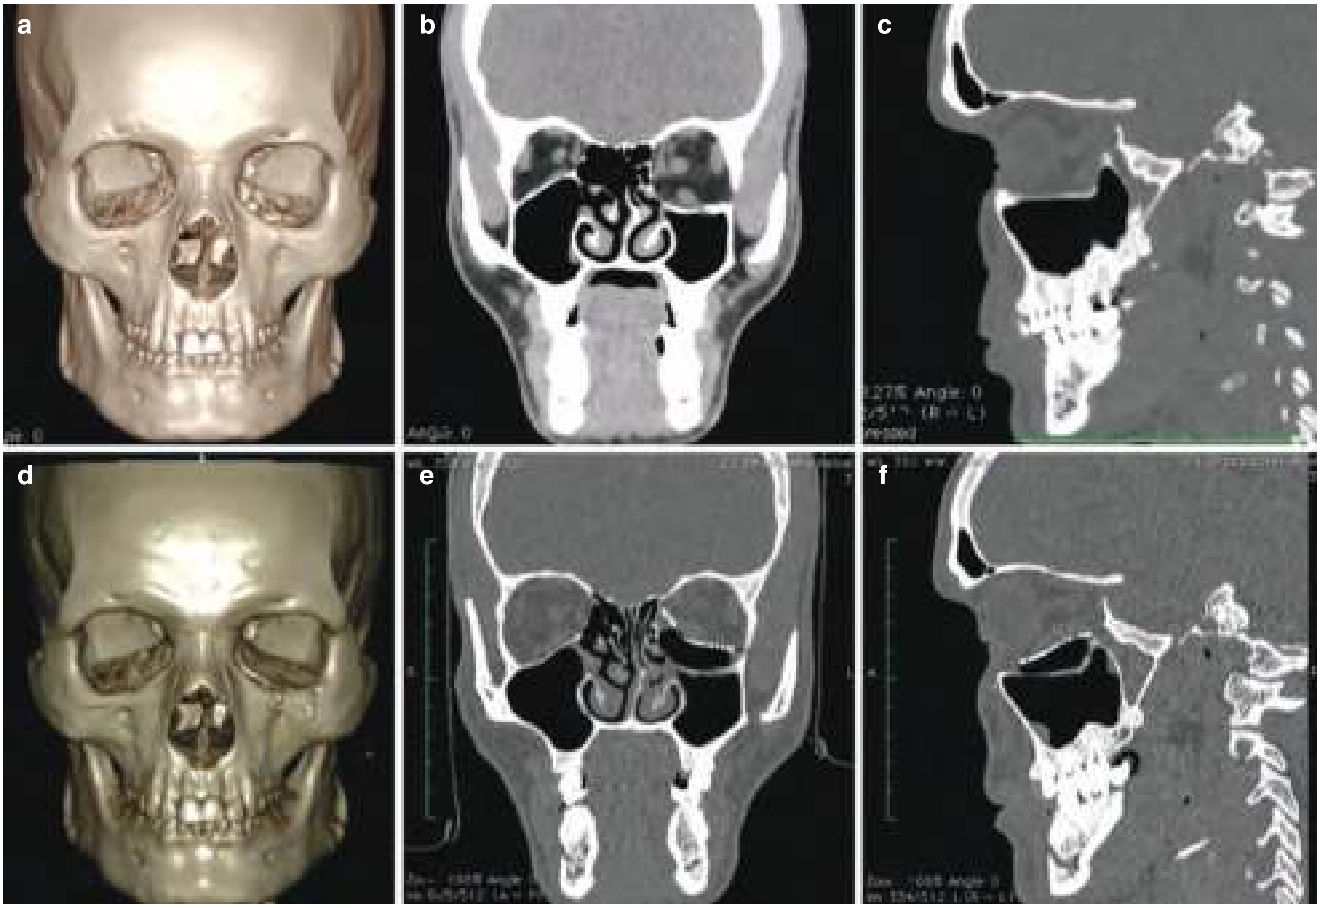

Fig. 57.40 CT scan images of patient with internal orbital fracture. (**a**–**c**) 3D, coronal, and sagittal images demonstrating isolated fracture of the left orbital floor and medial wall. (**d**–**f**) post-operative images demonstrating reconstruction of the defect with anatomical orbital implant

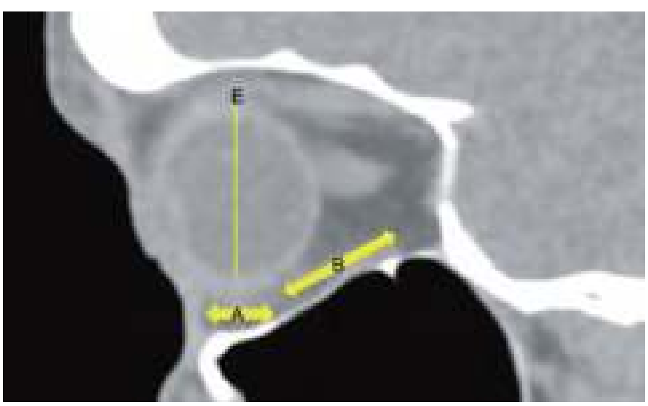

Fig. 57.41 Graphical representation of the equator of the globe (E) and the associated equatorial (A) and post-equatorial (B) zones of the floor

Diplopia can manifest in two forms:

(i) Monocular (diplopia present when seeing through one eye with the other eye closed) which is of more concern where the pathology is generally due to an ophthalmic problem (corneal, retinal, etc.) or neurological where the problem may be due to the optic nerve or the optic disk being injured.

(ii) Binocular diplopia (diplopia present only when seeing with both eyes, while absent on seeing with one eye) with CT proven muscle entrapment is seen as an indication for immediate intervention. However, it may also be attributed to other reasons including (a) intra-orbital edema or hemorrhage, physical bony spicules or fragments acting as impediments following trauma, (b) entrapment of the periorbita, and in rare cases (c) large changes in intra-orbital volume including massive

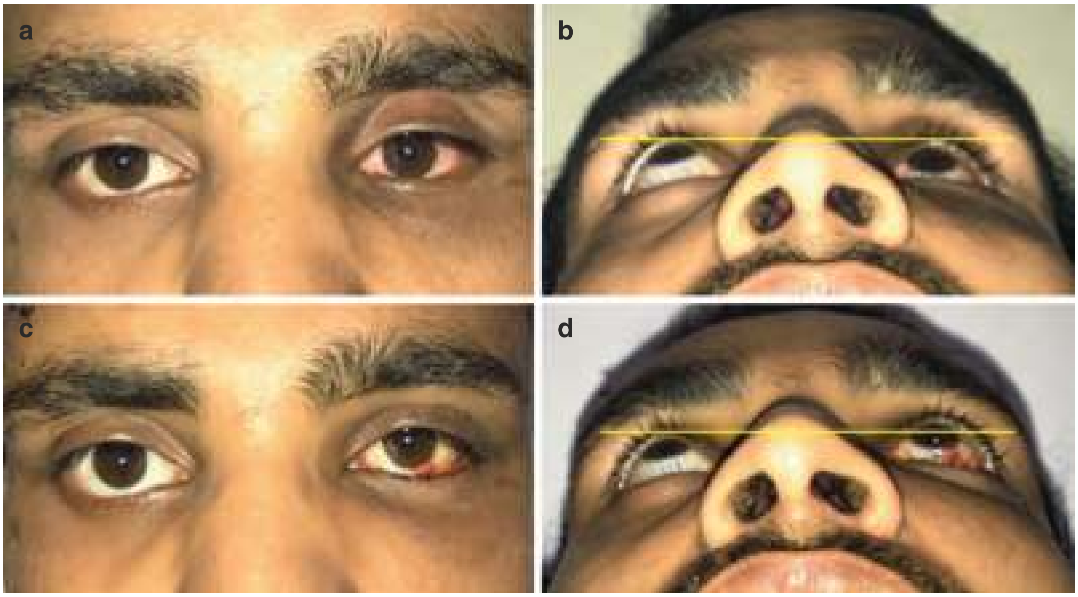

Fig. 57.42 Clinical photographs of patient with enophthalmos. (**a** and **b**) Pre-operative pictures demonstrating significant enophthalmos of the left globe. (**c** and **d**) Post-operative pictures demonstrating good surgical outcome

herniations or atrophy of periorbital fat, which do not mandate immediate intervention. Refer to clinical scenario 2.

When Is the Right Time to Intervene?

The timing for intervention for fractures of the orbital floor can be divided into three categories—immediate, early, and late. The indication for all three categories are well discussed in literature [57] and are listed in Fig. 57.43.

Indications for immediate repair are of an urgent nature and may require priority as surgical emergencies, generally less than 6 h following trauma.

What to Use for Reconstruction of the Orbital Defect?

A plethora of material both autogenous and alloplastic have been used and documented. A table is provided with the list of the most commonly used materials and their relative merits (Table 57.1). However, contemporary literature favors the use of stock titanium meshes and custom patient specific implants which provide optimal corrections (Fig. 57.44a, b).

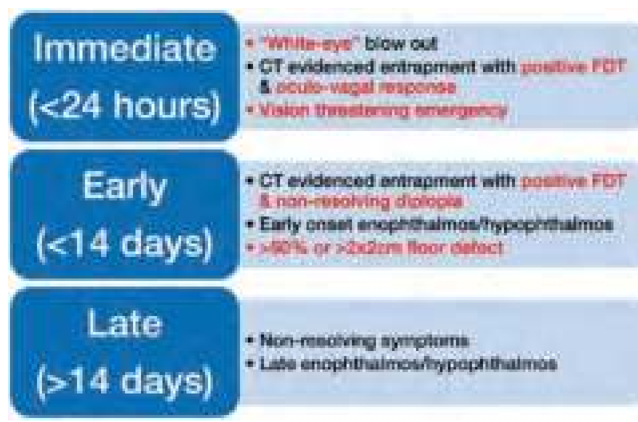

Fig. 57.43 Chart showing timing for intervention for orbital reconstruction

Guidelines for Deep Orbital Dissection

The dissection of the deep orbit is always a challenge for the surgeon due to the high concentration of vital structures within a limited space [60]. A few anatomical landmarks that have been suggested for guidance while dissecting in the deep orbit include:

(a) *Infra-orbital nerve*: the course of the infra-orbital nerve within the orbit is a very important landmark in floor dissection. The point of its entry from the pterygopalatine fossa at the genu/bend where inferior orbital fissure takes a turn and ascends laterally to continue as the superior orbital fissure signifies the safe limit for the posterior extent of floor dissection. Even in the case of badly comminuted fractures or delayed corrections, the nerve may be identifiable and provides a reliable clue to the end of the pre confluence area.

(b) *Inferior orbital fissure*: the inferior orbital fissure forms a pathway for an extended exposure of the lateral orbit as the contents of the fissure can be safely divided using bipolar cautery dissection. This facilitates easy navigation into the deep orbit behind the fissure and trace the greater wing of sphenoid. It may be of clinical relevance to note that the structures of the lateral orbit are much stronger and less prone to comminution when compared to the medial orbital structures. This makes the lateral approach to the deep orbit more predictable. Furthermore, the medial strut of the inferior orbital fissure is an important entity to identify and utilize for reconstruction of the internal orbit.

(c) *The greater wing of the sphenoid*: this is a thick and strong bony structure which forms the majority of the lateral orbit and bridges the inferior and superior orbital fissures. Its robust nature makes it less prone for comminution and hence forms a predictable landmark to find even in severe trauma.

(d) *Orbital process of the palatine bone*: the Orbital process of the palatine bone forms the highest point of the posterior-medial bulge of the orbital floor. This is an integral part of the posterior orbit that needs to be reconstructed to get adequate positioning of the globe in the anteroposterior and vertical directions.

(e) *Orbital confluence*: the orbital confluence (Fig. 57.45a, b) is formed by the convergence of two bony shelves forming the genu of the internal orbital fissures. This signifies the safe limits of the dissection of the orbital floor. The confluence is formed by the perpendicular plate of the palatine bone on the medial aspect and the bony inferior margin of the greater wing of the sphenoid laterally.

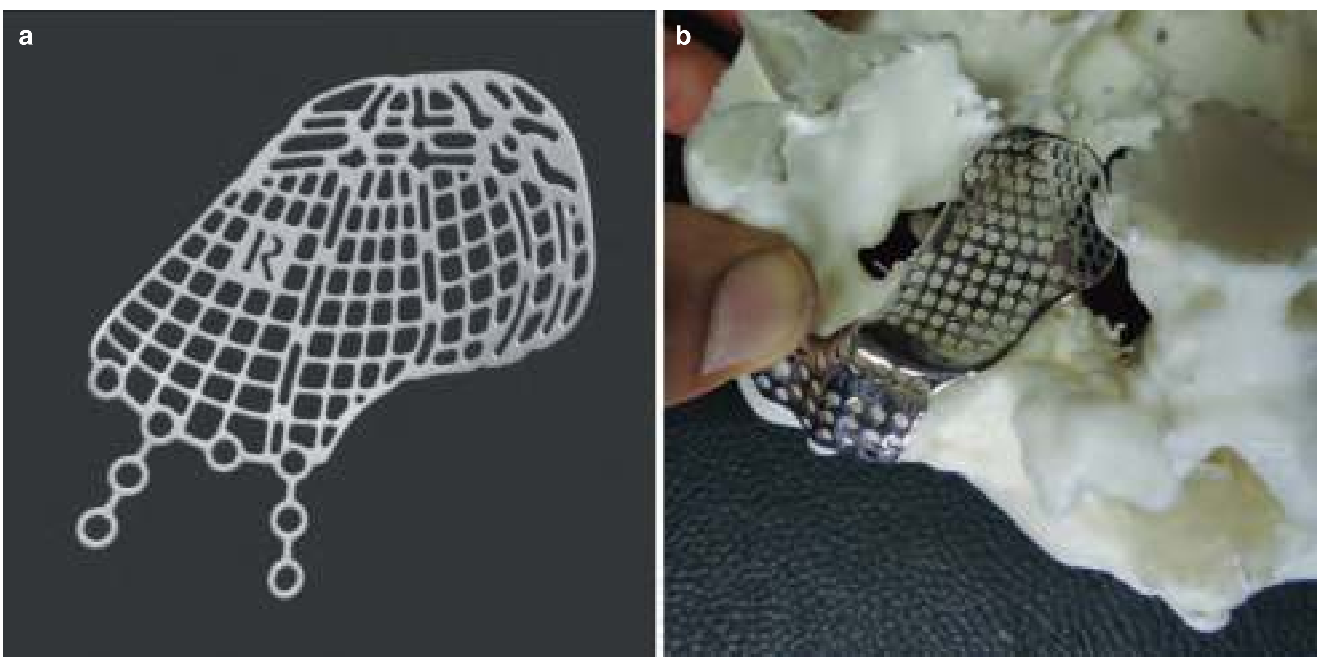

Fig. 57.44 Photographs of (**a**) Stryker[R] preformed anatomical orbital floor implant and (**b**) titanium “patient-specific implant” (PSI)

(f) *Safe distances within the orbit*: an important formula to remember safe distances within the orbit is 24-12-6, where 24 is the distance in mm of the anterior ethmoidal foramen from the medial orbital rim; an additional 12 mm deeper (36 mm) would indicate the posterior ethmoidal foramen followed by another 6 mm deep for the optic nerve (42 mm) [6].

(g) *Globe protection*: protection of the globe is of vital importance in orbital surgery. Adequate care should also be exercised for the protection of other vital structures like nerves and vessels also. Use of protection devices like specific retractors (Fig. 57.46a, b, c) and corneal shields is mandatory.

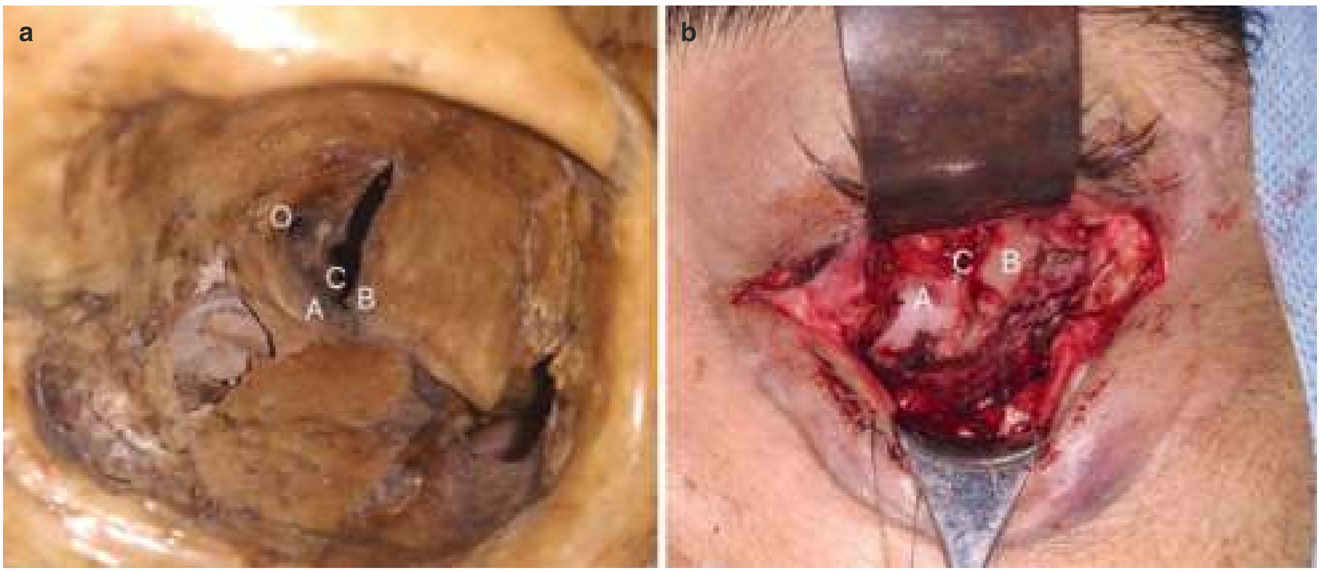

Fig. 57.45 (**a**) Demonstration of landmarks on dry skull. (A) Perpendicular plate of the palatine bone. (B) Medial lip of the greater wing of the sphenoid. (C) Orbital confluence and (O) Optic foramen. Fig. 57.47 CT scans images demonstrating optimal de-herniation of orbital contents and restoration of intra-orbital volume. (**a**–**c**) Pre-operative, (**d**–**f**) post-operative

De-herniation of the Orbital Contents and Locating the Posterior Ledge

Two important aspects of floor reconstruction are:
- (i) De-herniation of the orbital (Fig. 57.47a–f) contents to *restore* the internal orbital volume
- (ii) Locating the posterior ledge (Fig. 57.48a–d) for optimal implant positioning

However, locating the posterior ledge in large defects and secondary corrections may be a significant challenge. Absence of posterior ledge in severe orbital trauma is an indication for cantilevered implants which are secured to the infra-orbital rim alone.

57.8.3 Type III (Naso-Orbito-Ethmoid Type) (Refer Chap. 58)

The NOE-type fractures are the most challenging of all the orbital fractures to manage in terms of achieving predictable results. The management of the NOE complex reconstitutes the facial form of the central midface: a key element in facial esthetics. This type is also prone to have concomitant injuries to the lacrimal system which should be identified and treated.

Figure 57.49a–f demonstrates the CT images of a patient with a residual deformity following pan-facial trauma with a right-sided type I NOE and neglected orbital floor fractures.

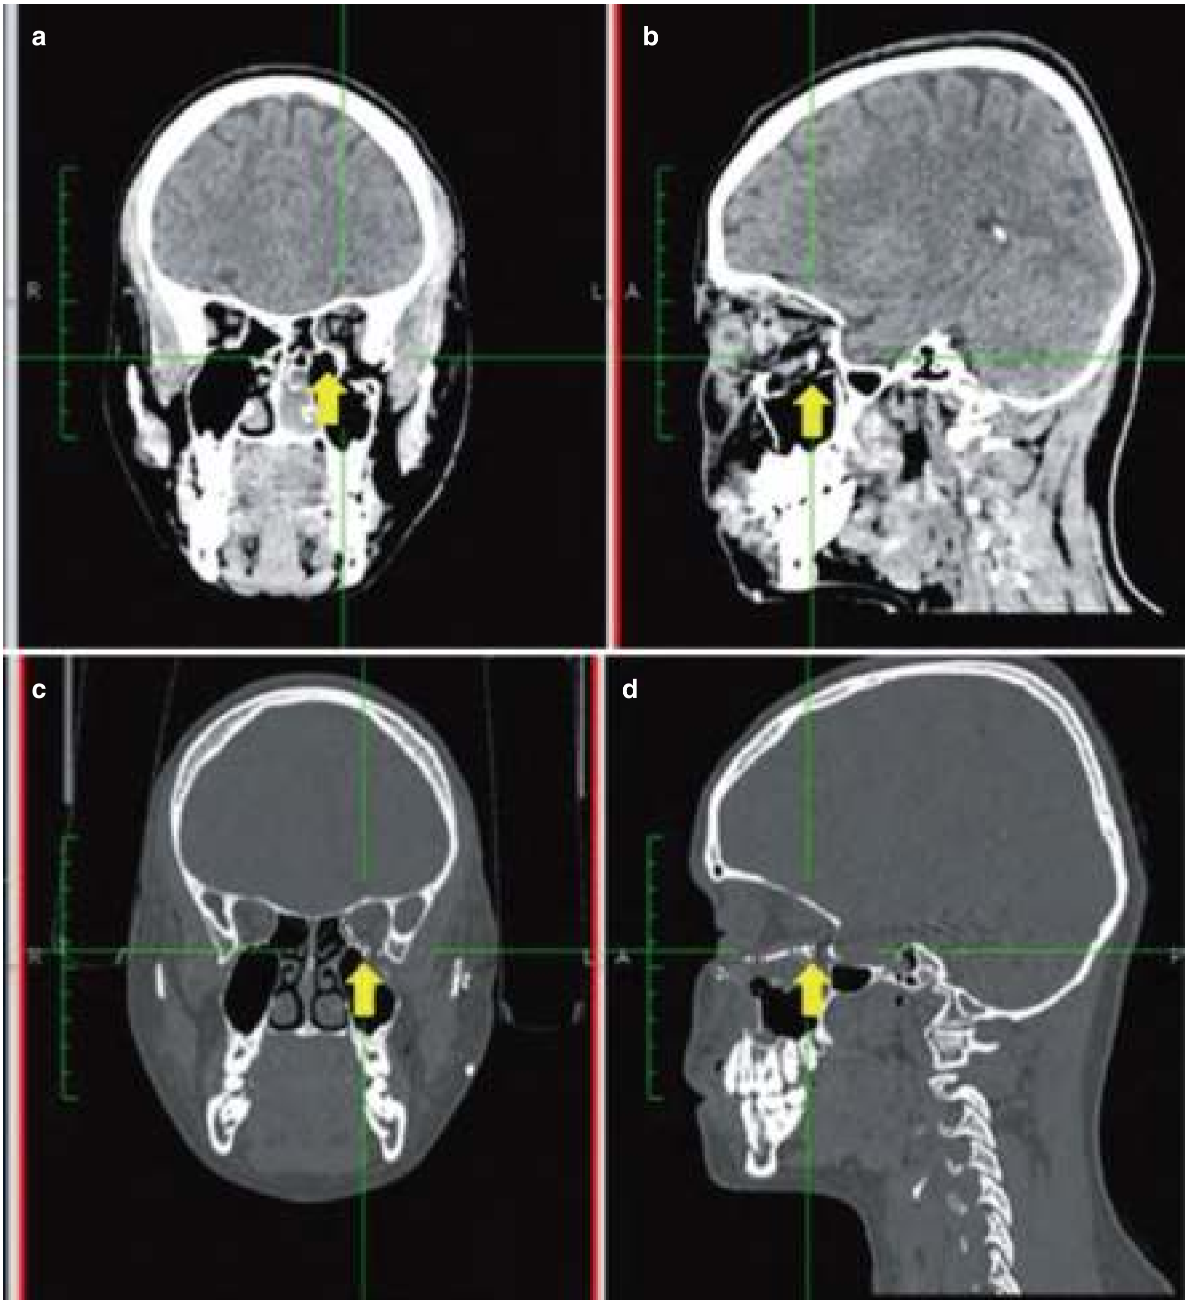

Fig. 57.48 (**a** and **b**) Pre-operative coronal and sagittal section CT images demonstrating the location of the posterior ledge of the floor defect. Box 57.11 The *Key Elements* for Managing Type III Fractures

- Management of the medial canthal tendon (MCT) as indicated: this can be performed according to the description of Markowitz et al. [61] with the focus being the attachment or avulsion of the medial canthal tendon (MCT) to the fracture fragment
- Management of the soft tissue drape after reposition of the MCT
- Restoration of the nasal dorsum projection, which is of paramount importance
- Evaluation of injuries to the lacrimal system: canaliculi, sac and the nasolacrimal duct (NLD), and its management

57.8.4 Type IV (Complex Fractures of the Face with Orbital Fractures)

This type includes all the combinations of the fractures of the face which do not fall into the types described above. Sequencing of fractures (refer Chap. 60) such as these including pan-facial fractures requires a thorough understanding of the principles to obtain optimal outcomes. It is to be borne that sequencing and fixation of all facial fractures need to be completed prior to the reconstruction of the internal orbit.

Figures 57.50a–d and 57.51a–d demonstrate a patient with residual facial deformity following RTA. Patient had sub-optimally treated pan-facial and orbital fractures and a malunited mandible fracture. He was operated for a revision surgery addressing his midface and dental occlusion.

57.9 Management of Orbital Emergencies

(a) *Retrobulbar hemorrhage*: investigations with a CT scan or an MRI as the clinical situation mandates help us with a diagnosis of retrobulbar hemorrhage. 20% mannitol 2 g/kg body weight or 500 mg acetazolamide is administered to reduce the intraocular pressure in conjunction with 100 mg hydrocortisone for management of edema. Hourly examinations of pupils, visual acuity, and IOP are of great significance as stable ophthalmic status with diminishing signs of vision can be managed medically. Deterioration of vision or changes in visual fields may be considered an emergency [62]. Inferior cantholysis is the most commonly employed procedure for decompression of the retrobulbar space [63–65].

(b) *Traumatic optic neuropathy*: the management of traumatic optic neuropathy includes observation, use of steroids, and surgical decompression [66]. However, the use of corticosteroids in acute brain trauma is now debatable, and the general consensus is non-use of steroids in patients having concomitant brain trauma [67]. Many clinicians now restrict the use of steroids (bolus

(**a** and **b**) Images demonstrating frontal and lateral views showing malunited pan-facial fracture with facial deformity and significant dental malocclusion. (**c** and **d**) Post-operative images demonstrating ORIF of the right orbito-zygomatic complex and a Lefort I osteotomy with restoration of skeletal form, midface projection, and restoration of functional occlusion

dose of 30 mg/Kg body weight of methyl prednisolone followed by 3 mg/Kg/h for 24 h) within the first 8 h of injury, in cases of severe primary vision loss or progressive vision loss.

(c) *Compartment syndromes*: this includes both superior orbital fissure and orbital apex syndromes. The current protocols indicate early surgical decompression where indicated. The role of steroids is debatable as indicated above.

57.10 Pediatric Considerations (Figs. 57.52a–d and 57.53a, b)

Pediatric consideration in orbital trauma necessitates the discussion of four important aspects which clearly delineate the management principles from adults.

(a) *Ratio of cranium to facial fractures in children*
The face to cranium ratio of an infant is 1:8, while that of a child who is between 4 and 6 is about 1:4. This clearly establishes the fact that the cranium in an infant or a child is much larger than the face and is more exposed to potential trauma. The incidence of orbital roof fractures is much more common in children who are younger than 5 years, while beyond the age of 7, the floor fracture is more commonly seen.

(b) *Pediatric orbital roof fractures*
Roof fractures in children occur in the growing age [68] and cause an entity called the "growing skull fracture," where the fracture fragments continue to separate due to growth, causing "leptomeningeal" herniation which involves herniation of the meninges and part of the frontal lobe into the orbital cavity. Management of these need to be planned in conjunction with neurosurgical support.

(c) *White eye blowout*
The presence of floor fractures with restriction in superior gaze, with or without oculo-vagal responses and devoid of any physical signs of hemorrhage or ecchymosis in the eye or periorbital region [69–71]. This is a feature which may be seen in children and young adults as a result of a "self-reducing trapdoor" fracture which entraps the inferior rectus. The white eye blowout is considered a surgical emergency and necessitates immediate intervention.

(d) *Role of resorbable implants*
The cranium and upper face exhibit rapid growth in the early years. The orbit completes almost 80% of its growth within the first 2 years of life and another 10% within the next 2–3 years. Choice of implants in the growing orbit is to be taken into consideration by the surgeon who has to plan for the residual growth of the orbit and possible chances of migration of implants.

57.11 Secondary Correction of Orbital Deformities

Secondary corrections of the internal orbit demand great degrees of skill and are technically demanding even for the trained surgeon due to the nature of fibrosis and contracture that is already set in and the distortion of bony landmarks within the orbit. This may necessitate more extensive dissection and mobilization of the orbital contents and yet yield sub-optimal outcomes.

57.12 Complications

Complications associated with management of orbital fractures may be categorized into immediate and delayed complications.

Box 57.12 Indications for Secondary Deformity Correction of the Internal Orbit Generally Are

(a) Restricted ocular movement, which may be either due to muscle entrapments or adhesions of intra orbital and/or periorbita
(b) Diplopia due to physical impediments like bony interferences and/or soft tissue adhesion/entrapment
(c) Enophthalmos and/or hypophthalmos

57.12.1 Immediate Complications

The most common immediate complications that are secondary to orbital surgery include:

- edema,
- infection,
- would dehiscence,
- aberrant implant position,
- extrusion of implants.

Hemorrhage may be an infrequent complication which may happen during the surgery or in the immediate post-operative period.

Complications associated with specific ophthalmic implications like injuries to the cornea, extraocular muscles, lacrimal apparatus, or the optic nerve also may occur.

Blindness is a rare but grievous complication which has to be borne in mind.

The last group includes neurosensory disturbances like paresthesia or dysesthesia associated with the infra-orbital nerve and carrying grades of facial nerve palsy or weakness [72, 73].

57.12.2 Delayed Complications

Delayed complication may present in the form of:

- Persistent enophthalmos/hypophthalmos
- Persistent or worsened diplopia with altered vision
- Restricted ocular movement due to fibrosis and adhesion

Other adverse outcomes include:

- Entropion
- Ectropion
- Hypertrophic scars/keloids
- Change in the axis of the palpebral fissure

57.13 Recent Advances in Management of Orbital Fractures

Orbital reconstruction still remains one of the most challenging and enigmatic areas in the management of cranio-facial trauma and most certainly attracts the latest in terms of technology and developments to refine and improve outcomes. Significant advances in the field of orbital reconstruction include:

1. Computer-assisted surgery
2. Intraoperative imaging and navigation (refer Chap. 41)
3. Patient-specific implants for reconstruction

57.13.1 Navigation and CAS for Orbital Fractures and Reconstruction

Computer-assisted surgery allows virtual pre-operative planning of the desired reconstruction using pre-operative CT scans (Fig. 57.54a–d) [74]. This virtual plan gives real-time guidance during surgery. Navigation helps visualize the actual surgical outcome during surgery in relation to the pre-operative plan (Fig. 57.55). With this technique, sub-optimal reduction of fractures and positioning of implants can be identified and corrected during surgery, thereby reducing the need for secondary procedures [75–77].

57.13.2 Patient-Specific Implants (Fig. 57.56a–c)

Custom implants for the reconstruction of complex defects and deformities have become vogue now. They offer the advantages of accurate planning and infallible positioning intraoperatively which enormously improve post-surgical

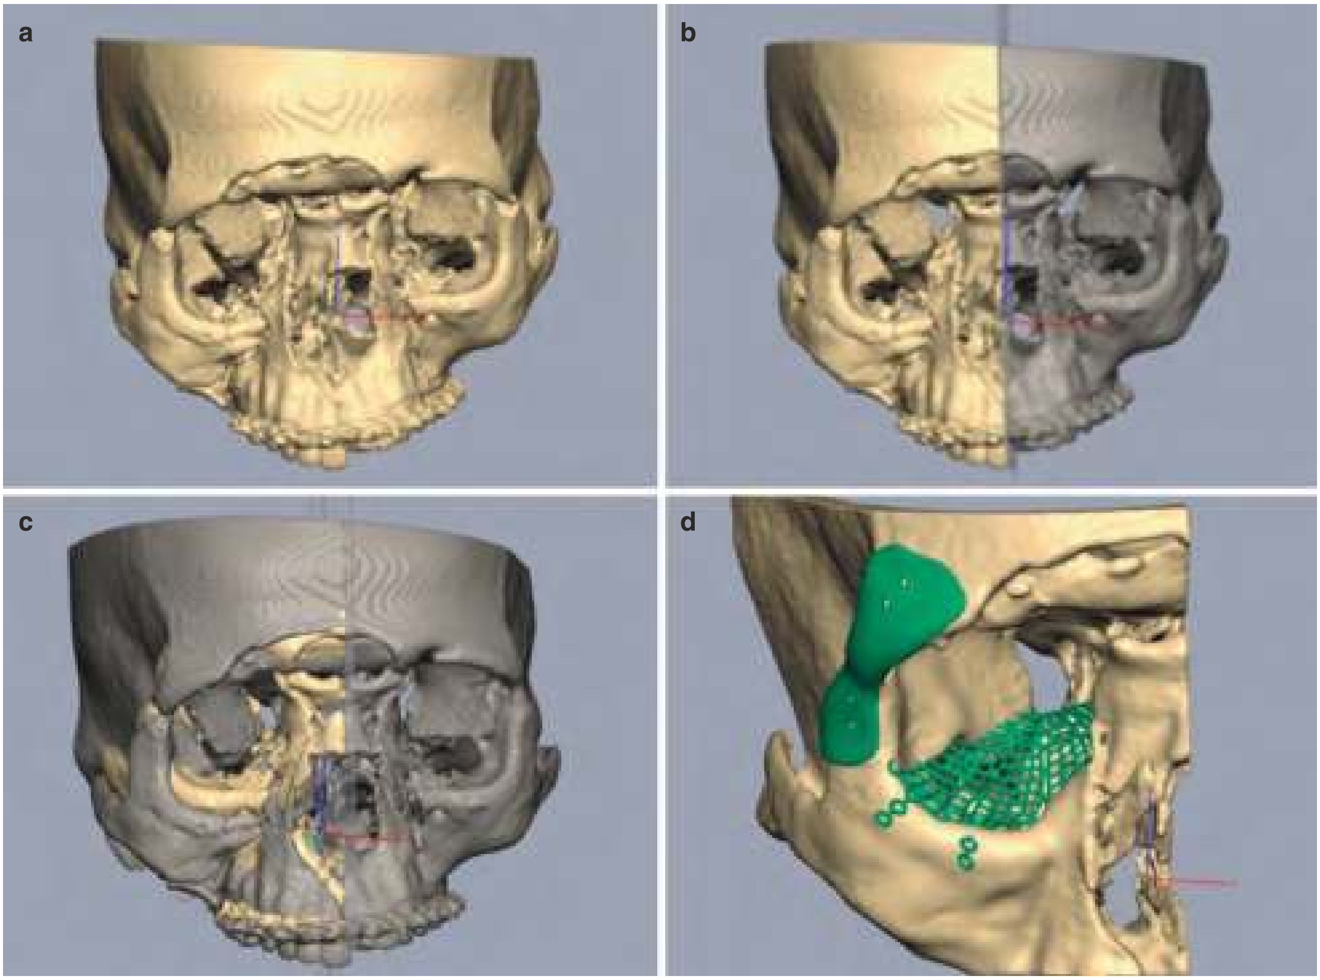

Fig. 57.54 Photographs depicting stages in computer-assisted surgery for orbito-facial reconstruction. (**a**) Generation of virtual 3D model; (**b**) segmentation and mirroring of normal side; (**c**) superimposition of the mirrored object on the affected side, enabling a better understanding of the deformity; and (**d**) creation of patient specific implant design for the fronto-zygomatic region and importing the virtual model of the anatomical orbital implant for floor reconstruction

outcomes. The defect can be mapped digitally and a construct can be made after virtual surgical planning to aid in intraoperative guidance. The implants may also function as guidance stents and double up as fixation devices too.

57.14 Conclusion

To conclude, all patients with orbital trauma need to be subjected to ophthalmological examinations both pre- and post-surgery. Globe protection, gentle retraction of tissues, and intraoperative testing for vision are mandatory during orbital surgery.

Box 57.13 Principles to Be Followed During Surgery for Orbital Floor Reconstruction

(i) Complete exposure of the fracture and defect
(ii) Meticulous de-herniation of the orbital soft tissues with restitution of intra-orbital volume
(iii) Identification of the posterior ledge in floor defects which is the posterior limit for reconstruction
(iv) Restoration of the posteromedial bulge of the orbit (Hammer's key area) [7]
(v) Choice for the reconstruction material should be based on the complexity of the defect (Dubois et al.) [55]

Fig. 57.55 Screenshot images of a left-sided orbital floor with an anatomical orbital floor implant that is virtually planned and executed with the help of intraoperative navigation

57.15 Case Scenarios

Case 1

Patient with a history of facial trauma 8 months back presented with complaints of change in the position of his eyeballs. He had a history of surgical intervention for management of his pan-facial fractures immediately following the trauma. No intervention was performed for the orbital fractures primarily. Subsequent clinical evaluation performed 8 months later revealed enophthamos, hypophtalmos and restriction in superior gaze in the right eye. CT scans revealed a large orbital floor defect on the right side with fibrosis and adhesion of the inferior rectus to the posterior ledge of the floor defect. The patient was subjected to secondary surgery for correction of the above mentioned complaints. An orbital exploration was performed on the right side to release the inferior rectus, the infra-orbtial rim was augmented with a ramal graft and the floor defect was reconstructed with a "Stryker" anatomical orbital implant. Post-surgical evaluation revealed optimal corrections of the enophthalmos, hypophthalmos and good repositioning of the inferior rectus muscle (Figs. 57.57a–d, 57.58a, b and 57.59a–f).

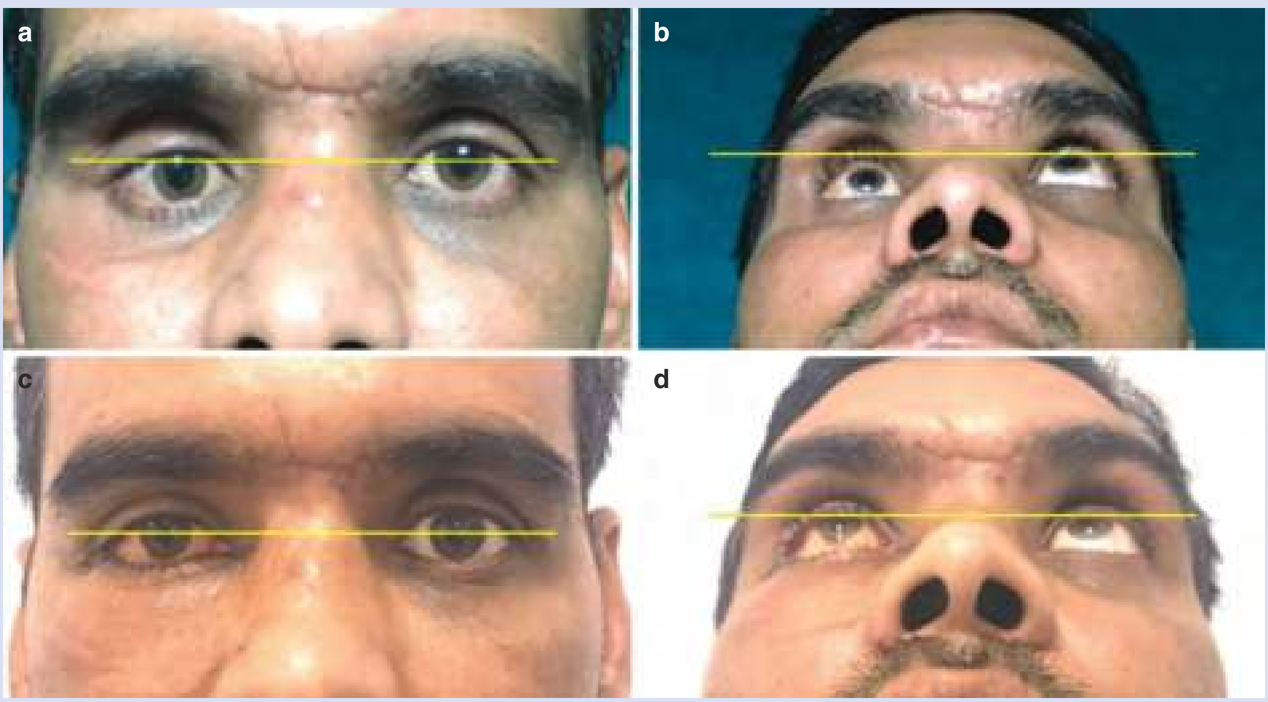

Fig. 57.57 (**a** and **b**) Pre-operative clinical photographs of patient demonstrating right sided enophthalmos and hypophthalmos. (**c** and **d**) Post-operative clinical photographs showing optimal surgical outcomes

Case 2

A 12 year old girl presented to the surgical OPD with history of blunt injury to the left eye. On examination she had no external signs of injury but revealed restriction in superior gaze in the left eye. CT scan revealed a springing trapdoor fracture of the left orbital floor with entrapment of the inferior rectus muscle. A diplopia charting was performed which revealed moderate to severe restriction of the left eye in the superior gaze. The patient was taken up for immediate surgery for orbital exploration and release of the entrapped muscle with/without floor reconstruction. The exploration was successful and the patient required no reconstruction of the floor. Post operatively the patient demonstrated complete resolution of the symptoms with the full range of ocular movements restored. 58 Frontal and Naso-Orbito-Ethmoid Complex Fractures

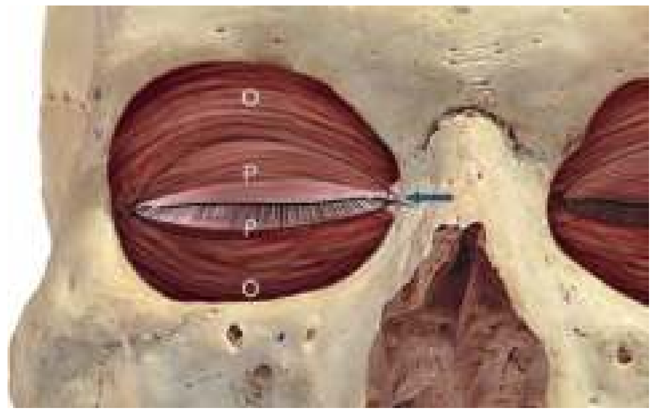
Kannan Balaraman

58.1 Introduction

Naso-orbito-ethmoid (NOE) region is a confluence of critical structures of the face including the nose, orbit and skull base. Hence injuries to the region have a major impact on the function of these regions as well as aesthetics. A deformity of the NOE region tends to catch the eye much more than a deformity elsewhere in the face and hence affecting the individual. The injuries to this area are about 5% of maxillofacial injuries in adults and about 15% in children [1, 2] and mostly occur as a result of road traffic accidents (RTA) [1] especially in the Indian subcontinent. This is especially so due to two-wheeler injuries. Considering the proximity of the region to the brain and globe, these injuries may need multidisciplinary evaluation before embarking on a definitive treatment plan.

58.2 Applied Surgical Anatomy

The NOE complex is a part of the medial vertical buttress system of the face abutting the cranium. It is made of the nasal bones, the ethmoid bones encompassing the sinuses which also form the medial wall of the orbit articulating above with the frontal bone at the anterior skull base. This ethmoid labyrinth which separates both the orbits acts like a shock absorber during trauma thus minimizing force dissipation into critical structures like the orbital and cranial cavities. Extensive injury or comminution can result in associated anterior cranial base fractures causing cerebrospinal fluid (CSF) leak as well. The frontal process of maxilla and the lacrimal bone also is an integral part of the complex owing to their proximity and involvement in the fracture pattern occurring in the region.



©Association of Oral and Maxillofacial Surgeons of India

Fig. 58.1 MCL anchoring eyelids (O-occular, P-palpebral)

Apart from the bony parts, the medial canthal ligament (MCL) is an important soft tissue of the complex (Fig. 58.1). The ligament not only anchors the upper and lower eyelids to the nasal complex but also encompasses the lacrimal sac at its anterior, posterior and superior aspect [3]. Certain authors have found that the posterior limb is not always present or clearly defined in certain instances [4]. The ligament being attached to the edges of the lacrimal fossa in the lacrimal bone in these areas helps in emptying of the lacrimal sac during blinking thus effecting drainage of the lacrimal sac. Hence injuries to the region affecting the attachment of the medial canthal ligament can impact the medial eyelid attachment and/or draining off tears from lacrimal sac. The skin and soft tissues drape over the complex like a cloth over a framework, and when the region crumples following an injury, the soft tissue envelope collapses as well causing distinct deformity which if not treated well can result in persistent deformity of the region. The collapsed soft tissue heals/scars over the deformed bony complex and secondary correction at a later date do not help achieve the pre-injury status. Hence optimal primary realignment and repair offer the best chance of achieving optimal results [5].

58.3 Historical Perspective and Classification [6]

The treatment of NOE complex injuries has evolved from the previous century. Though nasal bone fractures have been recognized for a long time, the fracture of ethmoids was highlighted by Dawson and Fordyce in 1953. Converse and Smith in 1963 identified the involvement of medial orbital wall and termed it as naso-orbital. Stranc was the first to in modern English literature to adopt the terminology naso-ethmoid. Epker recognized the present-day terminology of naso-orbito-ethmoid in 1973, whilst Gruss in 1985 preferred the term naso-ethmoid-orbital [6].

58.3.1 Classification

Rowe and Williams [7] in their classic text highlighted the complexity of the area and stressed the need for primary management. Their classification was quite simple, depending on side involved and association with other fractures.

- Unilateral or bilateral
- Isolated or associated with other facial fractures

Markowitz and Manson (1991) [8] identified the importance of canthal ligament, and their classification reflected the need for getting the position of the canthal ligament either by manipulating the fragment or anchoring the canthus directly. Their classification was as follows (Box 58.1):

Box 58.1 Markowitz and Manson Classification

Type I	Simple fracture with canthal ligament attachment intact
Type II	Comminuted fracture with intact canthal attachment in the large fragment (positioning this fragment helps in securing the canthus in the right place)
Type III	Gross comminution with the canthal attachment in a small fragment or detached canthus both necessitating canthopexy

58.3.2 Paediatric NOE Fractures (Fig. 58.2) Classification: Burstein et al.'s [9] (Box 58.2)

Box 58.2 Paediatric NOE Fracture Classification
Paediatric NOE fractures classification types are:

- *Burstein type I fracture*—localized to the upper NOE complex and frontal bone, medial to superior orbital foramen
- *Burstein type II fracture*—involves half of the superior orbital wall, although it does not involve the NOE
- *Burstein type III fracture*—is bilateral and involves the superior orbital walls, upper NOE and bilateral frontal bones

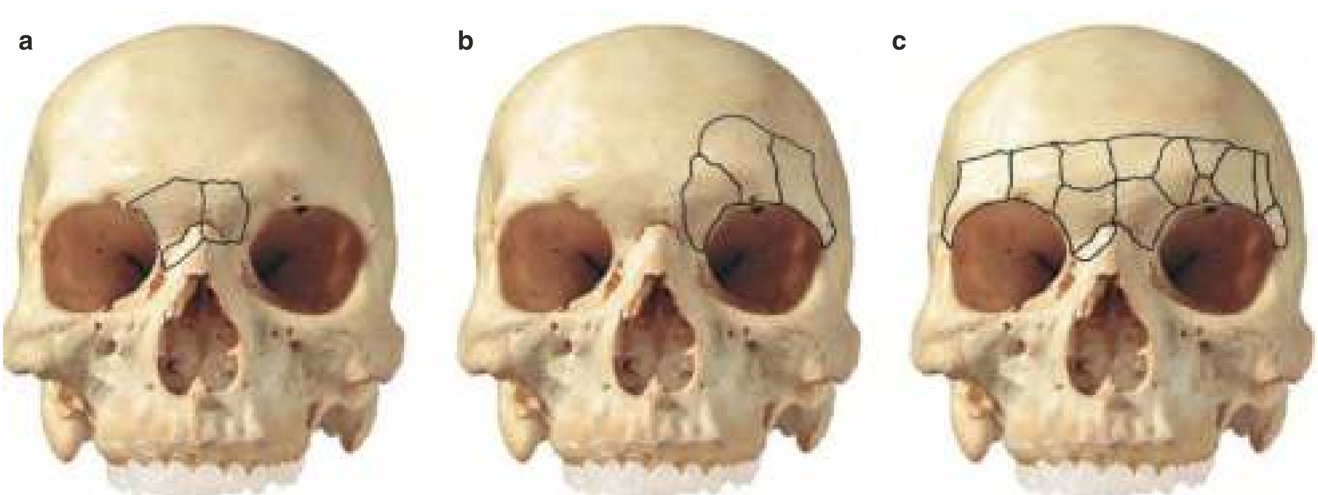

Fig. 58.2 Paediatric NOE fractures classification

Markowitz classification of adult NOE fractures does not take into account the differences in paediatric population such as:

- Midface-skull proportions
- Frontal sinus pneumatization

58.4 Aetiology, Clinical Features and Diagnosis

The most common aetiology of the fracture of NOE complex is trauma be it road accidents in unprotected individuals, assaults or fall from height [10].

Initial presentation can be disconcerting for the individual and bystanders due to profuse nasal bleeding and gross oedema around the midfacial skeleton. The signs and symptoms are given in Box 58.3 (symptoms) and Box 58.4 (signs).

Box 58.3 Symptoms of NOE Fracture

Periorbital swelling
Pain and discomfort
Epistaxis
Nasal blockade
– Widening of NOE area

Box 58.4 Signs of NOE Fracture

Nasal deformity with crepitus
Epistaxis—blood or mixed with CSF
Depressed nasal bridge
Upturned nasal tip
Rounded medial canthus
Altered palpebral fissure shape
Blockage of nasolacrimal duct – Accentuation of the nasojugal skin fold – Formation of obtuse angle at the base of columela with tension on upper lip – Lip separation caused due to ruptured tip of nose
Telecanthus (a) lose of almond shape of palpebral fissure (b) Transverse shortening of the palpebral aperture (c) Eyelids become lax (d) Epicanthal fold become more prominent (e) Flattening of the bottom of naso-orbital valley (f) Obliteration of the caruncle (g) Diminished tension of canthal ligament

From the point of view of the examining clinician, Advanced Trauma Life Support (ATLS) protocols take precedence however gross the presenting scenario is (Refer Chap. 48 of this book). Once primary survey is completed and the patient cleared for secondary survey, definitive clinical examination starts. It is also imperative to rule out underlying injuries to the head/brain, ophthalmologic or associated structures prior to comprehensive maxillofacial assessment.

The main indicators suggesting an underlying NOE fractures include:

- Depressed nasal bridge (with or without upturned nasal tip) is a result of the loss of bony morphology (Fig. 58.3a, b). When the medial canthal ligament attachment is lost, the manifestations include loss of contour of palpebral fissure with rounded medial canthal region. The almond shape of the palpebral fissure is lost and becomes larger, and Bowstring test becomes positive (Fig. 58.4).
- Traumatic telecanthus is a direct indicator of the MCL disruption or widening of the fragments. When there is an intercanthal distance of 35 mm or more, then it may be an indication of the fragment with MCL being displaced. Direct physical examination is useful in identifying the collapsed complex.

Measurement of Intercanthal Distance (ICD):

Normal values are 32–33 mm for females and 33–34 mm for males. The rule of thirds can be applied whilst evaluating NOE fractures. Normally ICD equals the palpebral fissure width. However, in NOE fractures, increased ICD is found, called telecanthus (Fig. 58.5).

Telecanthus deformity is characteristic; the lateral displacement of MCT leads to rounding of the medial palpebral fissure, widening of the NOE region and transverse shortening of the palpebral aperture.

- Care should be taken to rule out CSF leak and also damage to the nasolacrimal duct. However the latter is difficult to assess primarily in some of the cases and may become apparent much later. Clear discharge from the nose or watery bloody discharge should arouse a high index of suspicion necessitating further biochemical investigations to differentiate CSF from nasal discharge. Glucose content is more in CSF, but assessment of Tau protein (beta 2 Transferrin) is the confirmatory diagnostic factor. Thorough neurologic and ophthalmologic assessment is also essential. In the acute setting, clinical examination is challenging due to the discomfort and

Fig. 58.3 (**a**, **b**) Depressed, widened nasal complex with upturned tip of the nose

always may be inadequate [11, 12], and hence radiological investigations are mandatory. The diagnosis and understanding of the fractures has evolved over the last century with the advent of CT imaging. CT scan imaging in all planes is the norm in these fractures and helps in ruling injuries to the adjacent structures as well as assess-

Fig. 58.4 Bowstring test for assessment of MCL attachment patency

Fig. 58.5 Traumatic telecanthus

ing the extent and nature of displacement of NOE complex injuries.

- High-resolution CT scan images in all planes (axial, coronal (Fig. 58.6a–d)) help to identify and assess the fracture pattern accurately. Thin sections (0.6 mm) not only help in better evaluation but also facilitate surgical planning or fabrication of models if required. The CT scans will be mandatory anyway to assess the head injury status in such cases, and these images can be a part of the head injury screening imaging. Communicating with the radiology department of the importance of such images will ensure that the required sections being done at the same instance of head injury assessment scans thus avoiding repeat scans. The axial sections show if there is disruption of the nasal complex or there is splaying of the ethmoid complex. The coronal sections depicts the displacement in the mediolateral aspect (thus the status of the fragment with the MCL), whilst the sagittal sections

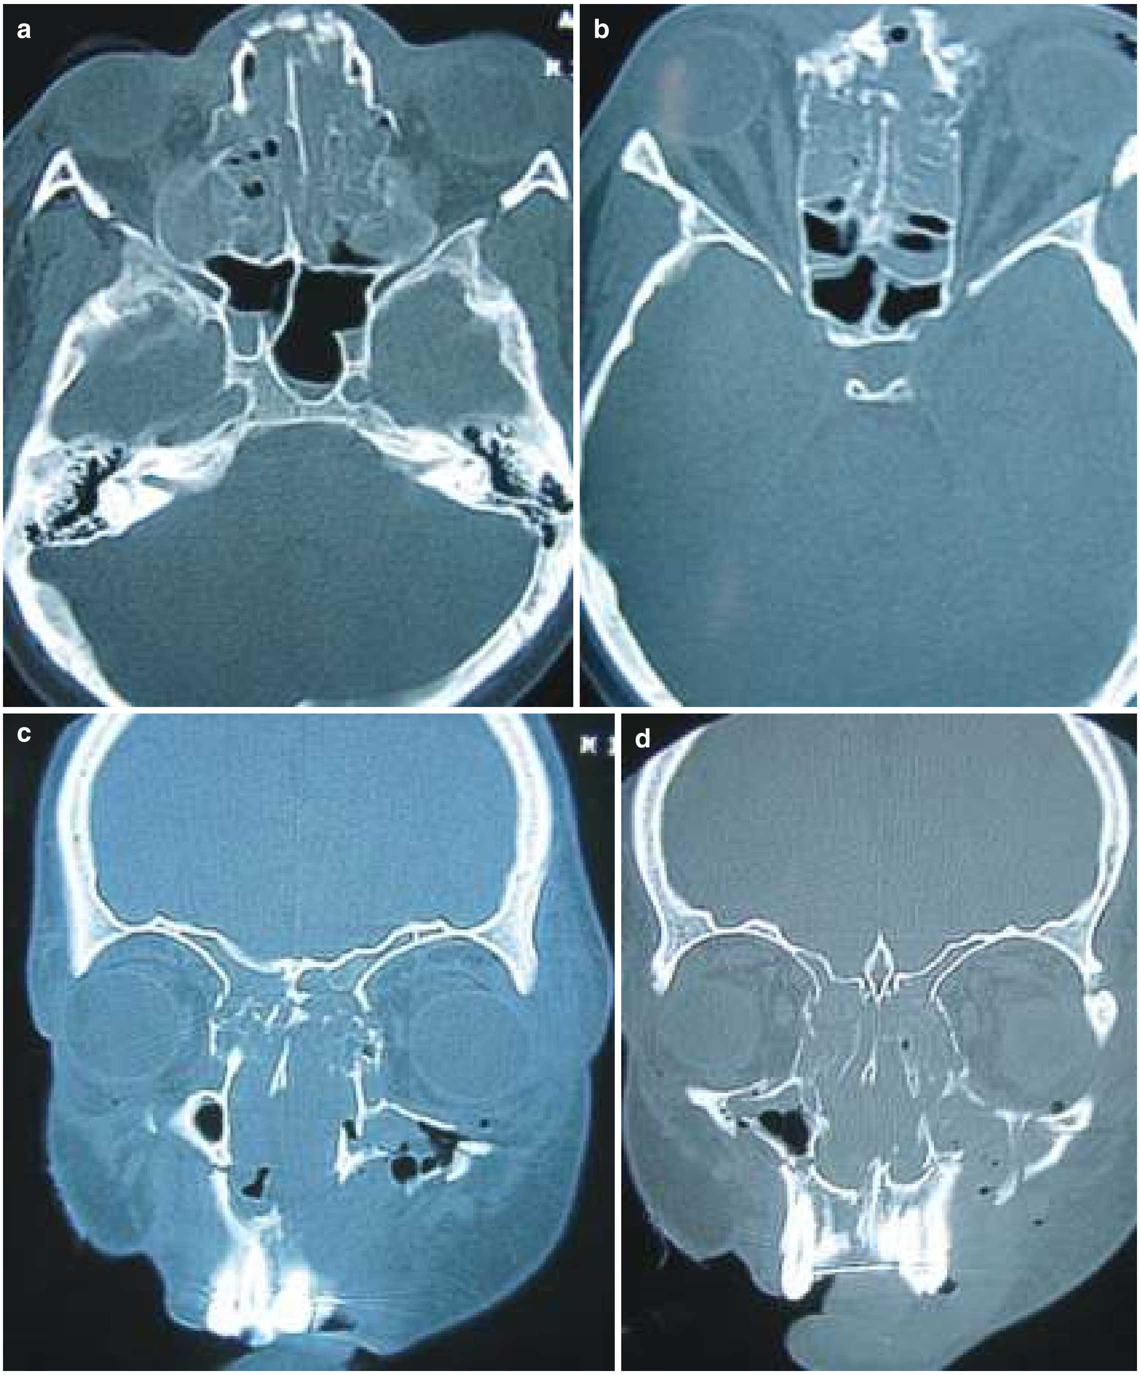

Fig. 58.6 (**a**–**d**) Axial and coronal CT scan images of NOE fracture

depict the displacement in the anteroposterior (AP) aspect (depression).

- 3D reconstructed images show the gross morphologic status and are as accurate as the thinness of the sections. Such images are good to plan the surgical management, discuss with the assistants the treatment goals and also explain to the patient the nature of the injury and proposed treatment plan as part of informed consent.

Test to Assess Integrity of MCT

NOE fracture is positive if mobility of the medial canthal tendon is appreciated.

It is revealed by a Bowstring or a bimanual test.

- Bowstring Test:
  When the eyelid is pulled laterally, a lack of resistance or detection of movement of the underlying bone at the tendon area is indicative of a fracture.
- Bimanual Test:
  An instrument is placed in the nose and pushed laterally. Instability and crepitation felt at the tendon area suggests NOE fracture.

58.5 Management

The initial presentation of such patients occasionally may be dramatic due to profuse epistaxis which may exacerbate in someone lying down. Keeping patients sitting up with packs in the anterior nostril might help reduce the bleed. Persistent profuse bleed may necessitate intubation to secure the airway and packs in both anterior and posterior nasal passages to help prevent aspiration.

The patient once stabilized, and fit to undergo surgery will need a discussion with the anaesthesiologist about options of intubation. Fractures not involving occlusion can be managed by oral intubation, whilst if involving occlusion then options like submental intubation or even tracheostomy of the patient requires prolonged ventilation or due to have further surgical procedures (as in poly trauma patients).

The presence of CSF leak might pose a tricky problem. Instances of CSF leak are higher whenever there is pneumocephalus. Hence in such instances, an approach combined with neurosurgical team may be mandatory, whilst involvement of an ophthalmologist is mandatory when there is involvement of lacrimal drainage system or lid adnexa. The treatment goals of NOE are shown in Box 58.5.

Box 58.5 Treatment Goals of NOE Fracture

Treatment goals
Restoring the nasal projection
Restoring nasal dorsal height with adequate nasofrontal angle
Re-establishing the MCL attachment
Restoring the latency of nasolacrimal duct

Conventionally the nasal complex was treated with closed reduction till Adam et al. [6] reported on the importance of nasal wiring. The importance of involving the medial canthal region in the treatment plan was initiated by Converse and Smith in 1963 [6]. They emphasized the importance of manipulating the segment with the MCL, forward positioning the fragment and trans nasal wiring over a perforated plate.

The case for open reduction and internal fixation (ORIF) was highlighted by Dingman and Natvig [13]. They reported superior results have been achieved in the more serious injuries (with minimum of effort and with the greatest degree of comfort to the patient) by open reduction with direct fixation. The need and feasibility of identifying MCL and anchoring it across to the other side was described by Mustarde in 1964 [14]. The need for primarily bone grafting when there is severe comminution of the nasal dorsum rendering primary reduction incomplete and also help achieve single-stage reconstruction was highlighted by Cruse [15] and Gruss [16].

Reduction of the nasal complex may be done with Walsham's forceps to realign the deviated/displaced complex. The collapsed complex may be out-fractured, and complex opened out may need to be in-fractured. The depressed complex may be elevated into position by the septal forceps (Ash's). However in displaced or comminuted scenarios, closed reduction isn't optimal. Hence trans nasal wiring may be needed to keep the splayed segments well reduced and minimize telecanthus. In the absence of gross comminution, closed reduction and trans nasal wiring has been proved quite useful and adequate to achieve optimal results as advocated by some authors especially in patients with associated maxillary fractures [17].

58.5.1 Surgical Access for NOE

1. Existing laceration (Fig. 58.7)
2. Glabella approach—a horizontal skin incision over the glabella region (Fig. 58.8)
3. Bicoronal approach (Fig. 58.9)
4. Butterfly incision (combination of Gullwing and open sky incision) (Fig. 58.10)
5. Vertical incision (Fig. 58.11)
6. H-shaped incision (Fig. 58.12)

Ed Ellis et al. [11] reported on having a sequential plan to proceed with the surgical sequence. They emphasized on adequate exposure for identification of the bone fragment with the MCL tendon, realigning the medial rim and canthopexy if required. The nasal dorsum reconstruction is planned at the end.

Fig. 58.7 Existing laceration used as an approach

Fig. 58.8 Glabella approach

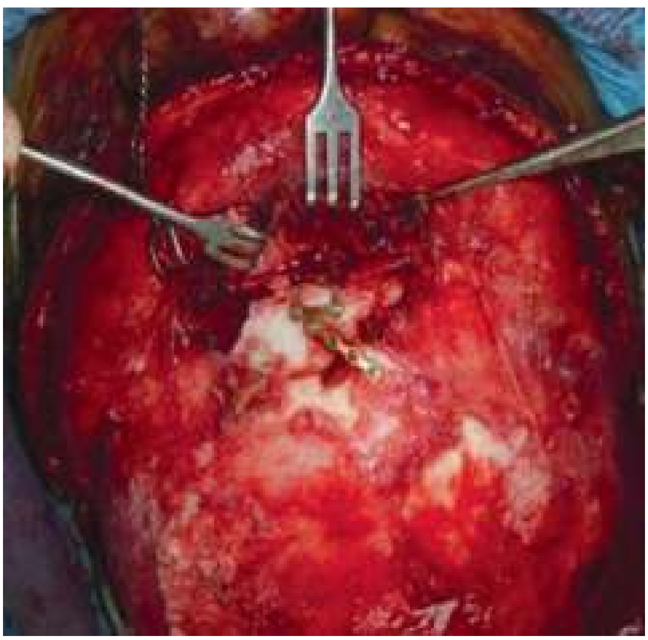

Fig. 58.9 Bicoronal approach

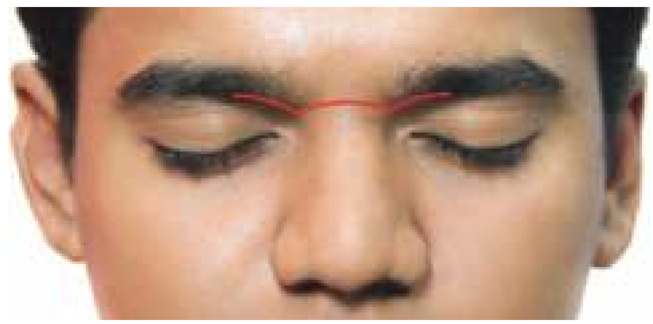

Fig. 58.10 Butterfly incision (combination of Gullwing and open sky incision)

According to them pre-treatment photographs are very important in getting good results, and deformity should be overtreated than undertreated because secondary deformity which occurs is difficult to treat.

Steps in Management

- Step1: Good exposure
- Step 2: Identify the medial canthal tendon/tendon-bearing bone
- Step 3: Reduce and reconstruct medial orbital rim
- Step 4: Reconstruction of medial orbital wall
- Step 5: Trans nasal canthopexy
- Step 6: Reduce septal fracture/displacement
- Step 7: Nasal dorsum reconstruction/augmentation with bone graft
- Step 8: Soft tissue readaptation (nasal splint, trans nasal bolsters, silicone sheeting)

Trans nasal wiring:

Closed reduction in established fractures with telecanthus rarely helps achieve adequate reduction and MCL repositioning and hence may need trans nasal wiring as well to help with MCL positioning [6, 13]. Using a K wire driver or an awl will help pass a trans nasal wire across the nasal complex and help narrow the area by bringing the sides together. To help achieve adequate narrowing and restore

Fig. 58.12 H shaped incision

the canthal distance, the entry area on the affected site should be just superior and posterior to the posterior lacrimal crest to which the posterior limb of the ligament is attached. The wire entry point anterior to the area can result in widening of the telecanthus as the posterior aspect flares laterally.

As long as a large fragment with MCL attachment is identifiable, open reduction and fixation of the fragment can help in achieving our objectives. Using very low profile titanium plates (1.1–1.3 mm depending on the system used) helps achieve adequate fixation. Rigid fixation needs exposure of a stable area to help achieve the same and may necessitate exposing the glabella or frontal bone superior to it for adequate results. Realignment of the fragments and fixation will help in achieving better results in cases of fracture having multiple fragments and reconstruction with bone graft wherever required (Fig. 58.13 a, b).

MCL disruption or a tiny bony fragment with MCL might necessitate a canthopexy.

58.5.2 Trans Nasal Canthopexy

The objectives of trans nasal canthopexy are:

- To medialize the central fragment
- To position the tendon posterior and superior to posterior lacrimal crest that would give an ideal vector.

The commonly used methods are the trans nasal wiring (Fig. 58.14) or using a canthal barb. The identified ligament edges are either anchored with a suture (size 2–0 prolene) or a wire (26 gauge) and guided to the opposite side. The entry point is posterior and superior to lacrimal crest to ensure adequate positioning. One way to help achieve this is to adapt a plate in medial aspect extending from lateral nose onto the medial wall extending just beyond the lacrimal crest (Fig. 58.15).

The wire or suture anchoring the MCL is passed through a hole of the plate just beyond the lacrimal crest brought to

Fig. 58.13 (**a**) Alignment and fixation of stable fragments. (**b**) Bone grafting of the dorsum of nose

the opposite side and secured around a screw in the forehead adjacent to the midline or a plate to prevent the wire cutting through the bone. Special barbed wires have been advocated by certain authors to engage the MCL and anchor it to help with medial canthopexy with small incisions around the medial canthus. These help especially when there is medial canthal disruption without bony disruption [18, 19].

Figure 58.16 shows a clinical case where the MCL has be anchored to the holes of the plate on either sides (arrows) with SS wires.

Paediatric injuries of the naso-maxillary complex are generally under treated, but they need similar management protocols like that of an adult to achieve optimal results [20]. The use of resorbable implants will be of prudence in the paediatric patients [3].

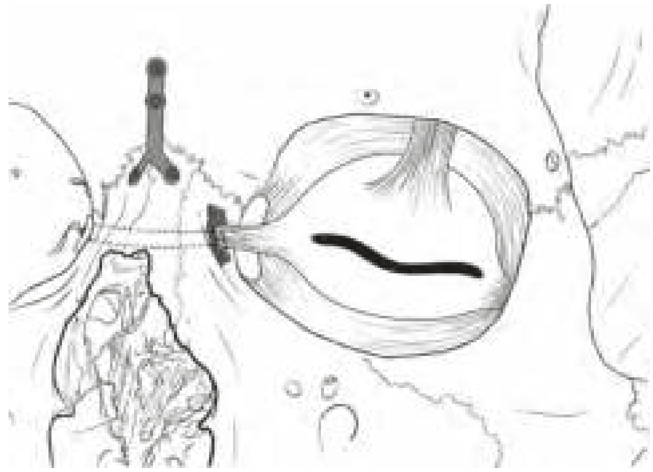

Fig. 58.14 Canthopexy with SS wire (note the wire shown as dotted lines)

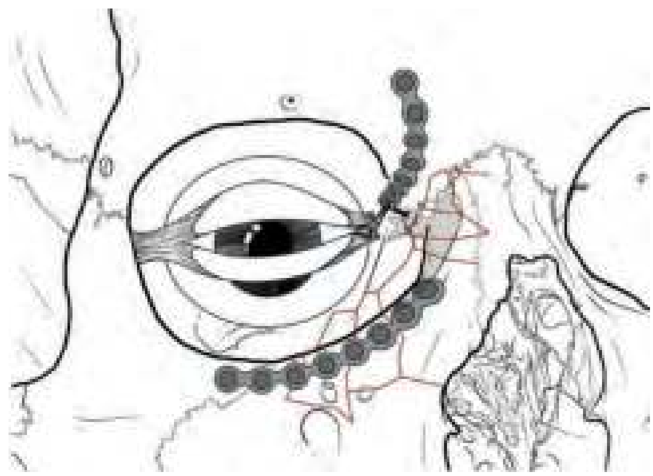

Fig. 58.15 Use of plate to guide MCL reattachment (note the MCL fixed to plate with a wire, the red lines denote the fractured bones)

Post-operative aesthetic assessments of outcomes done for the management options comparing the canthal position and nasofrontal angle measurements have indicated that bone grafting may result in obtunded nasofrontal angle as compared to ORIF. Closed reduction of the complex has resulted in under projection of the nasal bridge region [20].

58.5.3 Soft Tissue Readaptation

A post-operative nasal bolster splint is very important after ORIF or NOE fractures. It plays the following functions:

- It reduces post-operative swelling due to oedema and haematoma.

Fig. 58.16 shows a clinical case where the MCL has been anchored to the holes of the plate (blue arrow) on either sides with SS wires (yellow arrow)

Redrapes soft tissues to underlying skeletal framework and prevents *pseudo telecanthus* (increase in intercanthal distance, in spite of accurate reduction and fixation of facture fragments. This occurs due to non-adaptation of soft tissues to the underlying NOE complex, with resultant fibrosis of tissues). *Bolster splints may cause skin necrosis if used inappropriately*. After reduction and fixation of NOE, nasal packing has been done with ribbon gauge soaked in paraffin/flavine emulsion or bismuth iodoform paraffin paste (BIPP). Over packing should be avoided. Sometimes it obstructs the airway and a potential source of infection and required removal after 72 h postsurgery.

58.5.4 Post-operative Evaluation [20]

It includes evaluation of:

- Nasofrontal angle
- Nasal prominence and
- Intercanthal width

The average distance between the medial canthus should be approximately 1/3rd (33%) of the distance between lateral canthus. The distance from the lateral canthus of the eye to cornea and cornea to nasofrontal junction will be compared, and they should be in 1:1 relationship. The ideal naso-orbital angle is approximately 115–130°. All the three parameters

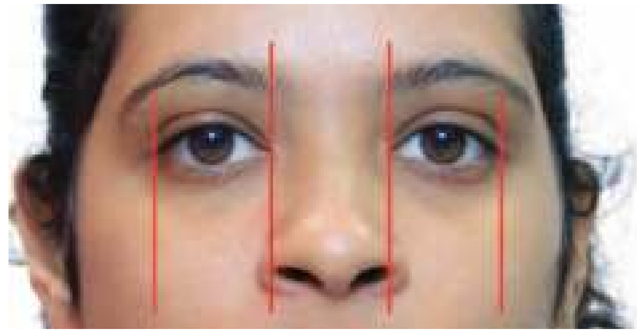

Fig. 58.17 Ideal intercanthal distance

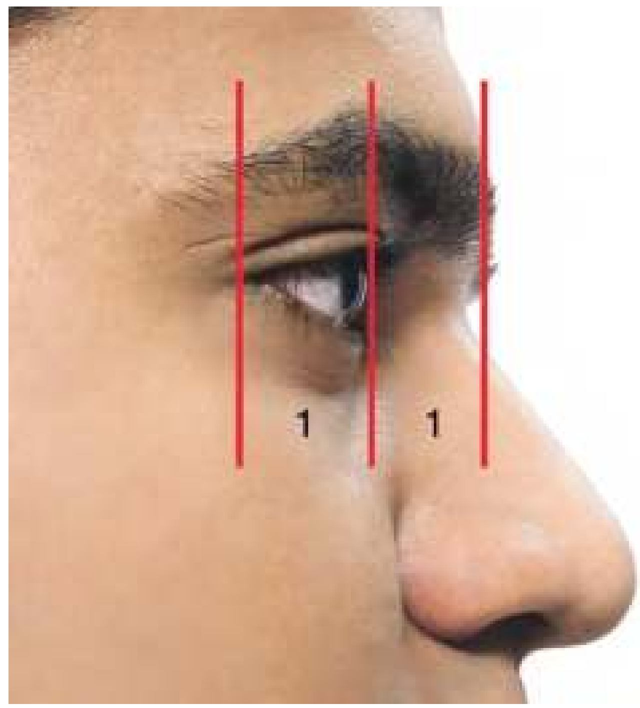

Fig. 58.18 Ideal nasal projection (1:1)

should be checked post-operatively to assess the surgical results (Figs. 58.17, 58.18, and 58.19).

58.6 Complications

Inadequate assessment and treatment planning may result in incomplete management of the NOE complex resulting in secondary deformity which can aesthetically inadequate. Deformities of the NOE are quite easily noticeable compared to those in other regions, and hence appropriate management helps achieve good results. The aesthetic issues like persistent telecanthus or depressed nasal bridge are difficult to correct secondarily with suboptimal results. Hence the first time is the best time to address the central nasal component [21,

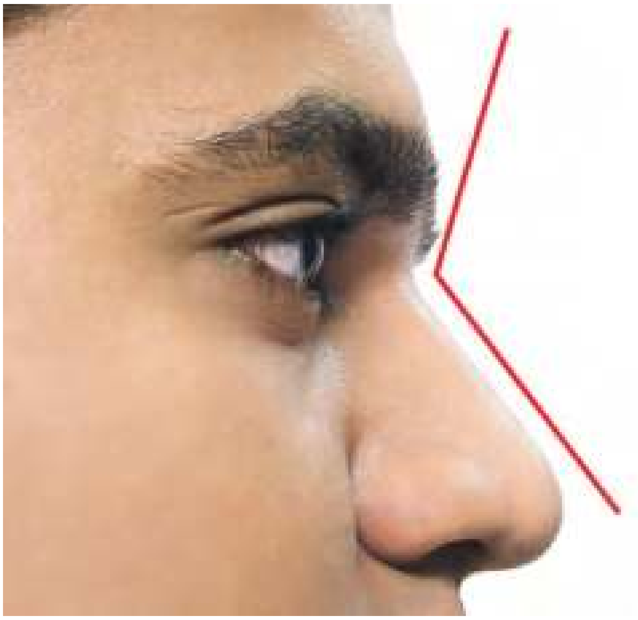

Fig. 58.19 Ideal frontonasal angle

22]. Apart from aesthetic complications, functional issues like epiphora due to nasolacrimal duct injury or obstruction may manifest which may need stenting [23] or dacryocysto-rhinostomy (creating a osteum in the lateral nasal wall adjacent to the lacrimal sac along with stenting) to establish patency. Involvement of the medial wall may result in diplopia [24] which if not addressed adequately may persist. Another important issue overlooked is anosmia, but if it should occur, recovery is unpredictable, and prior discussion with patients is better. In cases with concomitant brain injuries or CSF leak, risk of associated sequelae is present, and a multidisciplinary approach helps. Though improperly placed trans nasal wires may occlude/impede the lacrimal drainage apparatus, it remains a popular modality to help treat these fractures [25, 26].

58.7 Frontal Sinus Fracture

58.7.1 Introduction

Fractures of the frontal sinus are frequently associated with orbital, NOE, nasal and anterior cranial fossa injury. Frontal sinus is most frequently damaged as a result of high velocity motor vehicle accidents. 70% of frontal sinus fractures were due to automobile accidents and 20% due to assaults. Proximity of sinus to the brain makes untreated disease in this area potentially fatal. Inappropriate treatment of frontal sinus fracture can lead to mucocele formation, recurrent sinusitis, osteomyelitis of frontal bone, brain abscess or thrombosis of cavernous sinus, encephalitis, etc. [27].

58.7.2 Applied Anatomy of Frontal Sinus

Frontal sinuses are two asymmetric sinuses separated by a thin bony septal plate. The average dimensions of frontal sinus are as follows [28]:

- Height: 32 mm
- Width: 26 mm
- Depth: 17 mm
- Surface Area: 720 mm^2

The frontal sinus is an air-filled cavity lined by pseudostratified ciliated columnar epithelium encased in bone. It becomes visible radiographically at the age of 6 years. The posterior table is thinner than the anterior table. The posterior table separates the sinus from dura of frontal lobe. Anterior table is covered by a soft tissue layer of frontalis muscle, orbicularis oculi muscle, supraorbital and supratrochlear nerves, vessels and skin. Posteriorly, the floor of the frontal sinus consists of orbital plate of frontal bone. Anteriorly, the floor of the sinus overlies the anterior ethmoidal sinus and nasal cavity. The frontonasal drainage area of the sinus originates from the posteromedial part of sinus floor. The frontal sinus drains through the frontonasal ducts into the middle meatus of the nasal cavity or directly through the ostia into the nasal cavity.

58.7.3 Functions of Frontal Sinus

Following are the various functions of the frontal sinus:

1. Production and storage of mucus
2. Resonator for voice
3. Humidification and warming of inhaled air
4. Accessory area of olfaction
5. Conservation of heat from the nasal fossae
6. Definition of facial contours
7. "Surge Tank" to dampen the pressure differential that develops during inspiration

The diagnosis of the frontal sinus fracture based on the proper history and physical examination of the patient which includes inspection and palpation of the affected area.

The detailed history includes the following points:

1. Information about events
2. Visual difficulties
3. Numbness
4. Pain
5. Rhinorrhea
6. Sense of smell
7. Previous history of nasal or sinus disease surgery

58.7.4 Clinical Features [29]

1. Forehead laceration (58%)
2. Forehead pain (82%)
3. Swelling
4. Frontal bone depression (25%)
5. Periorbital ecchymosis
6. CSF rhinorrhea (1/3rd patients)

58.7.5 Radiographic Features

For an accurate diagnosis of frontal sinus fracture, a CT scan (Fig. 58.20a, b) in different views must be examined [30].

1. Axial view: It reveals location, severity and degree of comminution of anterior and posterior table fractures.

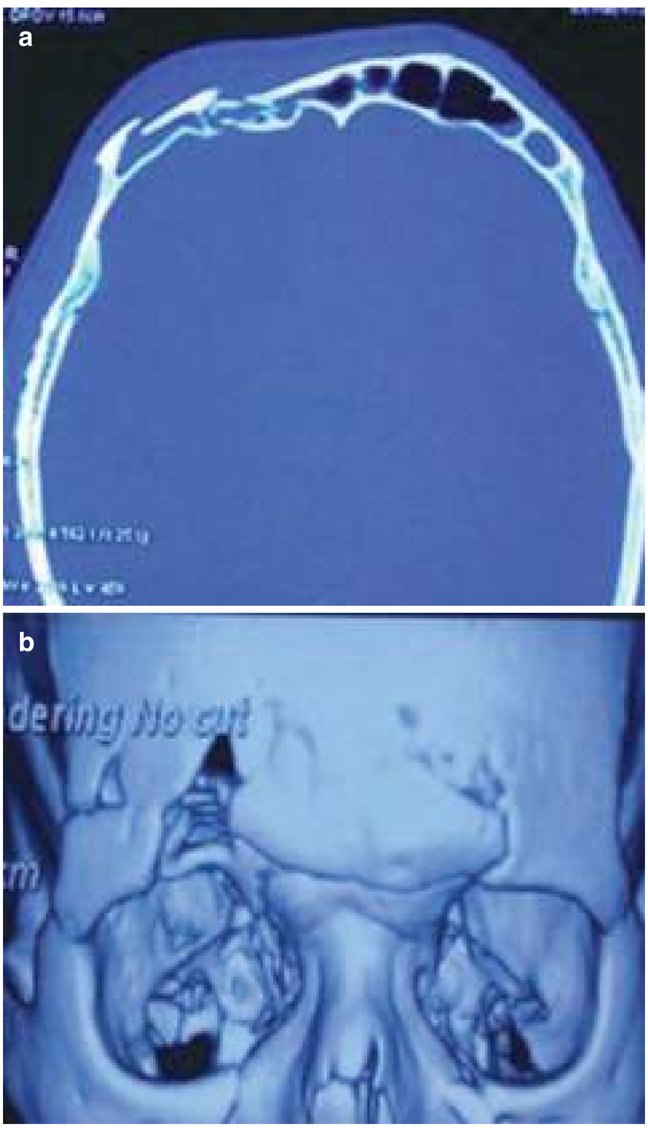

Fig. 58.20 (**a**, **b**) 3D CT and axial CT image with frontal sinus fracture

2. Coronal view: It reveals frontal sinus floor and orbital roof fractures.
3. Sagittal view: It assesses frontonasal duct.
4. Submentovertex view and lateral view: It visualizes anterior and posterior tables.

58.7.6 Classifications

Frontal sinus fractures are usually classified based on:

- Location
- Extent of injury
- Involvement of frontonasal duct
- Current injury to the dura

58.7.7 Stanley's Classification of Frontal Sinus Fracture [31]

- *Type I: Anterior Table Fracture*
  - Isolated to anterior table
  - Accompanied by supraorbital rim fracture
  - Accompanied by naso-ethmoid complex fracture
- *Type II: Anterior and Posterior Table Fractures*
  - It is a linear fracture either on transverse direction or in vertical direction
- *Type III: Comminuted Fractures*
  - Isolated to both tables
  - Accompanied by naso-ethmoid complex fracture

58.7.8 Gonty Et al. Classification of Frontal Sinus Fracture [32]

- *Type I: Anterior Table Fracture*
  - Isolated to anterior table
  - Accompanied by supraorbital rim fracture
  - Accompanied by naso-ethmoid complex fracture
- *Type II: Anterior and Posterior Table Fractures*
  - A linear fracture either on transverse direction or in vertical direction
  - Comminuted fracture either isolated to both tables or accompanied by naso-ethmoid complex fracture
- *Type III: Posterior Table Fracture*
- *Type IV: Through and Through Frontal Sinus Fracture*

58.7.9 Management (Box 58.6) [33]

Surgical Access:

1. Through existing laceration
2. Butterfly incision (Fig. 58.10)
3. Gullwing or eyeglass incision (Fig. 58.21)

Box 58.6 Guiding Principles for Frontal Sinus Management

- To separate nasal cavity from sinus
- To eliminate dead space
- To separate the frontonasal duct from frontal sinus by obstructing the duct
- To eliminate a functional sinus, sinus mucosa is removed, and sinus is obliterated

4. Bicoronal approach (Fig. 58.9): Khan et al. in 2018 [34] suggests sterile surgical glove tourniquet intraoperatively to get the haemorrhage control and blood less surgical field in elevation of bicoronal flap for the surgical management of frontal sinus fracture.

58.7.10 Indications of Surgery in Frontal Sinus Fractures [35]

1. To avoid immediate complications such as CSF leak, meningitis
2. To avoid long-term complications such as frontal sinusitis, meningitis and brain abscess formation
3. To provide aesthetic contour to the forehead
4. To provide exposure for anatomic reduction of NOE fractures

58.7.11 Management of Anterior Table Fracture [36–38]

Decision-Making:

- Simple greenstick or undisplaced fracture does not require surgical intervention.
- In depressed anterior wall fracture, frontal sinus explored, careful irrigation carried out, fragments reduced and stabilize by internal fixation. In posterior wall fracture without CSF leak or pneumoencephalus, reconstruction of only anterior wall is done.

Other than surgical intervention, antibiotics, sinus decongestants and analgesics are prescribed to keep the frontonasal duct patent and to prevent infection.

Rai et al. [39] suggested bone mapping/sketching in management of anterior table frontal sinus fracture with great success. To get good post-operative contour, each fracture fragment is to be placed at the original position after debridement of the sinus. For the same purpose, numbers have to be given to the fracture fragments on a plane paper (sterile glove covering paper) or green sheet (Fig. 58.22a–c).

Yoo MH et al. suggested endoscopic trans nasal reduction of anterior table fracture [40]. To support the reduced fragments, they advocated use of custom made latex glove balloon to be inserted into the frontal sinus then expanded and maintained for 3 weeks. It avoid use of coronal incision is the advantage of endoscopic reduction. It should be avoided in severe comminuted fractures, displaced posterior table fracture with evidence of dura tear, associated orbital roof blow in fracture and extensive skull bone fractures.

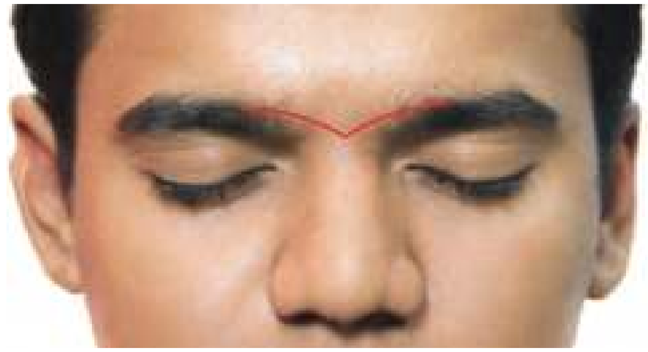

Fig. 58.21 Gullwing or eyeglass incision

58.7.12 Treatment of Posterior Table Fracture [41]

Patients with displaced and comminuted posterior wall combined with or without anterior wall require the support of a neurosurgeon because of dural and intracranial lesions. To get the good exposure, bifrontal craniotomy is indicated to eliminate the posterior wall.

To widen the neurosurgical access to the anterior floor of the cranium, the supraorbital bandeau will be temporarily removed. The sinus mucosa carefully removed with bur, and sinus is cranialized, and then repair of the dura will be carried out: Calvarial bone graft used to obliterate the nasofrontal duct and bone powder can be used to cover the remaining dead space. Anterior table can be stabilized with bone plates and screws. Bone defect will be treated with calvarial bone graft or titanium mesh. With patent duct and no concurrent dural tears or brain injury exist, any amount of posterior table displacement is inconsequential and managed by observation.

58.7.13 Methods of Treatment of Damaged Frontonasal Duct [42]

The damage to the nasofrontal duct and frontal sinus obstruction increases the risk of mucocele formation and inflammatory complications post-operatively. Obliteration of the duct is indicated in such situation. The muscle, temporalis fascia, bone chips, etc. are the materials used commonly to obstruct the duct.

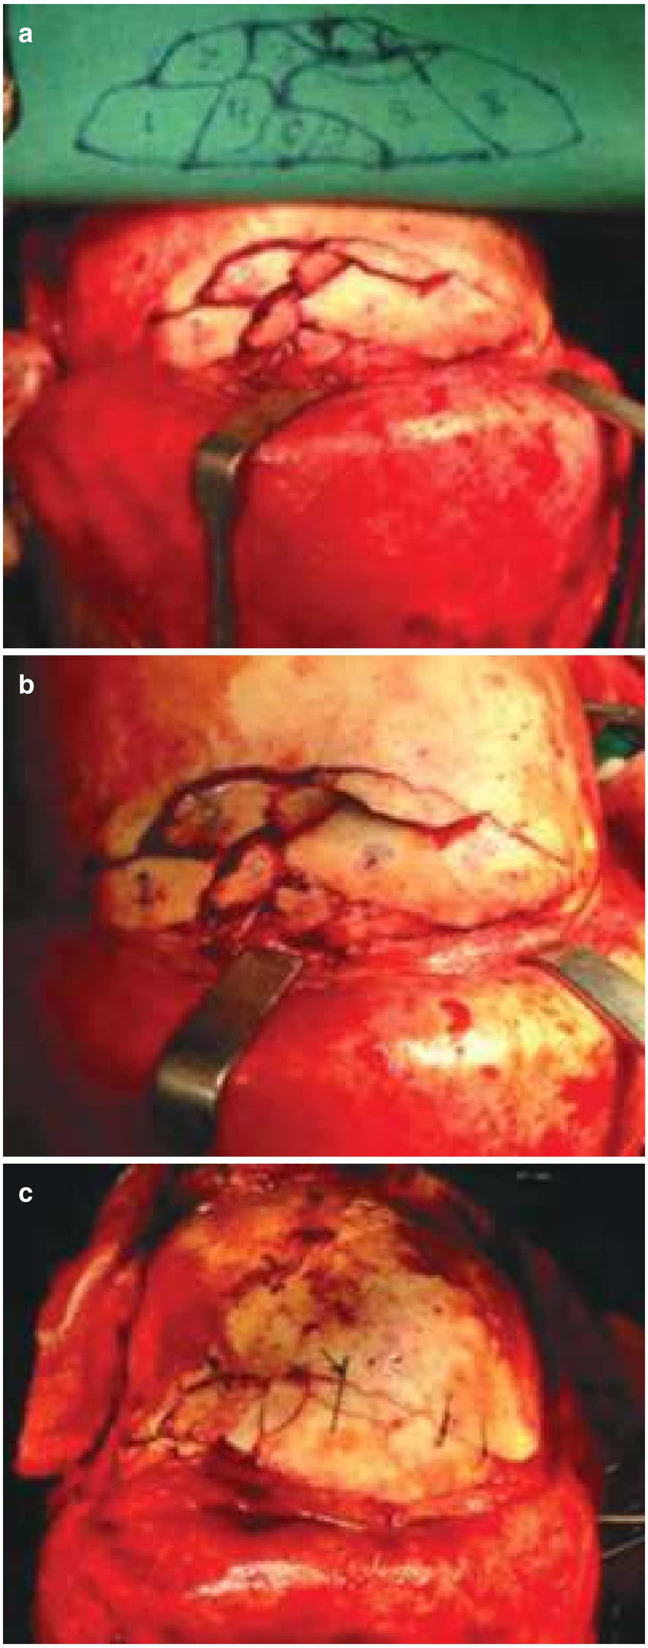

Fig. 58.22 (**a**–**c**) Bone mapping/sketching in management of anterior table frontal sinus fracture

Box 58.7 Complications of Frontal Sinus Fractures [46]

Immediate complications	Late complications
1. Wound infection 2. CSF leak 3. Paresthesia of supraorbital nerve 4. Frontal sinusitis 5. Meningitis 6. Neurological injuries secondary to penetrating trauma or displacement of frontal bone into neurocranium	1. Mucocele 2. Mucopyocele 3. Late frontal sinusitis 4. Brain abscess 5. Osteomyelitis of frontal bone

58.7.13.1 Material Used for Sinus Obliteration [43]

1. Hydroxyapatite
2. Glass wool
3. Bone
4. Cartilage
5. Muscle
6. Absorbable gelatin sponge
7. Temporalis fascia
8. Oxidized segmented cellulose
9. Acrylic or methyl methacrylate
10. Fat (commonly used)

58.7.14 Cranialization [44, 45]

It is another technique to minimize the dead space in sinus. It involves removing posterior table thus permitting brain to expand into frontal sinus resulting in confluence between sinus cavity and anterior cranial fossa. It is done in cases with CSF leak and neurological injury due to displaced posterior table fracture. To isolate the splanchnocranium from the frontal sinus, a pericranial flap is used.

58.7.15 Key Points

- Actual or suspected fractures involving the frontonasal duct are an indication to remove the outer table, so the duct can be inspected.
- If outer table is comminuted and a bony segment over 1.5 cm in missing, a bone graft should be harvested to restore the outer table contour.
- The most common treatment for outer table fracture with injury to duct without inner table fracture is obliteration of frontal sinus to seal the frontonasal duct to prevent nasal infection.
- Adipose tissue from abdomen is used to fill the dead space of frontal sinus because of its resistance to infec-

tion, slow resorption rate, and it is gradually replaced by the fibrous tissue.

Complications of frontal sinus fractures is given in Box 58.7.

58.8 Conclusion

The management of NOE and frontal sinus fracture is always a challenging task .The proper handling of MCL and naso-frontal duct is mandatory to get good post-operative results. Proper treatment planning in the form of incision selection, method of fixation and use of bone graft should be done to avoid unaesthetic results.

59 Gunshot Injuries of the Maxillofacial Region

Lt Col Rohit Sharma and Maj Anson Jose

59.1 Introduction

Gunshot injuries to the maxillofacial region in particular present a challenging situation for the facial reconstructive surgeon. These injuries are relatively rare and hence the true incidence is unknown [1]. Feature common to most maxillofacial gunshot injuries is extensive tissue destruction. The degree of tissue loss, depth of the injury, associated necrosis, and concomitant central nervous system (CNS) injuries may not be apparent at initial presentation [2]. Comprehensive management of such wounds is often challenging because of its heterogeneous nature, composite 3D tissue destruction, and complex structural and functional anatomy of the face.

In contrast to blunt facial trauma, the literature on the management of ballistic facial injury is relatively scarce [1]. The management strategies for patients with facial gunshot wounds are almost as diverse as the case presentation itself. While there has been a gradual shift from conservative delayed operative repair to an early aggressive one-stage management approach, the controversies surrounding the timing and extent of intervention have not yet ceased to exist. Such an ongoing debate is largely due to the fact that the majority of treatment outcomes of gunshot facial injuries continue to be unsatisfactory regardless of treatment methodology adopted. On the other hand, new principles have evolved including the early definitive repair of hard tissues with precise anatomic rigid fixation using bone grafts and definitive soft tissue management with local or vascular flaps allowing for early rehabilitation of patients to their pre-traumatic appearance. This paradigm shift away from delayed to a more immediate definitive reconstruction has been predominantly due to the widespread use of free tissue transfer, diagnostic computed tomography (CT) scan, and deeper understanding about zone of injury in such cases [3].

Presently the management of gunshot injuries comprises the following steps:

1. Conservative debridement followed by fracture stabilization and primary closure
2. Early reconstruction of missing hard and soft tissues
3. Antibiotics and prevention of infection
4. Postoperative physiotherapy and psychiatric assistance
5. Residual deformity correction and oral rehabilitation [3–6]

This review describes the current management strategies, damage control surgery, and basic protocols employed in the management of high-velocity ballistic injuries to the face.

59.2 Pathologic Anatomy and Classification

Traditionally gunshot injuries have been classified as penetrating, perforated, or avulsive [7]. As the gamut of injuries continues to evolve, the severity and magnitude of facial ballistic wounds demand an expanded classification and can be appropriately classified based on the wounding effects and terminal location of projectile as:

- Penetrating
- Perforating
- Avulsive
- Blast
- “Chop off” injuries

Lt Col R. Sharma (✉)
Department of Oral and Maxillofacial Surgery, 11 Corps Dental Unit, Jalandhar Cantt, India

Maj A. Jose
Department of Oral and Maxillofacial Surgery, ADC R&R, New Delhi, India

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_59

Penetrating injuries are caused when a low-velocity projectile pierces the tissues without making an exit wound (Fig. 59.1).

On the other hand, perforating injuries are distinguished by the presence of a definite exit wound in addition to the entry wound (Figs. 59.2 and 59.3). The exit wounds are often larger with ragged or stellate margins. Avulsive injuries are basically penetrating injuries, characterized by an acute loss and destruction of tissue as a consequence of the passage of the projectile within and out of the body (Fig. 59.4). Blast

Fig. 59.1 Penetrating injury with bullet lodged inside the neck

Fig. 59.2 Perforating injury caused by 7.62 × 39 mm AK-47 rifle. Note the effects of high-energy bullet impact and explosive effects of cavitation on soft tissues resulting in stellate wound margins at the exit

Fig. 59.3 Avulsive injury of midface caused by a short-range high-velocity impact. The hallmark of high-velocity injuries are comminuted fractures of the facial skeleton with avulsion of soft tissues

Fig. 59.4 “Chop off” injury with complete avulsion of the mandible and associated soft tissue caused by velocity projectile from a military assault rifle

injuries are the result of direct or indirect exposure to an explosion caused by military weapons or explosive devises (Fig. 59.5). "Chop off" injuries represent wounds with extensive hard and soft tissue loss as a consequence of high-velocity close-range gunshots [8]. In all these varieties of injuries, the tissue damage is directly proportional to the kinetic energy transferred by the bullet, time taken for the energy transfer, and area over which the energy is transferred. Hence, the type and variant of injury have significant implications in management.

Apart from this conventional nomenclature, various other classifications have been used for categorizing penetrating

Fig. 59.5 (**a**, **b**, **c**) Blast injury caused by propagation of shock waves from the projectile. Soft tissue injury is minimal in such cases with severe comminution of the underlying skeleton

facial injuries; however, its application in clinical scenario is debatable. Similarly, many authors have developed an algorithm for the workup of ballistic wound based on the location of entry wound. Despite having limited application, no significant correlation has been found between site of entrance wound and therapeutic outcome of gunshot wounds [9].

A pragmatic approach to the management of such injuries involves:

1. Establishing an airway
2. Control of hemorrhage
3. Damage control surgery and identifying concomitant injuries
4. Early definitive repair of hard and soft tissues
5. Aesthetic refinements and rehabilitation

59.3 Initial Evaluation, Triage, and Damage Control Surgery

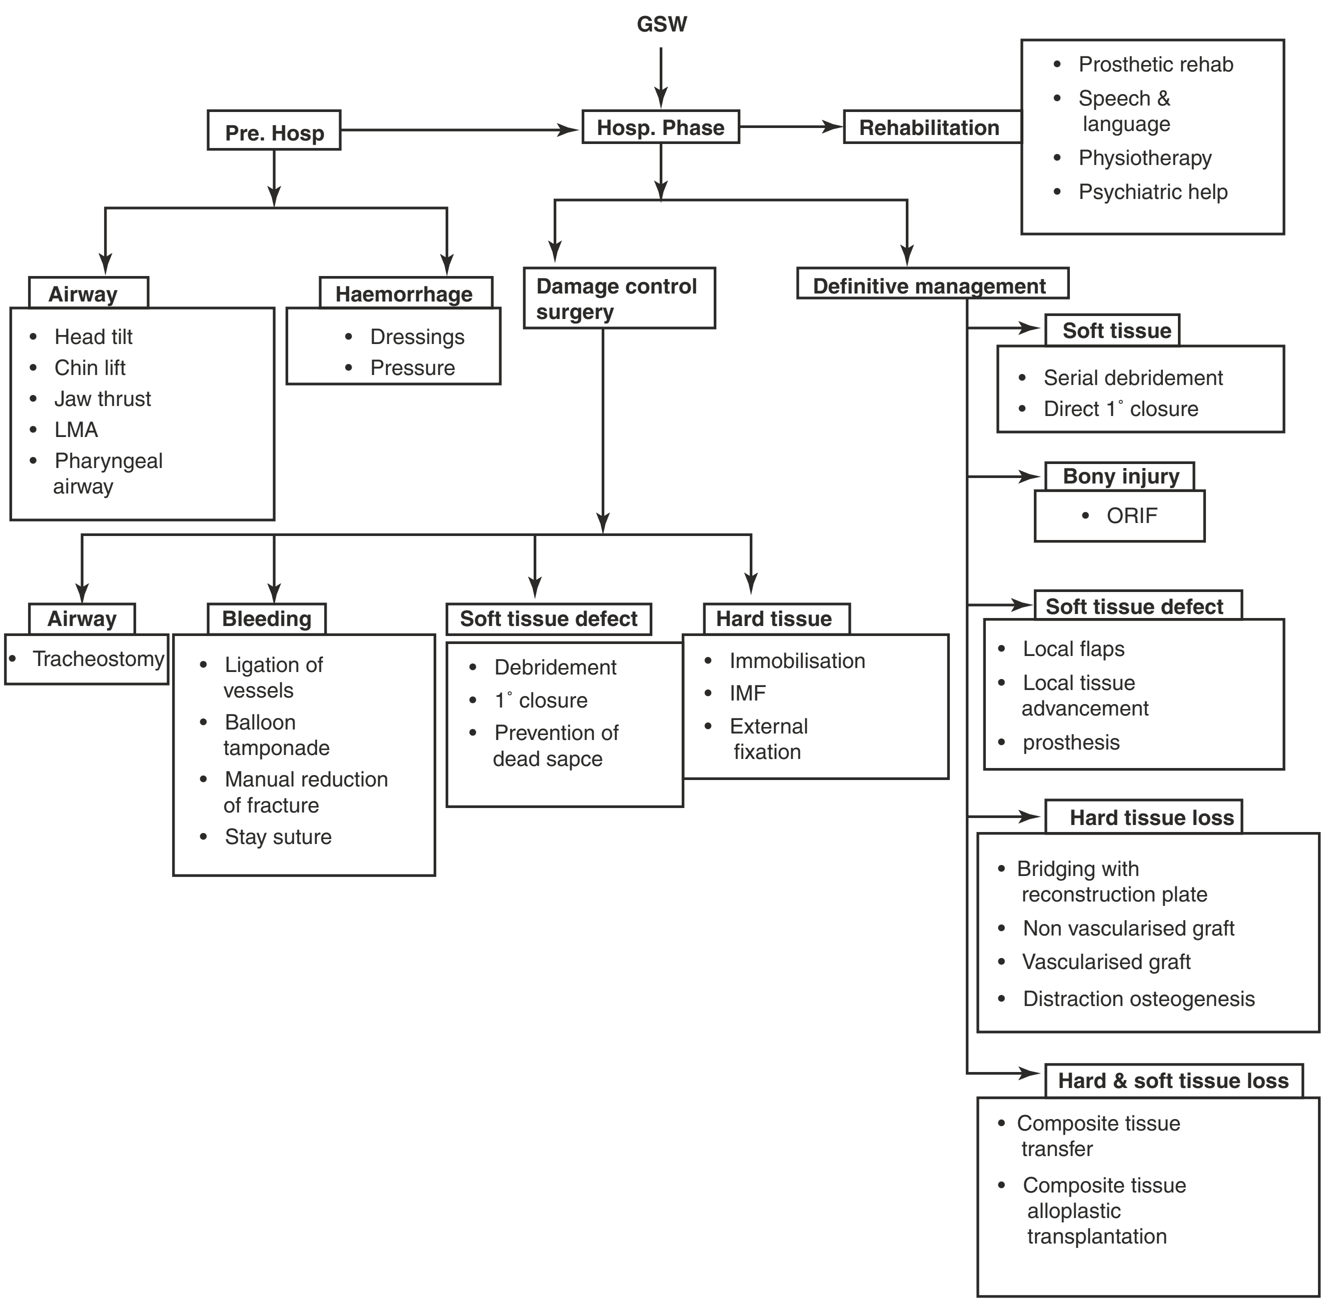
Initial management of gunshot wounds is based on the advanced trauma and life support protocols (also refer Chap. 48 of this book). Gibbons and Breeze [10] have elaborated the modified military protocols pertaining specifically to combat-related ballistic facial injuries. These include emergency management procedures that followed the CABC (catastrophic hemorrhage, airway, breathing, circulation) protocol proposed by Hodgetts et al. [11] which focused the need to control catastrophic bleeding as a priority over airway complications in a polytrauma patient. In a parallel manner, initial evaluation and damage control maxillofacial surgery should commence within the golden hour for effective patient management. Damage control surgery may be perceived as an immediate assessment of life-threatening injuries and addressing them promptly by means of early life-saving resuscitation and surgeries [12]. It is not regarded as a separate entity; it is seen as an essential, initial component in the management of any severely injured patient. In order to clear confusion clouding this highly debated area, a proposed set of damage control procedures that can be applied to ballistic maxillofacial injuries involving the maxillofacial region is given (Table 59.1).

Fortunately, the mortality rate directly attributable to maxillofacial firearms injuries is as low as 2–3% and predominantly due to a compromised airway [10]. Airway compromise is a serious consequence of all gunshot injuries to the face, and it can be due to a direct or an indirect injury to the airway. Injury to tissues and resultant edema in the vicinity of the air passages invariably handicaps the airway indirectly. Additionally, loss of muscle attachments and fractures of the anterior mandible significantly debilitates the airways. Manual repositioning of the fractured segments of mandible and base of tongue are the fundamental measures to be executed to prevent posterior airway collapse. While nasopharyngeal and oropharyngeal airways afford interim relief, endotracheal intubation is the established approach in emergency condition. This however presents a challenge on account of the edema, bleeding, and avulsed soft tissues that may possibly block the airway [13].

In the author's experience, a vast majority of maxillofacial gunshot wounds require surgical tracheostomy. The probability of concomitant intracranial injuries with low Glasgow Coma Scale (GCS) is also high in such patients [14]. Since most patients in this category require prolonged intubation and most gunshot wounds to the face require multi-phased surgical approach, the authors view surgical tracheostomy as having distinct advantage over other methods. Management of hemorrhage and its allied complications are well known in maxillofacial injuries as emphasized by previous writers on war surgery, yet it needs a descriptive analysis owing to the fatality it can cause. Hemorrhage is an inevitable consequence of all gunshot injuries to the face. Management of bleeding is an important aspect of damage control surgery, and adequate hemodynamic resuscitation is essential for the early physiological recovery of the victim [15].

Bleeding from high-energy ballistic injuries is practically impossible to control by external pressure tamponade due to the presence of bony structures and the inherently vulnerable condition of fragile anatomic structures like the eyes, brain, and airway seen in such injuries. In open injury scenario, hemorrhage can be easily managed by meticulous examination to recognize all the bleeding vessels followed by their ligation. Closed injuries necessitate balloon tamponade with Foley catheter (Fig. 59.5) to control bleeding. If bleeding is not controlled by the usual techniques, external carotid ligation or selective embolization method is used, which is by far the most predictable method to control bleeding from external carotid artery and its tributaries [13, 16].

Table 59.1 Algorithm in the treatment of Gun Shot Wounds (GSW)



59.4 Diagnostic Imaging

Once airway is secured and bleeding is controlled, attention should be directed toward radiological assessment of the injury. Depending on the severity of injury a plain X-ray, CT scan and CT angiography can be requested [15]. The extent of injury, degree of hard tissue fragmentation, location of metallic splinters, damage to C-spine, and any occult brain injuries can be easily delineated with the help of a CT scan. Similarly, involvement of great vessels, any concealed bleeding, and flow dynamics of vessels suitable for microvascular reconstruction can be studied using CT angiogram. Apart from the damage characteristics of the wound, another crucial factor which needs to be assessed during radiological examination is the status of C-spine.

Any injury of such magnitude enough to fracture the facial skeleton can invariably cause an occult C-spine injury. The incidence of C-spine injuries varies from 8 to 11% in all maxillofacial traumas [17]. Hence, potential cervical spine injury should be always considered unless proven otherwise clinically or radiologically. It is pertinent to immobilize the cervical spine to prevent further damage especially in unconscious patient (Fig. 59.6). However, substantial evidence is still lacking about the safety and efficacy of cervical collars

Fig. 59.6 (**a**–**e**) Low-velocity close-range handgun injury—3D CT showing comminution of maxilla and NOE complex. The case was treated by ORIF mandible, maxilla, frontal bone, and cathopexy using iv cannula and wire. Three years post-surgery—adequate restoration of width and projection of midface

used in such injuries. Moreover, placement of rigid collars interferes during airway management, central line placement, and definitive repair of facial injuries [13].

59.5 Definitive Management of Facial Gunshot Wounds

The prime goal in the management of facial gunshot wounds is to rehabilitate the patient to pre-injury function and aesthetics. However, it is not always easy to get a flawless postoperative outcome with one particular treatment modality or a particular surgical technique. Hence, the treatment should be timed and tailored depending upon the type and severity of the injury, amount of tissue loss, general health status of the patient, surgeon's expertise, and availability of resources. Before initiating any treatment procedures, a thorough assessment of the wound by a multidisciplinary team is imperative as gunshot injury cases are seldom comparable. A comprehensive evaluation and discussion by a diverse panel gives the surgeon valuable perspectives which in turn has a positive impact on the final outcome.

59.6 Debridement

Modern high-velocity firearms transfer heavy cavitation energy inside tissues causing physiological and morphological alterations resulting in hemorrhage, thrombosis, and necrosis [18]. The tissue response toward the high-velocity projectile varies with the type of tissues and elastic deformation it can sustain. The dermis is viscoelastic, and injuries will result in abrasion, traumatic tattooing, and contusion particularly in close-range shots. Muscle tissues can withstand elastic deformation up to four times the size of the projectile, but at a cellular level, it may undergo significant necrosis, devitalization, and denaturation rendering the microenvironment favorable for bacterial multiplication [19]. The injuries to neurovascular bundles behave similar to muscles, thereby causing tearing, shearing, and rupture of blood vessels. At microscopic level, all the three layers of blood vessels get affected resulting in the formation of thrombus, inflammation, and persistent spasm [20]. Cortical bone on the other hand is crystalline in consistency; therefore, penetrating injury causes fragmentation of bone with formation of multiple secondary projectiles. Conventional management of firearm injuries involves initial wound debridement, wound toilet, adequate soft tissue closure, and administration of antibiotics followed by delayed repair of deformities [4]. However, with the advent of vascular flaps and new reconstruction methods, there has been a colossal shift in the management of such injuries to a more definitive early single-stage repair [21].

The management commences with meticulous debridement of wounds to the point of active surgical bleeding. This strategy is particularly important in case of crushed and contaminated wounds wherein the active surgical bleeding encourages the formation of a healthy granulation tissue [18]. Furthermore, it also improves adequate microcirculation at wound margins, thereby promoting rapid healing and tissue resistance to infection. A serial debridement with judicious excision of the necrotic and non-contractile muscle tissues is done to achieve a wound with non-contaminated healthy margins [22].

After generous tissue excision, debridement should be assisted with soft scrubbing brushes and copious irrigation. Removal of deeply embedded splinters or metallic foreign bodies is controversial regarding any particular clinical benefits it offers [10]. The wound debridement should be prompt, and any delay (6–12 h) further complicates the wound management by progressive tissue necrosis. The development of progressive necrosis is a salient feature of gunshot wounds, and contrary to the popular belief, the tissue necrosis is not directly related to energy transfer but rather to the depth of tissues destroyed by the movement of the projectile. Animal studies have shown that beyond that critical time period, identification of necrotic margins will be difficult and hence it complicates the debridement and surgical control of the wound [23].

There are two main areas of conflicts pertaining to debridement in gunshot wounds. Many authors recommend immediate careful conservative soft tissue excision followed by secondary debridement of all tissues with questionable viability at a later stage [24, 25]. These researchers are of the view that it is practically impossible to distinguish between vital and non-vital tissues at initial intervention. On the contrary, a few other professionals believe in single-stage radical debridement on initial intervention [26].

Experimental evidences have shown that the extent of tissue necrosis after gunshot injury is 2 mm and 8 mm from the wound margins in skin and muscle tissues, respectively. In bony skeleton, it may extend up to 5 mm from the fracture line [27]. Thus, there is no convincing evidence to preserve fragmented bone of 1 cm or less during debridement even if it is attached to soft tissues. Similarly, a serial debridement of such wound is often required to deal with the evolving pattern of tissue necrosis over a period of 24–36 h. This allows for early identification of the demarcation zone between vital and non-vital tissues before reconstructive procedures are planned. The consensus of radical wound debridement at initial intervention aims to remove foreign bodies, necrotic tissues, and microbial contamination as early as possible. It also minimizes inflammation, prevents infections, and helps in achieving favorable wound healing. Any late wound management in our opinion eventually increases the chances of infection, operating time, toxemia, and subsequent surgical intervention.

Concomitant injuries to salivary gland ducts and facial nerve are often encountered during initial debridement. The ducts and facial nerve are usually tagged with Prolene sutures for future repair. Most of the ductal injuries can be managed by cannulation and primary repair or by rerouting it into oral cavity. Non-salvageable glands should be removed without hesitation to prevent sialocele, salivary fistula, and complicated wound healing. Damage to facial nerve is mainly by thermal, avulsion, and stretch injury caused by the cavitation. Preferably the nerve should be repaired within 72 h for predictable results. Lacerated nerve is repaired primarily by coaptation or using nerve grafts harvested from greater auricular nerve. The nerve damage caused by cavitation may extend as far as 1.8 cm from the bullet track, and that should be considered during nerve grafting procedure [19]. Any facial nerve injury anterior to a line connecting mental foramen and lateral canthus is generally not repaired as spontaneous recovery is very likely in such cases.

59.7 Infection and Role of Antibiotics

Ballistic facial injuries are often compound and contaminated with high propensity for infection (class IV wounds). Contrary to the popular belief, all ballistic injuries are inherently contaminated, and the infection is primarily by the inoculation of microorganisms carried by the bullet and secondarily as a result of wound contamination in transit or in hospital environment. The actual incidence of infection rates remains elusive and ranges from 7 to 100% of all military facial injuries [28]. However, a general consensus is lacking in the timing, choice, and duration of antimicrobial therapy in combat injuries. Nonetheless the usage of broad-spectrum antibiotics for 10–14 days which provides cover against staphylococci, *Clostridium perfringens*, and *Acinetobacter baumannii* is commonly used [14, 29]. The critical level of bacteria required for initiating an infection reaches peak at 6 h of injury (10^5 bacteria/gm. of tissue), and studies have shown that early administration of antibiotics is paramount and any delay of greater than 6 h renders the treatment ineffective [30]. The accepted guidelines for combat-related injuries recommend administration of short-course, broad-spectrum antibiotics preferably within 3 h of injury [31]. The use of antibiotics is an adjunct to scrupulous debridement for the prevention of infection and should always be considered in the initial management of ballistic injuries.

59.8 Soft Tissue Reconstruction

Gunshot wounds result in composite 3D defects with involvement of the skin, musculature, facial skeleton, and mucosa. The various reconstruction methods for wounds of these natures are prosthetic obturation, non-vascularized grafts with local tissue advancement, loco-regional flaps, and free flaps for large composite defects (Also refer Chaps. 86 and 88 of this book). Before initiating the reconstructive procedure, it should be kept in mind that the management of such wounds is often complicated by the ambiguity in prognosis caused by tissue loss, progressive necrosis, and infection. Therefore most critical facet while handling avulsive wounds lays in achieving and maintaining a favorable intraoral wound closure to minimize the chances of wound infection and wound dehiscence due to oral contamination [32]. It is always crucial to close the wound primarily because of the high propensity toward scarring and functional debility of wounds that heal secondarily. Most gunshot wounds can be closed primarily, and delayed wound closure in maxillofacial region is rarely necessary. However, two exceptions to this are (1) wounds which are not possible to debride completely at initial operation and (2) wounds with questionable vitality of tissues.

Sequencing of primary reconstruction of oro-facial region should follow an inside-out principle [33]. The injuries of the oropharynx are first addressed by repairing the musculature and mucosa. This is followed by repair of oral mucosa, floor of the mouth, and the tongue. The reconstruction of lips, cheeks, and other extra-oral tissues is performed later after oral cavity has been reconstructed. Nonetheless if an acceptable intraoral closure is difficult to achieve, a maxillomandibular fixation is done, and it is prudent to leave the wound to heal secondarily. While selecting a reconstructive option, it is important to consider a treatment plan which reduces the treatment time, patient morbidity, number of surgical intervention, and hospital stay [34]. The best possible function and aesthetics are achieved when debridement and reconstruction of hard and soft tissues are done at an early stage and the residual soft tissue deformities are addressed at a later stage with revision surgeries and local flaps [2]. Extra-oral wounds that cannot be closed primarily due to excessive tissue loss are best managed by employing local, regional pedicled flaps and microvascular flaps.

Use of local flaps and regional flaps at the initial operation appears to be most favorable as far as aesthetics and function are concerned (Fig. 59.6a). Motamedi [2] advised early use of local flaps in patients with gunshot wounds of the face. He reviewed 30 GSW patients and reported excellent cosmetic and functional outcomes. However, the disadvantages of local flaps are that composite defects cannot be addressed and its availability, limited bulk, and pedicle length. Local tissue rearrangements and local flaps with nonvascular grafts like iliac crest, rib, or cranium can be used for small defects. But large 3D defects and poorly vascularized surrounding tissues caused by cavitation often preclude the use of bone grafts with local tissue rearrangements unlike in tumor reconstruction.

Major avulsive and chop off injuries demand vascularized bone grafts with skin paddle for their reconstruction. Composite free tissue transfer is predictable, provides adequate bulk of well-vascularized tissue to fill the dead space, rehabilitates the buttresses, and reinstates the soft tissue envelope in a limited period of time [15]. The variables affecting the selection of flap depend on the type and amount of tissue loss, location, length of pedicle, donor site injury, and, certainly, surgeon's preference. The most commonly used flaps for facial reconstruction are anterolateral thigh flap, radial forearm, and fibula with skin paddle [5]. It is obligatory to reconstruct both bone and soft tissues in composite defects, and without osseous support, soft tissue-only reconstruction tends to droop over time. After primary healing, the flap is contoured, subsequently unaesthetic skin paddle is excised, and local tissue can be re-advanced for better aesthetic outcomes. Similarly, if adequate vascularized tissue is not used for reconstruction, complications like scar contracture, bone graft resorption, fistula formation, and ultimately collapse of facial envelope will result.

It is clear that reconstruction of avulsive facial defects with free flap should be addressed as early as possible to prevent soft tissue contracture. Nonetheless, how much grace period is required before initiating a free flap reconstruction for optimizing the reconstructive outcomes is still not clear. High-energy cavitation in soft tissue may temporarily damage the local vasculature and hemodynamics at a distance from the margin of permanent wound. While planning a treatment based on microvascular reconstruction, it is imperative to have a conception of the zone of injury in its actual extent. Animal studies have shown that it is safe to place an anastomosis 3 cm away from the margin of wound track [35]. Furthermore, experimental evidences have shown superior results in integrity and patency of facial vessels anastomosed 3 days after injury than those repaired immediately after the injury [20]. If it is so, a composite free tissue transfer as a part of immediate reconstruction in avulsive ballistic injuries should be delayed till 3–4 days. This time period helps in adequate assessment of the extent of devitalized tissues, formulating a treatment plan based on available resources and optimizing the results by executing the treatment before the onset of soft tissue fibrosis and when the blood vessels are devoid of spasm.

Despite several arguments favoring immediate reconstruction for excellent aesthetic outcomes, it is to be noted that scar contracture is inevitable irrespective of the timing of treatment and reconstruction method adopted, although the frequency is more with delayed treatment [36]. Therefore, a review to determine the need for secondary corrective procedures should be conducted in consultation with the interdisciplinary team. Scar contracture is usually managed later by revision surgeries after the maturation of scar. The total number of revision surgeries required for a free flap is less as compared to local or regional flaps. The outcomes of revision surgery depend on the type of flap used, complexity of the defect, and location of the defect with nasal, orbits, and lips requiring the highest number of aesthetic refinements [5]. Similarly other expected soft tissue complications like trismus, microsomia, and other functional disabilities can be addressed by fat grafting, coronoidectomy, commissuroplasty, and Botox injections [37]. Very often the reconstructive surgeries of aesthetically prominent regions of the face like nose and orbits are always suboptimal, and in such cases, prosthetic rehabilitation can be considered even though not physiological and patient compliance is less.

59.9 Fracture Stabilization and Hard Tissue Reconstruction

The methodology for treatment varies and ranges from:

1. Debridement only
2. Debridement and closed reduction with or without fixation
3. Debridement, open reduction, and plate osteosynthesis

In patients without continuity defect, infection and minimal comminution open reduction and internal fixation (ORIF) is simultaneously done along with debridement at the initial stage.

Once initial stabilization is ensured, fixation is generally accomplished by miniplates or reconstruction plates. However, wounds with limited soft issue coverage require a different strategy as the granulation tissues may fail to cover thickness of plate resulting in subsequent plate exposure. Thus, if adequate soft tissue cover cannot be achieved, debridement, external pins, and maxillomandibular fixation (MMF) are the method of choice [33]. Until the introduction of surgical screws and plates, closed treatment was the preferred mode of treatment. The treatment ideology was directed to treat the whole wound as a "bag of bones" using external fixation or MMF in order to avoid periosteal stripping and devitalization of small fragments of bone. Although this therapeutic concept is advocated by several authors, who have reported significantly lesser rates of infection with this technique when compared with ORIF and plates, the value approach continues to be underestimated [38].

The advantages of external fixation are manifold. It helps to prevent bone devascularization, allows for bone regeneration, and also provides adequate support to the comminuted fracture fragments. Additionally, it also enhances the osteogenic potential of the injury site by helping in spontaneous bone regeneration. This phenomenon is more commonly seen in young patients due to hypoxia and acidosis-induced activation of local bone morphogenic proteins (BMPs). The high-velocity trauma causes extensive damage to adjacent muscles and periosteum. This damage along with the effects of local inflammation, hypoxia, and increased carbon dioxide concentration activates BMPs resulting in spontaneous bone formation. The concept and knowledge regarding facial buttress and its implication in trauma management have added a new dimension in the functional and aesthetic reconstruction of the face. As a result, internal fixation using locking plates has greatly replaced external fixators over a period of time. It is currently the most widely used technique in management of GSWs with bone loss and is used if the fracture fragments are large enough to accept screws.

Additionally, bone defects if any should be grafted with harvested iliac crest, ribs, or cranium depending upon the size of the defect (Fig. 59.7). However, the infection rates associated with internal fixation are comparatively higher as quoted by many authors. The increased rates of infection associated with ORIF are due to loosening of hardware and subsequent micromotion at the fracture site and possibly by contamination by oro-nasal flora. Motammedi [2] reported that it is almost impossible to achieve occlusion without arch bars and MMF in majority of gunshot fractures. Presently ORIF along with arch bars continue to be the mainstay in the management such patients. With the advent of new techniques of reconstruction supplemented by innovative plates and screws, vascular grafts and antibiotics have heralded a paradigm shift in the treatment philosophy. Current principles clearly favor early definitive reconstruction of hard tissues with ORIF using rigid fixation supplemented by MMF and bone grafts whenever required (Fig. 59.8).

59.10 Timing of Definitive Reconstruction

An area of ongoing debate and controversy in the management of gunshot wounds of the face is regarding the timing of definitive reconstruction [6, 39]. Although previous teachings and practices were in favor of delayed reconstruction, the more recent studies demonstrate predictable functional and aesthetic outcomes with immediate definitive reconstruction [40–42]. Scientific studies suggest carrying out definitive reconstruction within a time frame of 48 h would yield the best possible outcome [2].

Advocates of delayed reconstruction believe that the delay in treatment reduces the probability of infection, necrosis, and postoperative wound complications exponentially. Additionally delay in treatment reduces the chances of mortality and morbidity due to infection and progressive tissue necrosis [43, 44]. Any increase in postoperative temperature, raised leukocyte counts, and other local signs of infection may invariably cause a failure in flap due to risk of venous thrombosis. It has also been suggested that the decreased inflammation and edema aid surgeons to have a better assessment of the extent of injury, thereby helping in precise and desired treatment planning which in turn could lead to a better outcome. Therefore in their opinion, it is prudent to wait before applying any principles of primary reconstruction until a healthy tissue bed is achieved. On the other hand, the disadvantages of delayed treatment are increased treatment time, prolonged hospital stay, increased cost of treatment, and patient distress caused by psychosocial impact of disfigurement associated with gunshot injury (Tables 59.2 and 59.3).

Advocates of early primary treatment claim superior functional and aesthetic outcomes, early restoration of facial form, and limited hospital stay with early return to normal

Fig. 59.7 (**a**–**d**) High-velocity close-range assault rifle injury with comminution of mandible and soft tissue loss. Managed initially by non-vascularized graft and later by free fibula osteocutaneous flap reconstruction. External fixator for stabilizing fibula in place. Follow-up after complete treatment

function [4, 14, 45]. These benefits are predominantly due to the elimination of soft tissue contracture by proper anatomic coverage of soft tissue at an early stage [21]. Vasconez et al. [42] compared the infection rates of gunshot wounds that have been managed by early and late reconstruction in a series of 33 cases. In their observation, they could not found any significant difference in infection rates between the two groups. However, the delayed group showed an apparent increase in the incidence of scar contracture with significant functional and aesthetic complications. Similarly, several other studies have also reported excellent clinical outcomes when immediate reconstruction is carried out [46].

Fig. 59.8 (**a**–**d**) High-velocity assault rifle injury to the face with loss of hemimaxilla and mandible along with partial loss of upper lip was done. Reconstruction of the upper lip by hair-bearing submental island flap. Mandible reconstruction is performed by vascularized fibula

Definitive management of most maxillofacial injuries is not a surgical emergency, and treatment is often delayed in polytrauma patients. A standard consensus for delaying treatment and adopting a staged approach in such cases is due to the inability of a critically injured patient to undergo surgical intervention. However, as soon the patient is deemed to be medically stable, operative intervention targeted toward managing the facial injuries should be initiated. It is imperative to address the bony and soft tissue injuries soon after the resolution of edema and before the initiation of fibrosis of

Table 59.2 Advantages and disadvantages of immediate reconstruction

Advantages of immediate reconstruction	Disadvantages of immediate reconstruction
Less scar contracture, better postoperative function and aesthetics	The margins of devitalized tissues and its extent cannot be appreciated during early repair
Early return to function and less hospital stay	Correction of subtle deformities is difficult and such minor correction always requires second intervention
Less psychological impact on patient because of early recovery	Surgeon's expertise and availability of resources
Proper anatomical coverage of defect so chances of infection are less	Tissue edema immediately following the injury will hamper the judgment of surgeon resulting in suboptimal outcome

Table 59.3 Advantages and disadvantages of delayed reconstruction

Advantages of delayed reconstruction	Disadvantages of delayed reconstruction
Correction of defects after the resolution of edema will give a clear picture of the defect size	Severe scar contracture, less postoperative functional and aesthetic outcome
Correction of minor deformities is possible which may have been missed during immediate reconstruction	Number of hospital stay is increased with more psychological burden to the family and patient due to disfigured face
The necrotic margins can be easily assessed before reconstruction	High chances of infection due to open wound

soft tissues and malunion of fractures. This grace period will allow the surgeon to have an accurate and swift identification of subtle deformities for a major single-stage intervention rather than repeated assault to soft tissues causing fibrosis and decreased vascularity.

The essential difference in the management of routine maxillofacial injury and gunshot wounds of the face is the requirement of a multidisciplinary team for the management of gunshot wounds. Therefore, a short-term delay or temporizing such wounds allows time to procure diagnostic images and study models and lastly for a discussion on inputs from the medical and surgical team. In general, the formulation of treatment plan should be based on the general health status of the patient, availability of resources, surgeon's expertise, and patient's will.

In a vast majority of cases despite the primary management approach, a significant number of gunshot injuries are plagued with residual functional and aesthetic problems. Hence, a good postoperative outcome is multifactorial and is the reflection of all the above factors and not just the early definitive repair. However, a large number of maxillofacial gunshot wounds can be treated definitively at the time of initial intervention if the general condition of the patient and expertise of surgeon permit and the benefits of such an approach are manifold.

> The general physical status of the patient, timing of surgery, extent of composite tissue damage, good surgical techniques, use of appropriate hardwares, antibiotics, and proper rehabilitation are the factors which determine the final outcome and aesthetic result in a penetrating facial injury.

59.11 Recent Advances

Several recent advances have significantly improved the morbidity and survival rates in complex maxillofacial gunshot injuries. More importantly they serve as a support system to the surgeons, enabling them to appreciate and attend to the finer aspects of complex composite injuries. This in turn paves the way to achieve far more superior reconstructive outcomes. Contemporary techniques employ virtual surgical planning, patient-specific stereolithographic models, as well as intraoperative navigation and imaging (Refer Chap. 41 of this book). These modern-day techniques help elevate the surgical experience to one that is more precise, faster, and minimally invasive.

Composite tissue alloplastic transplantation or face transplantation is yet another recent innovation in this field. This treatment is rendered for patients with massive loss of hard and soft tissues of the face or in cases where the final outcome is suboptimal even after multiple surgeries. However, it is not in the mainstay treatment of gunshot wound of the face because of the difficulties in finding an appropriate donor, lack of expertise, requirement of long-term immunosuppressants, absence of long-term follow-up, and associated ethical issues.

59.12 Conclusion

In conclusion, the management strategies of patients with facial gunshot wounds are almost as diverse as the case presentation itself. This chapter ascertains that the blueprint for actions in the management of facial gunshot injuries has undergone significant change over the last decade. A new understanding of the inherent osteogenic potential of the human body in the face of contemporary warfare coupled with the availability of state-of-the-art equipments and facilities favors a brisk early approach. Thus, present guidelines essentially direct surgeons to do as much as possible for the gunshot patient with regard to hard and soft tissue reconstruction of the face and jaws within 48 hours. The treatment in such cases is more comprehensive with intent to simultaneously debride and reconstruct.

Panfacial Fractures

60

Kiran S. Gadre, Balasubramanya Kumar, and Divya P. Gadre

60.1 Introduction

Most facial fractures occur in combinations involving various subunits of craniomaxillofacial (CMF) skeleton [1] (Fig. 60.1). Severity of these injuries is determined by multiple factors such as its aetiology, causative factor, force of impact, pre-existing patient factors, etc. High velocity road traffic accidents RTA / assaults are the most common cause of panfacial fractures. With a large number of different patterns these fractures project, it is challenging to have a proper definition of "panfacial fractures". It is well-known that fractures involving multiple bones of the face is known as panfacial fracture. It could be described as "fractures involving upper third, middle third, and lower third of face with at least one condyle, palate and fronto-naso-orbito-ethmoidal complex (FNOE) fracture" (Fig. 60.2). When there is skull base or co-existing neurosurgical involvement, it is termed as craniofacial fracture. Managing these cases is extremely complicated as each of them present with unique pattern of hard and soft tissue injury. This demands a team approach as these injuries are commonly seen in polytrauma with multisystem involvement. Airway compromise, severe haemorrhage, large open wounds, severe ocular/orbital injuries and coincidental surgical procedure being performed are the only indications for immediate definitive surgical intervention. Restoration of form and function at the earliest opportunity should be the goal of maxillofacial surgeons.

60.2 Epidemiology

Global status report on road safety (2015) indicates that more than 1.25 million deaths, and 15–20 million injuries occur in road traffic accidents (RTA) costing most countries 3% of their GDP [2]. Countries with low and middle income having 54% of vehicles account for 90% of RTA-related fatalities, mostly of subjects aged between 15 and 44 years. RTA is the main cause of mortality in three quarters of males in 15–29 years age group. The true economic and public health impact is not estimated in most developing countries due to lack of infrastructure and resources [3].

Panfacial fractures are caused by high-energy impact, usually generated as a result of RTA or firearm injury directed at CMF skeleton, and it also has a contrecoup component causing associated cranio-cerebral or cervico-spinal injuries with a low Glasgow coma scale. These injuries can also cause associated injuries like rib fracture/pulmonary contusion, pneumothorax or intra-abdominal injuries, limb and pelvic injuries and require immediate treatment.

60.3 Management Philosophy

Restoration of form and function is the ultimate goal in treating panfacial injuries. Proximity to important structures like the brain, eyes, auditory apparatus and spine necessitates a holistic approach to their management involving neurosurgeons, ophthalmic surgeons, ENT surgeons, maxillofacial surgeons and anaesthetists.

It is challenging to follow an established pattern of repair as each case is unique and requires skill and expertise of the surgeon to restore the pre-traumatic anatomy of facial function with aesthetics. Despite all the aggressive treatment, many patients with panfacial trauma may need further correction of residual deformities.

Fig. 60.2 3D CT scan image showing panfacial fracture involving the upper, middle and lower third of face

60.3.1 History of Management

The management of panfacial fractures has changed during past few decades, particularly after the 1990s, when indigenous plating systems were more freely available.

1. Prior to the 1980s, most panfacial fractures were treated with closed reduction using Plaster of Paris (POP) head caps and cranial frames. A variety of trans/interosseous wiring techniques (see Chap. 50 for details on various wiring techniques) and internal suspension methods like cranio-mandibular/maxillary suspension were used (Figs. 60.3a, b and 55.15).
2. The surgeons of the 1990s generation started using combination of plating at key buttresses and internal suspension techniques [4]—the approach which may be attributed to early learning curve of internal fixation (Fig. 60.4).
3. Use of internal fixation has revolutionised the management of panfacial fractures [4] (Fig. 60.5a, b), leading to faster recovery and satisfactory outcome of these injuries. (See Chap. 51 for details on Principles of internal fixation)
   A better understanding of anatomy, pathophysiology, anaesthesia, sterilization and asepsis with advances in intubation techniques (transmylohyoid/submental, bronchoscopic) and instrumentation (fiberoptic and endoscopic) and instrumentation has influenced the management of these complex injuries significantly (Chap. 7 deals with Anesthesia and intubation techniques in maxillofacial surgery). Use of engineering technology like three-dimensional planning, stereolithographic models, endoscopic and navigation techniques has simplified the accurate treatment of these fractures, avoiding injury to other vital structures and saving intra-operative time (Fig. 60.6a–d).

60.3.2 Indications

Panfacial fractures can be disfiguring and cause significant functional problems like difficulty in mastication, deglutition, speech, olfaction and abnormalities of vision. Early fixation of displaced fractures causing the above problems is warranted. Undisplaced/minimally displaced fractures can be left for a few days, buying some time to manage other grievous injuries. It is necessary to understand that sense of urgency for treatment should exist in treating any panfacial fracture (within 15 days, provided other parameters are permitting).

60.3.3 Contraindications

There are no absolute contraindications but relative contraindications which cause delay of treatment, are presented below.

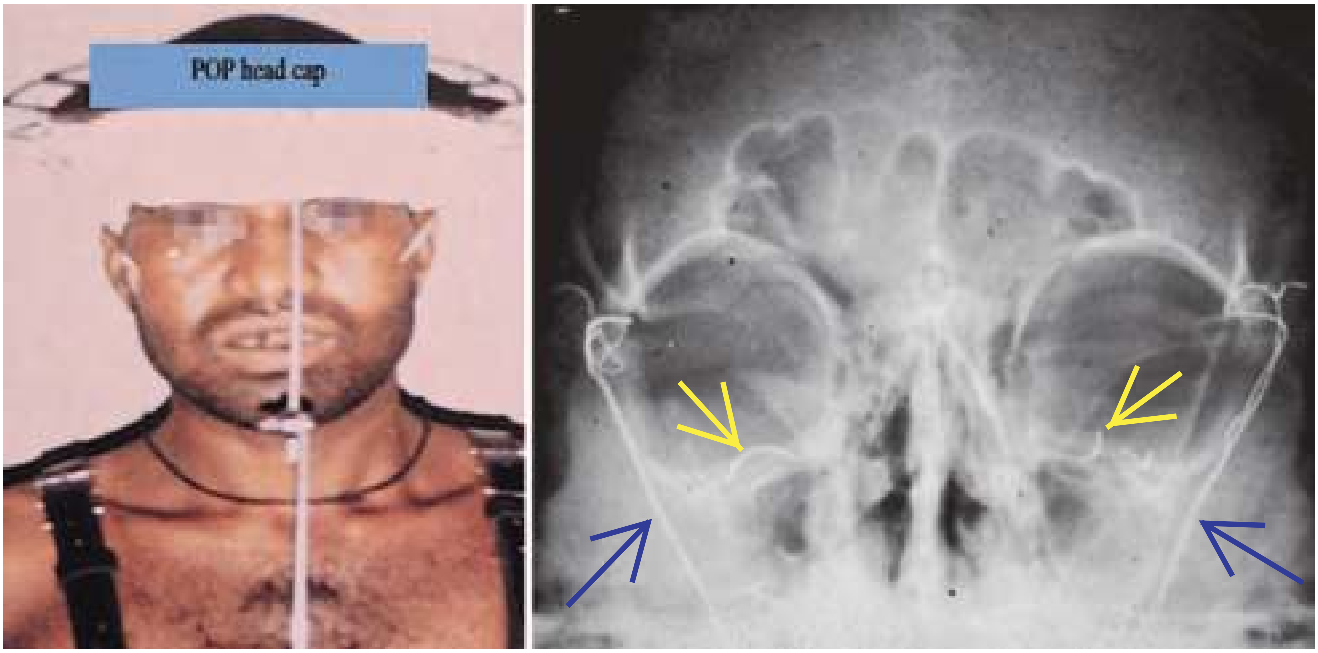

Fig. 60.3 (**a**) POP head cap used in traditional days. (**b**) Interosseous wiring (yellow arrow) with internal suspension (blue arrow)

Fig. 60.4 Plating with internal suspension (blue arrows)

1. Definitive treatment of panfacial injuries may be delayed up to 2 weeks in presence of severe, compromising, concomitant systemic or head injury.
2. It is advisable to operate only when patients are neurologically and systemically stable. This period should be used for further surgical assessment and planning.
   Reduction of facial oedema further unmasks the underlying fractures and facial deformity. This gives an opportunity to review the imaging and prepare necessary splints (see Sect. 55.7.1) (Fig. 60.7a, b). These are very essential to establish width, height and anteroposterior projection of the facial skeleton, particularly where large dento-alveolar segments have been lost along with the presence of bilateral condylar fracture.
3. When a combination of avulsive injury (Chap. 49 deals with management of Soft tissue injuries in maxillofacial region) and panfacial fractures is present, golden hour reconstruction should be utilised, if circumstances and conditions permit. This is the best time as patient is in optimal physiologic and physical condition.

60.3.4 Clinical Findings

The clinical findings in panfacial trauma are a combination of signs and symptoms as seen in various subunits of facial fractures with increased severity (readers are advised to refer the respective chapters on maxillofacial trauma for signs and symptoms and management of fractures of mandible in Chap. 52, Fractures of the Condyle in Chaps. 53 and 54, fractures of maxilla in Chap. 55, fractures of the zygomatic complex in Chap. 56, fractures of the orbit in Chap. 57, fractures of the frontal naso orbit ethmoid region in Chap. 58 and Gun shot injuries in Chap. 59).

Facial oedema makes examination and standard radiography difficult. Bilateral raccoon's eyes and elongated dish-shaped face, with presence of orbital dystopia, traumatic telecanthus and deranged occlusion, are commonly seen. There may be elements of severe dento-alveolar trauma and soft tissue injury which may vary from minor contused or lacerated wounds (CLW) to avulsive injuries.

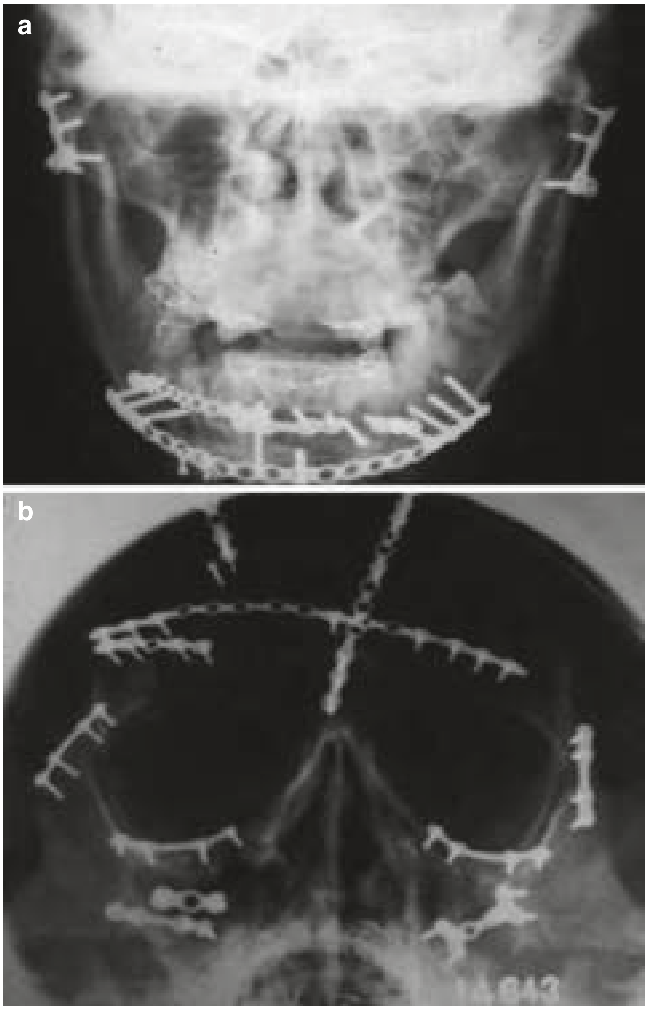

Fig. 60.5 (**a**, **b**) Plating of panfacial fractures as seen on (**a**) posterior-anterior Caldwell view of mandible and (**b**) posterior-anterior Water sinus view radiographs

Presence of cervical, cranial and other concomitant injuries must be assumed till proved contrary. Similarly absence of teeth, dentures in mouth must be assumed to have been swallowed or aspirated until proven otherwise.

60.4 Workup

The pre operative planning consists of two parts: (a) imaging and (b) diagnostic procedures.

Imaging:
Standard radiographs like posterior-anterior (PA) view, Caldwell view of mandible, Water's view, submento-vertex view, cervical spine radiographs have been used as a baseline in any emergency and are easily available in most settings. Computed tomography (CT) images with 3D reconstruction is now considered the gold standard in complex facial trauma patients as it provides a 1:1 information of the fracture pattern. 3D planning softwares help the surgeon in meticulously planning cases preoperatively.

CT imaging is commonly done for assessment of brain and spinal cord in a head injury patient to exclude intracranial haemorrhage and other grievous injuries. Facial skeleton should be included in the same scan in suspected facial bone fractures.

Coronal and sagittal sections of the CT scan could be obscured by the endotracheal tube in intubated patients. Axial and three-dimensional images with computer-generated models can be used for assessing most facial fractures in these cases (Fig. 60.8a, b).

Diagnostic Procedures:
Occlusion of teeth is the key to reduction and fixation of facial bone fractures. Mock surgery using dental models help in repositioning the teeth-bearing segments including dento-alveolar and palatal fractures and aid in fabricating acrylic stents and splints (Fig. 60.7). They are essential in cases where there is gross occlusal disturbance, splaying of basal bone or multiple fractures of dento-alveolar segment.

60.5 Emergency Treatment

Complex maxillofacial trauma are mostly high impact injuries and are usually a part of life-threatening injuries involving other organ systems like central nervous system, chest, abdomen, pelvis or limbs. It is important that these injuries be assessed and managed prior to or simultaneously as facial injuries.

Current standards of care for trauma patients, whether polytrauma or those involving the CMF skeleton, mandate that one must follow the Advanced Trauma Life Support (ATLS) protocol relating to airway, breathing, circulation, disability and exposure in that sequence. Airway and circulation should have the highest priority (Table 60.1). This is followed by an assessment of the patient's neurological, visual and cervical spine status. The details of primary and emergency management of polytrauma patients are dealt in Chap. 48 of this book.

Patients with polytrauma/panfacial fractures can require immediate or late treatment depending on the mechanism and kind of injury. Occasionally, immediate treatment can be the definitive procedure. An immediate intervention may be done merely for initial stabilization of the patient; procedures demanding a more detailed assessment and planning will need to be postponed. Immediate initial treatment in patients with maxillofacial injuries is indicated in following situations.

Fig. 60.6 (**a**–**d**) Showing few of advances from various specialities of medicine and engineering contributing to advances in management of panfacial fractures. ((**a**) Bronchoscopic intubation, (**b**) transmylohyoid intubation, (**c**) fibreoptic instruments, surgical saw, (**d**) stereolithographic model)

60.5.1 Airway Compromise

Obstructed airway is an important sequel of panfacial fractures and is managed either by temporarily reducing and stabilizing the fractured facial bones and attached soft tissues or performing a surgical tracheostomy. Patients with C-spine injury can be challenging to intubate due to inability to flex or extend the neck, as is establishment of a surgical airway like tracheostomy.

60.5.2 Severe Haemorrhage

Reduction and stabilization of fractured segments not only helps to correct airway but also controls severe bleeding. Haemorrhage not amenable to the above procedure may necessitate packing, identification of causative bleeder and its cauterisation or ligation. Occasional ECA control may be required, if multiple ipsilateral bleeding areas or unidentified areas of bleeding are seen. In centres where the facility is available, uncontrollable bleeding from facial region (especially after comminuted midface fractures) is controlled with selective embolisation by a interventional radiologist.

60.5.3 Large Open Wounds

These are commonly used to fix the fractures beneath them. In such situations initial washout and primary approximation should be done when possible for haemostasis and maintaining continuity of vascular supply, especially in cartilaginous areas like the ears and nose. This closure is basically a primary tacking of the wound margins. Layered closure is better done under controlled conditions along with fixation of the fractures under anesthesia [1].

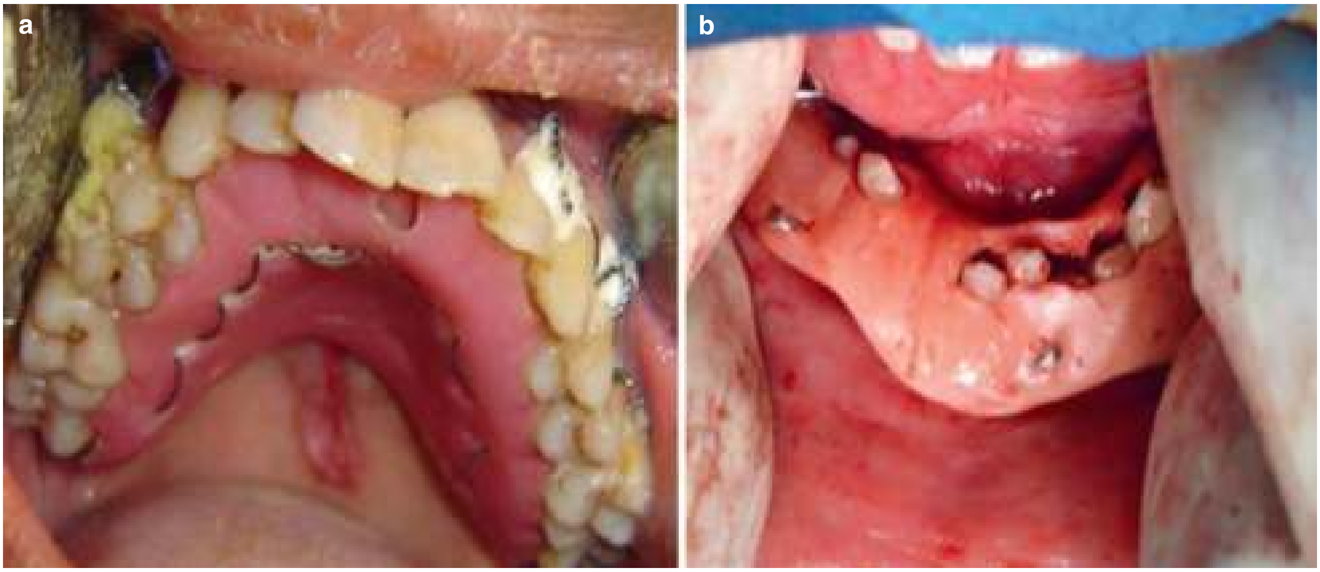

Fig. 60.7 (**a**, **b**) Showing utility and essentiality of splints in management of panfacial fractures

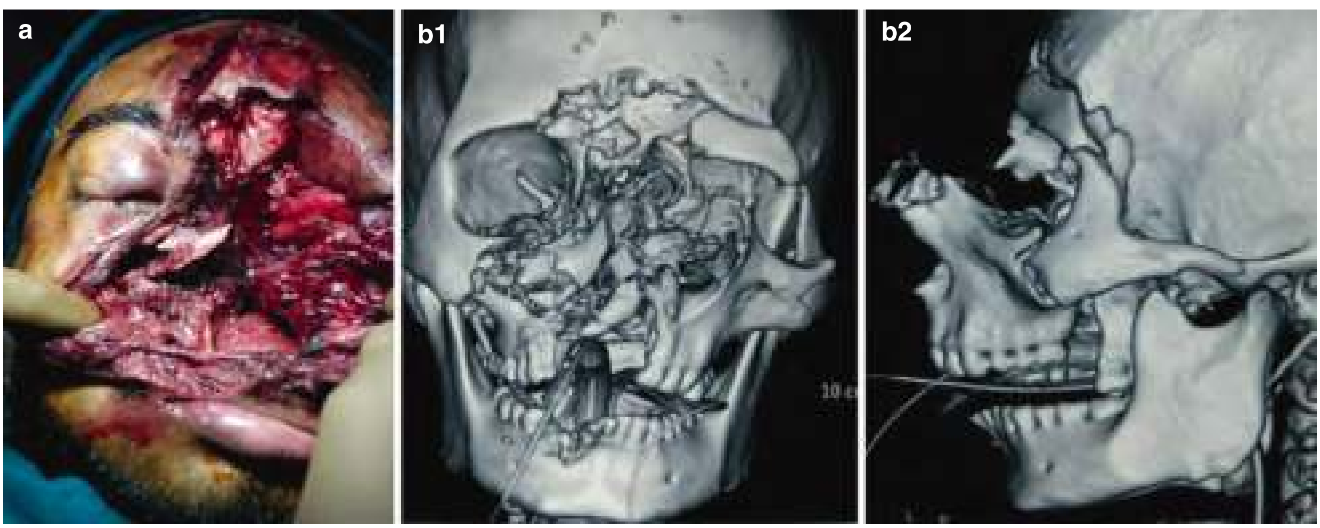

Fig. 60.8 (**a**, **b**) Depicting importance of high-resolution CT scan in an avulsive injury to assess nature and extent of injury and achieve predictable outcomes

60.5.4 Surgery for Associated Life-Threatening Injuries

Occasionally, patients with polytrauma undergo immediate surgery to treat other grievous injuries. This provides an opportunity to perform initial debridement, assessment and stabilisation and make dental impressions for fabrication of a customised splint. Considering the planning and surgical time required for comprehensive management of panfacial fractures, it is usually not advisable or possible to perform fixation during emergency management of other more severe injuries (neurological/abdomen/long bones/chest).

It is always wise to initiate assessment of a head injury or polytrauma patient using the ATLS (Advanced Trauma Life Support) protocol. A detailed record of all maxillofacial injuries should be made. Diagrams and representations of fracture patterns and soft tissue injuries make it easy for the understanding and execution of treatment. It is important to document the whereabouts, mechanism and time of injury accurately, to minimise medico-legal problems at a later date. Photographs are a good medium of educating the patients with their attenders and recording the preoperative soft tissue injuries.

Table 60.1 Immediate management of a polytrauma patient

Management	Option 1	Option 2
Airway	Suction, recovery position, Intubation	Tracheostomy. More so with C spine injury
Hemorrhage	Pressure	Ligation
	Grouping cross-matching	Fluids 1–2 liters in adults and 20ml/kg for children
IV	Peripheral with 16 G intra-cath	Central
Catheterization	Nasogastric tube insertion; caution when FNOE fractures	Foley's catheter for input - output chart
Immunisation	Anti gas gangrene	Tetanus
Laboratory	Routine	ABG
Imaging	CT scan: HFN, Chest, Pelvis	Chest X-ray, USG abdomen
Assessment	Circulatory	Neurological

60.5.5 Definitive Treatment

Paul Manson's quote "you never get a second chance" has to be kept in mind, i.e. the time frame [5] regarded appropriate for primary fracture treatment is limited to 2 weeks. After 2 weeks, the treatment is regarded as delayed and may necessitate secondary post-traumatic reconstruction (see Chap. 60 on residual deformities of the maxillofacial region).

60.6 Preoperative Documentation and Planning

Preoperative treatment planning is essential for successful outcomes. One must gather enough information and documentation to help in formulating an accurate treatment plan.

This can include:
1. The topography and extent of fracture involvement
2. Loss of hard and soft tissues with their residual defects
3. Involvement of teeth and teeth-bearing segments
4. Assessment of important structures like parotid and submandibular glands, nasolacrimal duct, trigeminal nerve, facial nerve, muscles of eye and most importantly vision

A proper evaluation by ophthalmologist, ENT surgeon and Neuro Surgeon is mandatory before proceeding with panfacial fracture fixation, and these allied specialities may be part of the surgical team for comprehensive management of the panfacial injuries.

Large bony defects with loss of soft tissue are best treated immediately or secondarily with local, pedicled non-vascularised or vascularised-free flaps provided the wound is clean and non-infected. Tissue shrinkage should be avoided as much as possible in these special situations by using techniques of maxillomandibular fixation (MMF) and internal or external fixation devices or splints. Immediate reconstruction can be planned in clean wounds. Need for transmylohyoid/submental endotracheal intubation as an alternative to tracheostomy should be explored in discussion with the anaesthesia team [6], especially in panfacial trauma involving nasal bones and skull base fractures needing fixation of maxilla and mandible.

60.7 Intra-operative Details

The essential in treating panfacial fractures is obtaining adequate fixation at key buttresses (Fig. 60.9a, b, Fig 55.2). Its description was first given by Cryer in 1916 [7]. This helps in creating the outer framework for fixation of other fractures.

60.7.1 Buttresses of the Facial Skeleton

These are the regions of thick bones which neutralise the forces applied onto them.

Outcome of maxillofacial reconstruction in terms of restoration of facial height, width and projection in addition to restoring the occlusion depends on proper reduction and fixation of these buttresses [8, 9] (Table 60.2).

They are important to:
1. Maintain projection and protection of airway
2. Anchor suspension of musculo-aponeurotic system
3. Protection of skull base and structures above like brain and eye with their adjoining structures from masticatory forces

60.7.2 Key Contributors to Facial Architecture

- Central facial width: fronto-naso-orbital-ethmoid (FNOE) complex, palate and the mandibular arch
- Lateral facial width: Frontal bar, zygomatic arches, malar eminences and mandibular angles
- Projection: frontal bone, frontonasomaxillary buttresses, zygomatic arches and mandible from angle to symphysis
- Facial height: frontal bone, midface buttresses, mandibular angles and condyles

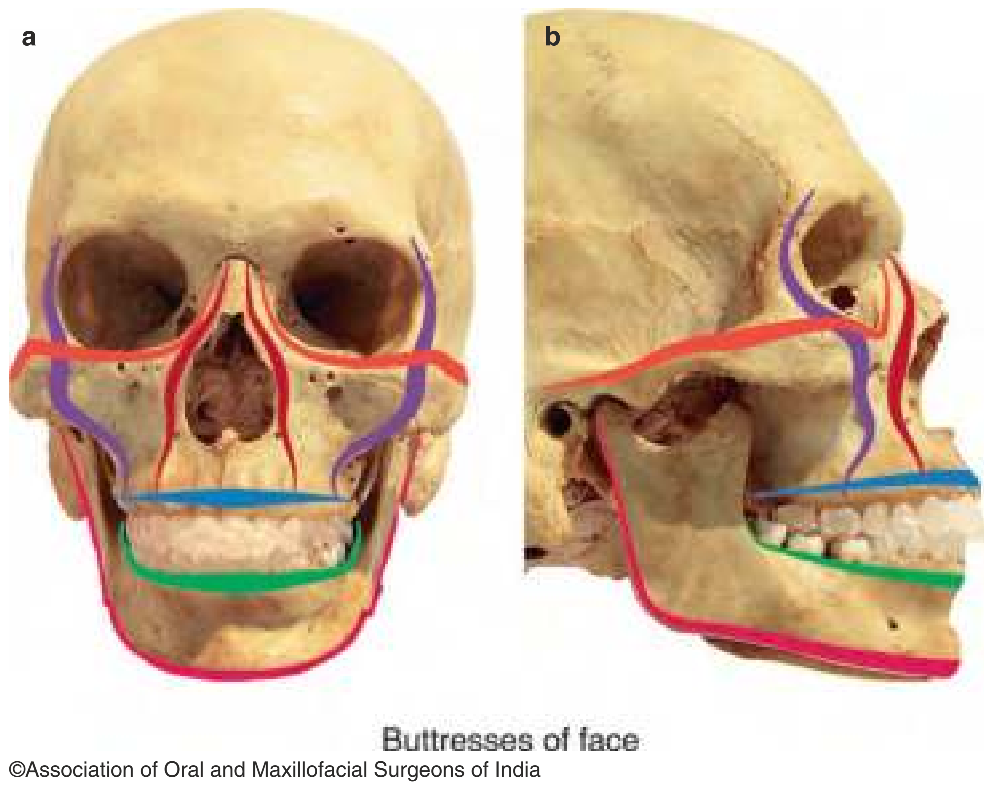

Fig. 60.9 (**a**, **b**) Schematic markings of facial buttresses (Correlate with Table 60.2) (Also see Fig. 55.2)

Table 60.2 Buttress of facial skeleton (colour codes of Fig. 60.9 marked)

Vertical buttresses	Horizontal buttresses
Nasomaxillary (red)	Frontal (orange)
Zygomaticomaxillary (purple)	Zygomatic (orange)
Pterygomaxillary	Maxillary (blue)
Condyle and posterior mandible (pink)	Mandibular (green)

60.7.3 Various Approaches to Facial Skeleton

Approaches to individual facial bones are discussed in the respective sections of the book. They are enumerated here for quick reference and revision.

Facial lacerations overlying fractures should be used for access when possible (Fig. 60.10a–d). In situations without any such lacerations, appropriate incisions for respective fractures should be used as described in other sections of this book.

Subciliary or transconjunctival incisions are commonly used to provide access to infraorbital rim and orbital floor; lateral brow or upper blepharoplasty incisions provide access to frontozygomatic suture and lateral wall of orbit; intraoral vestibular incision provides access to maxilla and zygomatic buttress; and coronal incision provides access to frontal, fronto-naso-ethmoid complex, zygomatic arches and roof of orbit.

Mandible symphysis, parasymphysis, can be approached through intraoral vestibular or crevicular incisions. Mandibular angle is approached intraorally through an extended 3rd molar incision alone or in combination with a transbuccal approach using a trochar and cannula. The condylar head will need to be approached through preauricular or bicoronal incision, whereas the mandibular subcondyle and ramus can be approached through retromandibular or peri-angular incision. Endoscopic approach to the mandibular condyle is been popularised in a few units (see Chap. 54 for details on endoscopic approach to condylar fractures).

Sequencing of fixation in panfacial fractures is a challenging task. The sequencing will alter slightly depending on clinical and radiological evaluation.

60.8 Sequencing Options

There are two options for sequencing:

1. *Bottom to top* [10, 11]: This involves restoring the maxillomandibular unit using occlusion as guide and fixing maxilla and mandible using semi-rigid or rigid fixation techniques. Thereon reduction and fixation proceeds in caudal direction starting from calvarium. The other fractures are then restored in a build-out fashion with maxilla and mandible being a stable base
2. *Top to bottom*: This involves starting with the reduction and fixation at the level of the calvarium. Then the operator proceeds in a caudal direction with reduction and fixation. In this top to bottom sequencing technique, establishing proper occlusion with MMF is no less

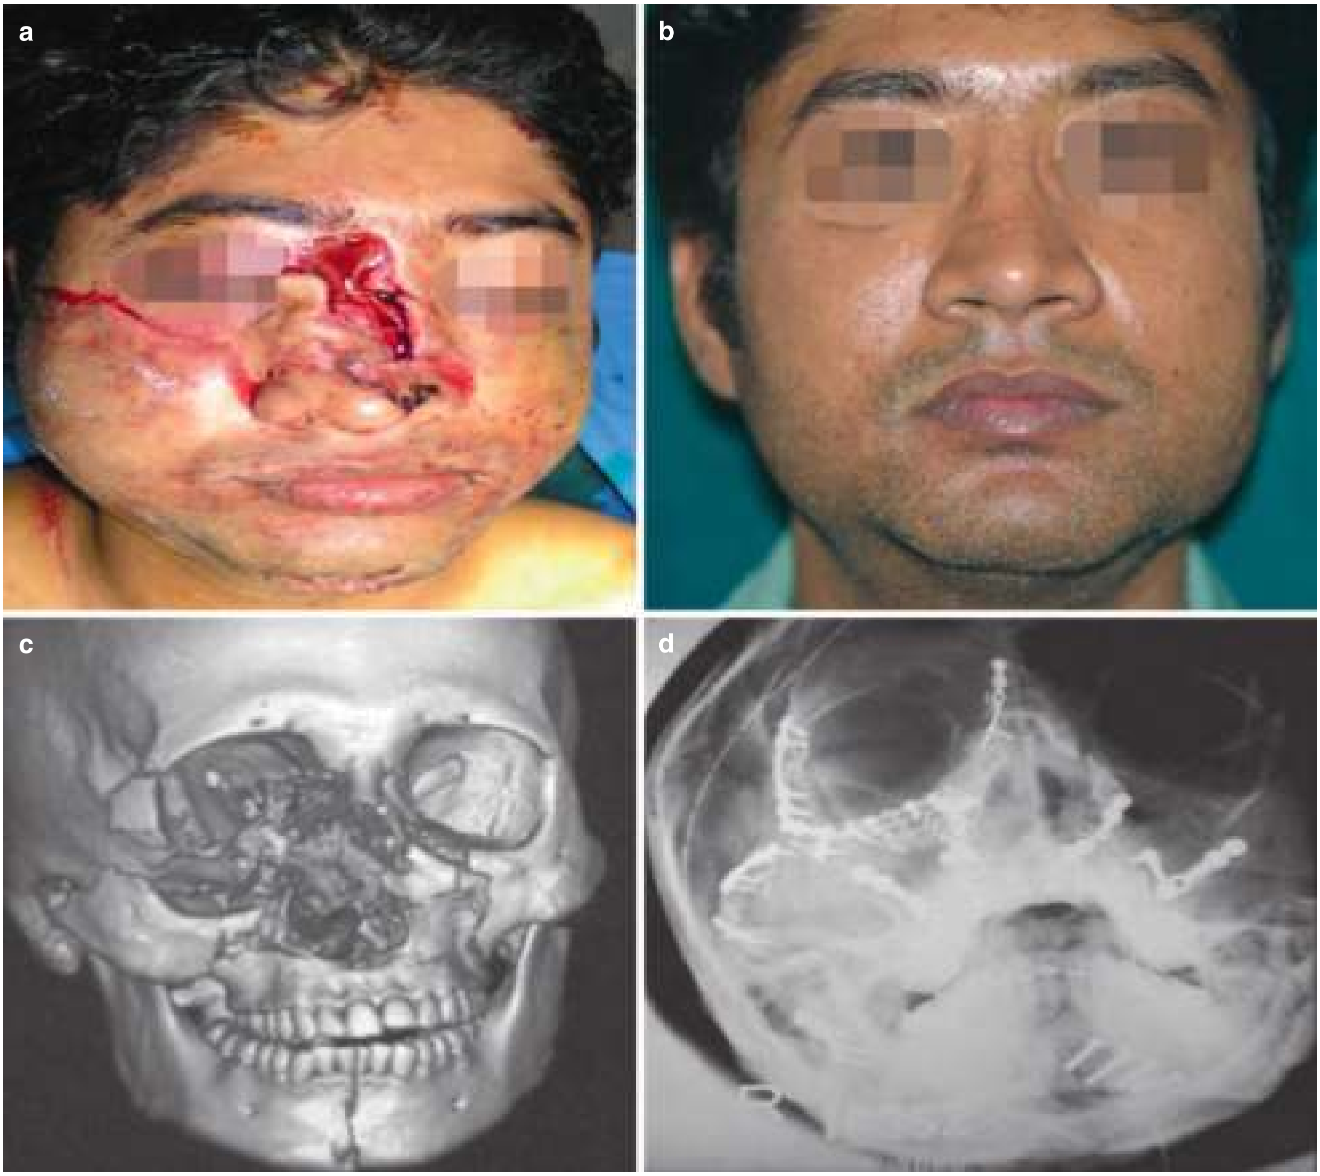

Fig. 60.10 (**a**–**d**) Use of existing laceration to achieve optimal results

important,and is surely done prior to rigid fixation of Leforte I and mandibular fractures.

Although author's preference is "bottom to top" approach, as establishing functional occlusion is of prime importance, a combination of both the approaches might be necessary in many situations (Fig. 60.11).

60.8.1 Bottom to Top Approach

1. When using this approach one is committed to using the mandible as guide for establishing the height, width and projection of face. Hence after occlusion is established, the mandible is rigidly fixed from one condyle to the other. This makes it necessary to plate minimum one condyle in case bilateral condylar fracture. It is necessary to ensure proper seating of mandibular condyle into the glenoid fossa.
2. Further sequencing will depend on presence or absence of palatal fracture and its nature (comminuted or not). In any case it is very important to establish width of midface correctly so as to achieve optimal functional and aesthetic results.
3. Use of splints made on dental models after model surgery serves an ideal and desirable method to establish correct width of middle and lower face particularly when there is comminution of maxilla and mandible. Use of conventional acrylic splints is the easiest and least time consuming. 3D splint has led to more accurate and predictable results but adds on to the time and cost.

Fig. 60.11 Use of combination techniques to achieve stable fixation schematic diagram

4. The next step is to begin the reduction and fixation of the remainder of the midface starting from the calvarium and working in a caudal direction similar to "top to down" sequencing.

60.8.2 Top to Bottom Approach

1. The reconstruction sequence to re-establish midfacial pillars (buttresses) and dimensions starts with the most reliable and stable point on calvarium and on the side with the least comminution.
2. The calvarial, frontal sinus and orbital roof fractures are addressed first using stable point/region on calvarium as reference point for reconstruction of midface.
3. The zygoma is positioned into its proper three-dimensional position, almost as a flat structure and confirming that lateral wall of orbit is in alignment with the greater wing of sphenoid. This helps proper establishment of width and anterior-posterior projection of face. Approximation of the sphenozygomatic suture in the lateral wall of the orbit should be a guide to reduction in cases of comminuted zygomatic fractures [12]
Fixing the zygomatic arch increases the accuracy of multidimensional reconstruction (frontozygomatic suture, infraorbital rim, zygomaticomaxillary buttress, zygomatic arch) of fractured and comminuted zygoma [13, 14].
4. The infraorbital rims and NOE complex are properly aligned to complete the reconstruction of the periorbital area.
5. Where reconstruction of the medial canthal tendon is necessary, it can be addressed towards the end of the procedure.
6. The next step in midface reconstruction is fixation across the Le-Fort I and II level. Maxillomandibular fixation may be done at this stage. If everything has been perfectly aligned, these fractures should also align adequately. Splints play a significant role in determining the facial width at Le-fort I level. Malalignment at this level signifies need for reassessment and realignment of previously fixed fractures.
The midface, because of weak bone structure and comminuted fracture pattern, must be considered a dependent and less stable structure.
7. From an aesthetic standpoint, a minimal malalignment at the Le-Fort I level is not as noticeable as a malalignment of the orbits.
8. Fractures of the inferior orbital rim and orbital floor can be now addressed as the true volume of the orbital defect can be seen once other fractures are aligned.
9. The mandibular fractures are then fixed. Condyle fractures may be addressed with separate incisions or managed conservatively depending on the displacement and influence on the vertical height of the mandible, as discussed previously.
Tulio etal advocated fixation of condylar fractures as the first step in fixation of pan facial fractures. In their study there was no evidence of dental or skeletal alterations and measurement of the mandibular ramus and radiographic examination show that posterior facial height as well as projection and width of the inferior lower third of the face, was restored. The correct timing of surgical intervention and the use of rigid fixation allows the restoration of the morphological and functional nature of the face after pan facial fractures [15].
10. The occlusion should be rechecked, and rigid or elastic maxillomandibular fixation may be considered as necessary for 4–6 weeks. The occlusal splints may be fixed using wires for the period of MMF as a guide to maintaining the occlusion.
The sequencing for pan-facial fractures depends more on the clinical situation, than on predefined algorithms as the patterns of clinical presentation may be diverse. However, the general consensus in current literature emphasizes that the the dental units are given priority for providing guidance. The dental arches are first stabilised to form a

Table 60.3 Bottom-up inside-out and top-down outside-in, comparison of sequencing

Bottom-up	Top-down
Maxillomandibular fixation (MMF), splints for palate and mandibular lingual in case of gross comminution	Fix calvarium, frontal sinus and orbital roof fractures sequentially
Fix mandibular fractures (symphysis/body/ramus)	Fix zygomaticomaxillary complex (including arch) fractures, with proper alignment of infraorbital rims
Fix condylar fractures, at least one when fracture is bilateral	Fix naso-orbito-ethmoid complex, and nasal fractures
Fix maxilla at LeFort I level	Maxillomandibular fixation (MMF), splints for palate and mandibular lingual in case of gross comminution
Fix calvarium, frontal sinus and orbital roof fractures sequentially	Fix maxilla at Lefort I level
Fix zygomaticomaxillary complex (including arch) fractures, with proper alignment of infraorbital rims	Fix condylar fractures, at least one when fracture is bilateral
Fix naso-orbito-ethmoid complex, and nasal fractures	Repair of Mandibular fractures

cohesive unit, followed by the mandible in its horizontal and vertical dimensions (10, 19) (also see Manson 2012 in additional reading). The mid face is then managed using a top-down or a bottom-up method depending on the presence or absence of bony defects in the calvarium.

60.8.3 Essentials in Either Approach

1. Soft tissue repair and closure of wounds/incisions of intraoral and pharyngeal areas should be done prior to maxillomandibular fixation. In some cases it might be essential to temporarily release MMF to close lacerations and redo MMF later.
2. Laceration which would be concealed under the splint should be closed prior to fixation of splints.
3. Thoroughly debride perforating wounds before closure.
4. Extraoral incisions and lacerations communicating with the oral cavity should be closed from deep (mucosal) to superficial (skin) in multiple layers.

The sequence of the above approaches are compared in Table 60.3.

Author follows the *"Wire before you plate"* principle.

It is author's preference to use initial wire osteosynthesis stainless steel (SS) for better alignment and anatomical reduction at multiple sites before plating. This technique also does away with the requirement of holding fragments together, and with less of instrumentation in the surgical field, there is an obvious ease of plating more precisely. Wire osteosynthesis should be removed following fixation of the fractures to avoid or prevent reaction between dissimilar metals, namely, SS (stainless steel) and Ti (titanium).

There are other sequencing methodologies and philosophies as suggested by other authors.

Manson et al. put forward a highly conceptualised treatment protocol where face is divided into groups, units and sections, and each section is assembled in three dimensions. Soft tissue is considered the "fourth dimension" of facial reconstruction. They advised bone reconstruction to be completed as early as possible to minimise soft tissue shrinkage, stiffness and scarring of soft tissues in non-anatomic position [1, 16].

Killey and Kay demonstrated the fixation of panfacial fractures first in the outer ring followed by the middle ring and lastly the nasal complex in the inner ring (Fig. 60.12).

Inside-out sequence was also found to show good results by Kim et al. [17].

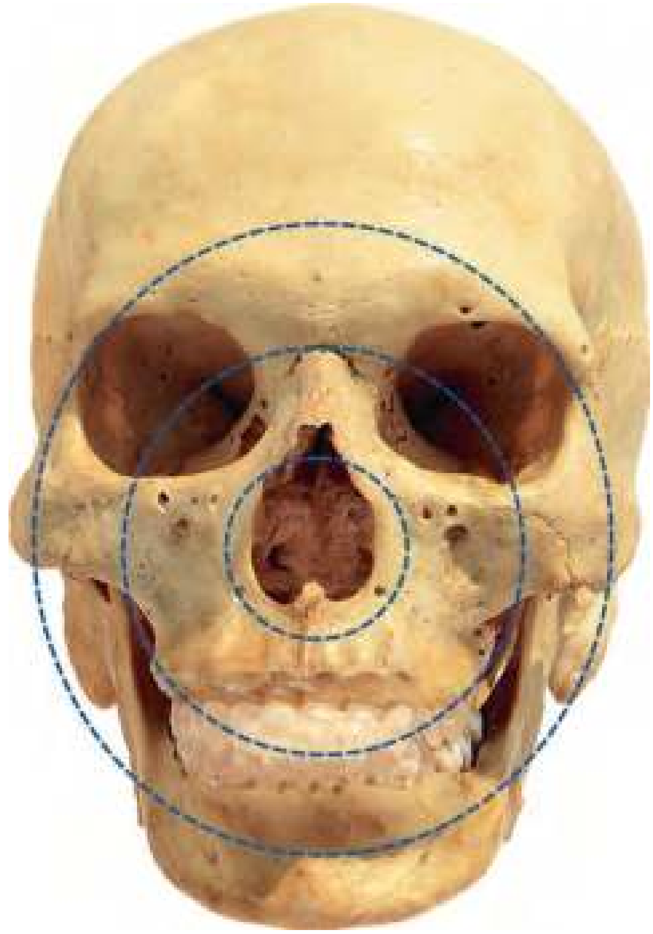

Fig. 60.12 Three concentric circles used as a guide to the reduction of panfacial fractures (Adapted from: H.C Killey. Fractures of Middle-third of facial Skeleton, Issue 3 of Dental Practitioners Handbook, No.3)

The occlusion first approach, with initial reduction of larger segments, enables effective reconstruction of multiple segments. Smaller segments can then be oriented to fixation of these fractures [18].

Role of bone grafts in very comminuted fractures or missing bone demands immediate bone grafting to produce a stable outcome. Commonly used areas of bone and cartilage grafts are rib, calvarium, iliac crest and conchal cartilage [19]. Recipient site requirements determine the ideal donor site for replacing bone. Revascularisation potential and mechanical needs of the donor site are two factors known to influence this [20].

60.9 Paediatric Panfacial Fractures

They are rare and different as the cranium to face ratio is 8:1, and also differential growth in eyes, brain and face makes a difference in pattern and incidence of fractures. Children should not be treated as small adults as its not only important to restore them to normal form and function, but the growth potential also should be taken into consideration. One must remember that both injury and treatment can lead to growth disturbances, and hence many times conservative management is preferred. Splints are the mainstay in treatment of paediatric fractures (Figs. 52.50 and 52.51). Panfacial fractures are preferably treated with resorbable plates to prevent growth disturbances and damage to tooth buds. This also avoids second surgery for plate removal. Furher, it must be kept in mind that minor occlusal discrepancies are self-corrective during transitional dentition phase or can be treated easily with orthodontics at later date. Major emphasis should be on preventing deformities in central midface. Paediatric patients have to be followed up till growth has completed. In developing countries wire/resorbable suture osteosynthesis can be utilised for economic reasons and availability [21].

60.10 Complications

Complications associated with panfacial injuries include those associated with individual fractures of frontal sinus, nasal and fronto-naso-ethmoid, zygomatic, maxillary and mandibular fractures.

- Motor and sensory deficits of motor and sensory nerves like anaesthesia, paresthesia and weakness
- Reduction in posterior facial height
- Anterior open bite
- Increase in facial width secondary to reduction of anterior-posterior facial projection
- Traumatic telecanthus
- Orbital deformities
- Lacrimal apparatus injuries/dacryocystitis
- Malocclusion
- Nasal obstruction and external nasal deformity
- Cerebrospinal fluid leak
- Anosmia
- Blindness
- Temporomandibular joints dysfunction
- Oro nasal fistula from wide palatal fractures (Fig. 55.25)

60.11 Tips and Tricks

1. Panfacial fractures do not follow specific patterns but occur in variety of combinations involving all facial subunits.
2. Discuss with patients' relatives about realistic outcomes of surgery. Use of patient photographs prior to injury may act as a guide for the surgeon to establish treatment goals. This may be challenging to assess with the oedema and disfigurement following trauma. Making a record of intra-operative and post-operative photographs is a good practice for comparison and documentation.
3. In patients with displaced midface fractures and bilaterally displaced mandibular condyles, it is important to fix at least one condyle anatomically by open method in order to obtain adequate mandibular positioning and posterior facial height.
4. In either approaches to panfacial fractures seating of condyle into glenoid fossa is absolutely mandatory.
5. If prolonged ventilation is anticipated tracheostomy, percutaneous endoscopic gastrostomy (PEG) should be considered.
6. Vertical and horizontal buttresses should be established and fixed (to attain correct facial width and height) before orbital walls and rim correction.
7. Special attention should be paid to soft tissue repair and need for suspension, more particularly to fractures involving FNOE region.
8. Bicoronal exposure allows simultaneous harvesting of calvarial bone graft for bony augmentation and reconstruction like in blow-out orbital fractures.
9. Establish zygomatic arch as linear structure to get perfect facial projection and width.
10. Inadequate and delayed FNOE complex fractures treatment is usually a disaster and at most times is only partially correctable by secondary surgeries.

11. Preoperative arch impressions and splints fabrication have a major role to play in preventing oro-nasal communication and establishing facial width.
12. MMF is mandatory for proper occlusion intraoperatively. Elastics may be needed during follow-up.
13. Most common residual deformity associated with panfacial fractures is lack of projection, increased facial width, malocclusion, enophthalmos and lacrimal dysfunction.
14. Complete removal of all mucosa and blockage/sealing of fronto-nasal duct should be done before cranialisation or obliteration of frontal sinus.
15. Documentation of details of injury is essential of medico-legal reasons, more so of the mechanism and time of injury; these details if necessary can be noted from other observers. Photographs can serve as legal documentation. These should be taken following a valid patient consent.
16. Close soft tissues from deep to superficial and from intraoral to extraoral. Complete intraoral closure prior to securing the MMF. Debride contaminated wounds thoroughly before closure.
17. Forced duction test is essential before and during surgery in fractures involving orbital walls (Fig. 56.21).
18. Caution: removal of throat pack is a joint responsibility of the anaesthetist and surgeon.

60.12 Case Scenario

Case 1:
(Figs. 60.13a–d, 60.14a–f, and 60.15a–c) Shows Management of a Case of Pan Facial Fracture

Figure 60.13 shows the pre operative CT scans, Fig. 60.14 show the various surgical approaches used for internal fixation and Fig. 60.14 shows the post operative radiographs showing the fixation.

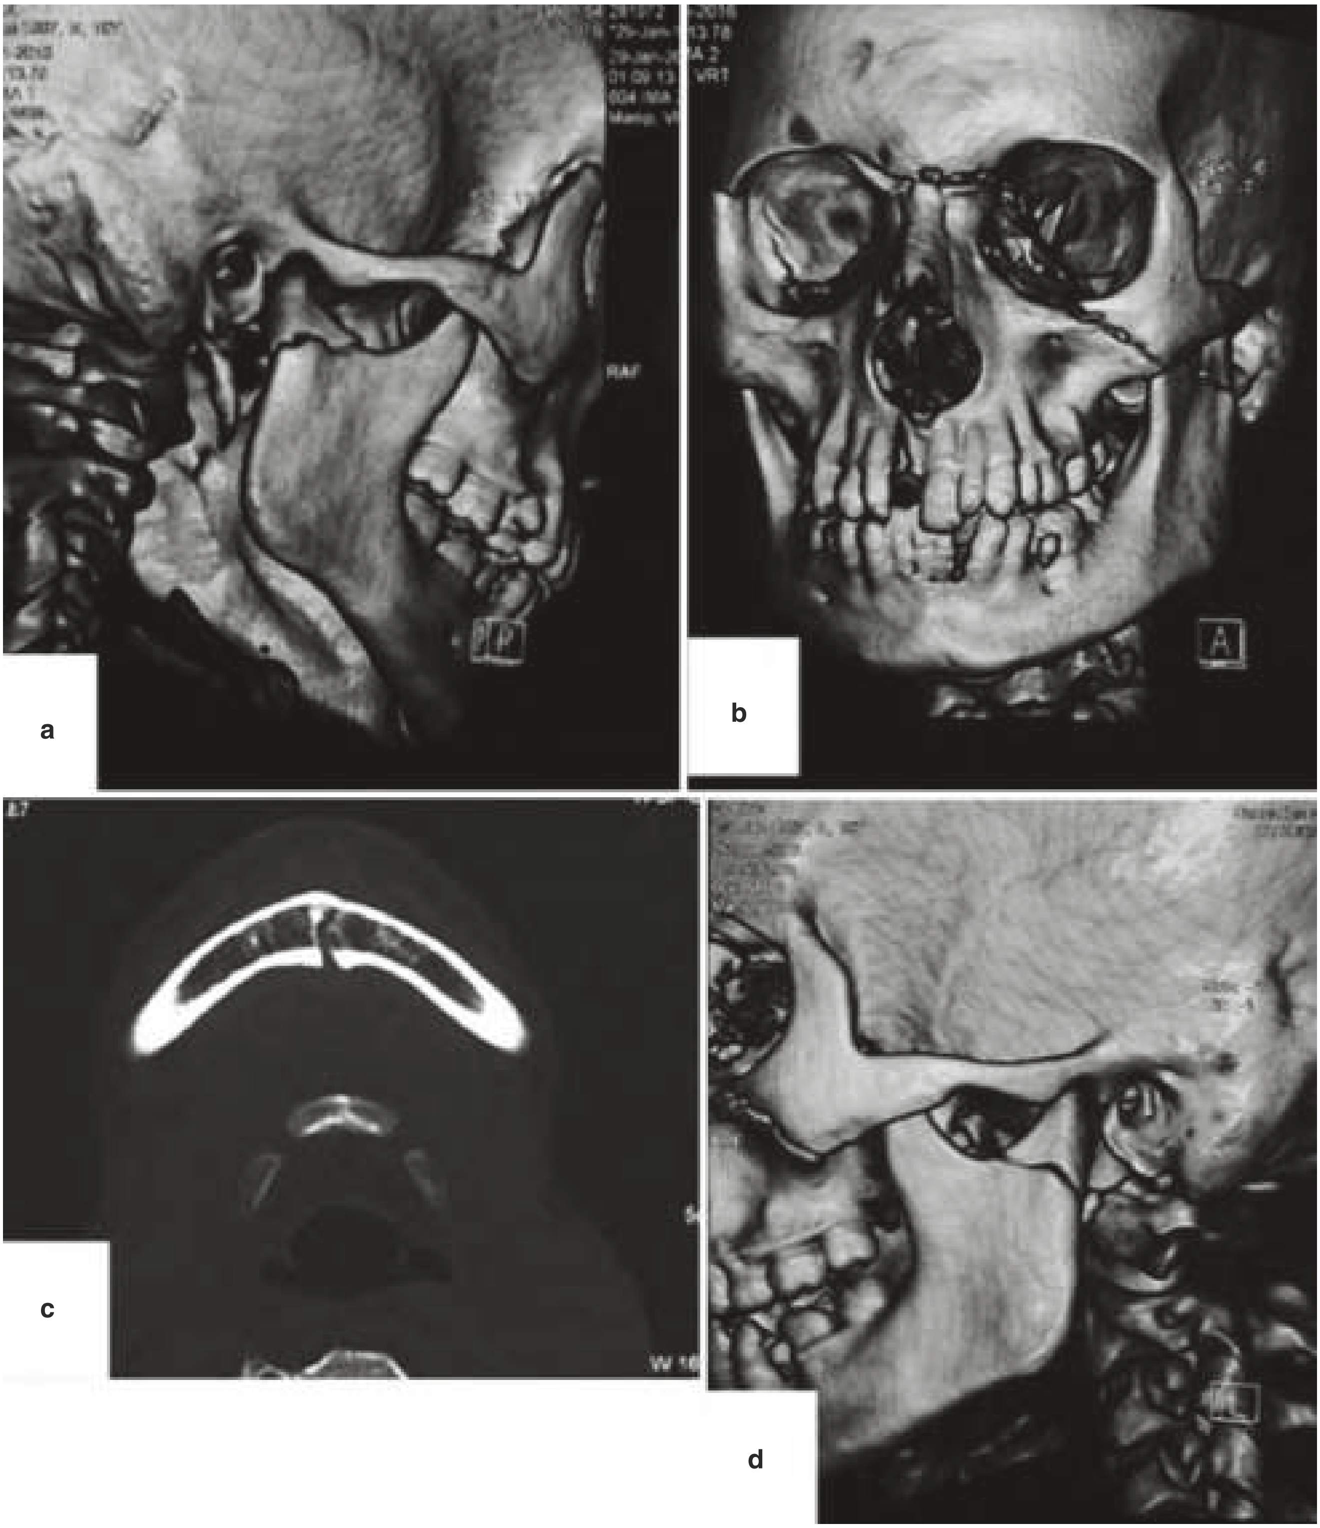

Fig. 60.13 (**a**–**d**) Panfacial trauma preoperative CT scan. (**a**) Right condylar fracture. (**b**) Naso-ethmoid complex fracture, left zygomatic buttress and infraorbital rim fracture. (**c**) Mandibular symphysis fracture. (**d**) Left condylar fracture

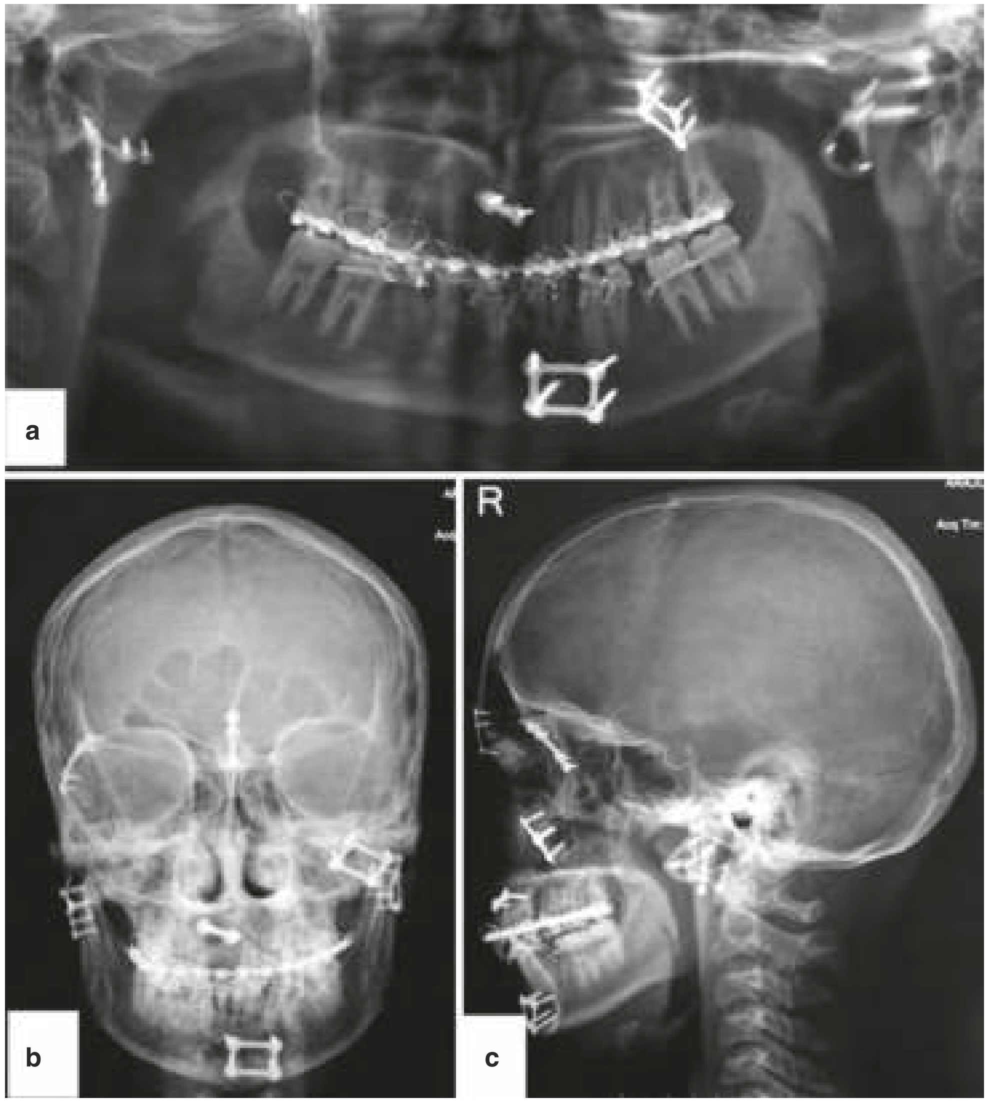
(**c**) Right condyle plating. (**d**) Symphysis exposure. (**e**) Right frontozygomatic fracture. (**f**) Naso-ethmoid fracture exposure

Fig. 60.15 (**a**–**c**) Panfacial trauma post-operative radiographs of case shown in Fig. 60.14. (**a**) OPG. (**b**) PA cephalogram. (**c**) Lateral cephalogram



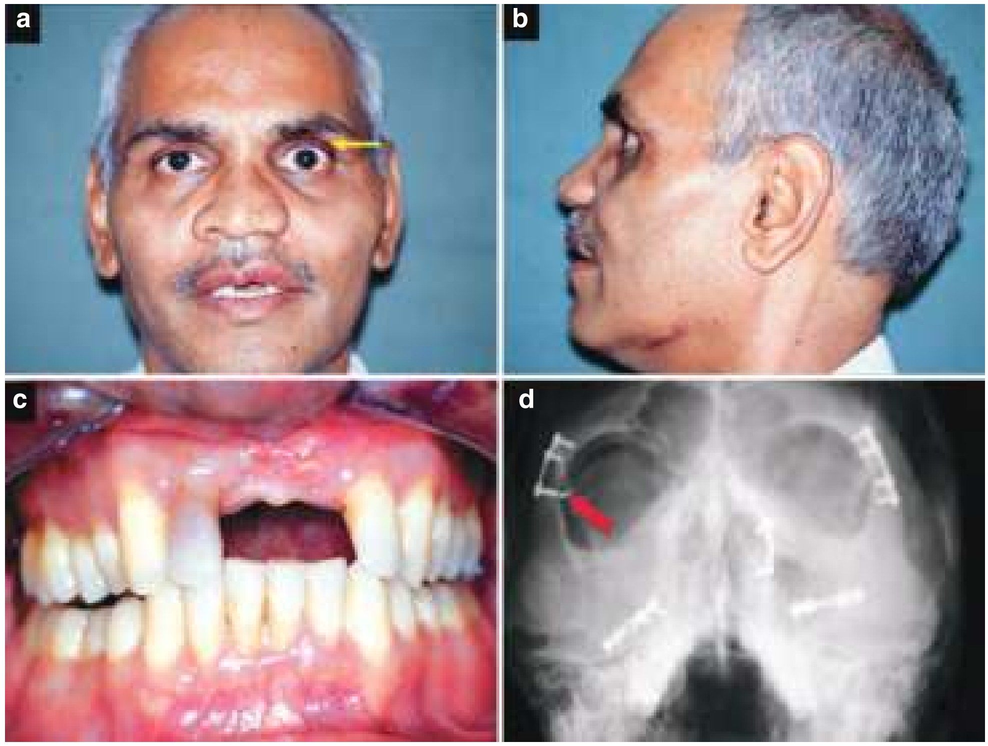


Fig. 60.16 (**a**–**d**) Pre-operative photographs. (**a**) Frontal view showing asymmetrical face, alar bases, lip and deepened supra tarsal fold (yellow arrow). (**b**) Lateral view showing upturned lip, increased vertical dimension, scar on left body of mandible. (**c**) Malocclusion with anterior open bite. (**d**) Pre-operative P.A. Waters view showing inadequate fixation of midfacial fractures and foreign body within right orbit (Red arrow)

Case 2 (Figs. 60.16a–d, 60.17a–e, and 60.18a–d)

Back ground:
This case was treated in 1997 by the first author, when CT scan was a novelty rather than necessity. Plating system used was stainless steel.

A 43 years male with no comorbidities was referred by dental surgeon for correction of malocclusion and asymmetrical face. Patient had a history of RTA with panfacial fractures, and head injury, cerebral oedema 3 months prior. He was treated conservatively for head injury and had no residual neurological deficit. He was treated by other specialist for panfacial fractures by ORIF and then referred to dentist for prosthetic correction of occlusion. Patient insisted upon simultaneous correction of occlusion and asymmetric face.

Patient reported with complaints of:
Inability to masticate, changed pattern of upper and lower teeth meeting , crooked nose with asymmetric nasal bases, sunken left eyeball, diplopia on superior gaze, and changed facial appearance compared to preinjury status.

Clinical Findings (Fig. 60.16a–d)

1. Significant change in facial appearance as compared to pre-trauma, pre-treatment appearance
2. Elongated face
3. Upturned upper lip and acute nasolabial angle
4. Deviated and depressed nose, with dissimilar alar bases
5. Enophthalmos with increased supratarsal fold left eye. (yellow arrow)
6. Changed pupillary levels, and excessive scleral show of left eye
7. Increased width of face more so on left side
8. Malocclusion, with anterior open bite, increased vertical dimension of face due to posterior and inferior displacement of maxilla with gagging.
9. Scars in Bilateral frontozygomatic, left infraorbital, left mandibular body region.
10. Left mandibular body fracture fixed adequately but patient had left marginal mandibular nerve paresis/ injury.
11. Total mobility of middle third of facial skeleton suggestive of non-union/malunion.

Fig. 60.17 (**a**–**d**) Intra-operative representative photos. (**a**) Fixation at FZ suture. (**b**) Fixation at inferior orbital rim. (**c**) Entrapment of inferior rectus, left orbital floor (yellow arrow). (**d**) Fixation of LeFort I fracture. (**e**) Fixation of bone graft to augment nasal bridge

Diagnosis:

1. Patient was counselled and asked to undergo X-rays to have 3 dimensional orientation. 1. PA Caldwell.
2. PA Water sinus (full face),
3. Base of skull for zygomatic arches and mandible.
4. Upper and lower occlusal topographic. CT scan of face with 3D reconstruction was not done for financial reasons. Remember CT scans were relatively expensive then.
5. Routine preoperative preparation.

Radiological Findings

Inadequate fixation seen at bilateral Fronto Zygomatic (FZ) suture, LeFort I,II,III level, and FNOE complex. A Foreign body (broken drill) was seen in Right orbit near FZ suture (red arrow). Mandible was fixed adequately both radiologically and clinically.

Plan of action/surgical approach (Fig. 60.17a–e)

1. Transmylohyoid intubation.
2. Mandible fracture being adequately fixed during previous surgery was not addressed
3. Mobilisation/osteotomy of midfacial skeleton to achieve adequate occlusion, projection of midface and reduce mid-facial width.
4. Approach midface fractures through existing scars at FZ suture, and left infraorbital region, subciliary approach to right infraorbital region.
5. Horizontal incision at nasal bridge for alignment of FNOE complex. (Fig 60.17e)
6. Intraoral sub labial approach for LeFort I fracture.
7. Iliac bone grafting at LeFort I level and nasal bridge to achieve prominence and augment the same.
8. Bone graft at left floor of orbit to correct enophthalmos and diplopia.
9. Alar cinch for flared left ala of nose.

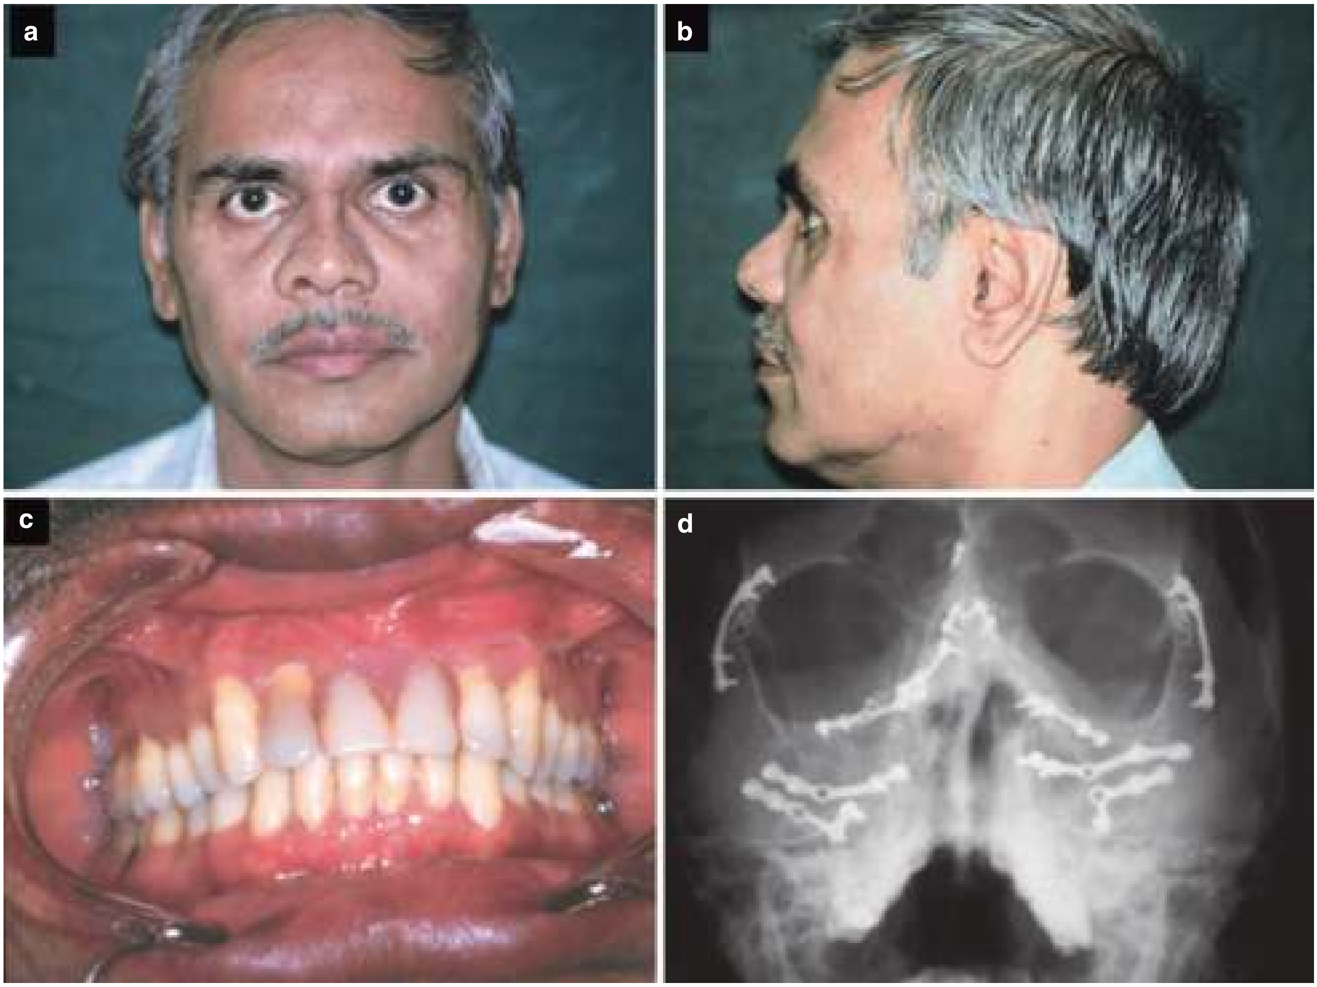

Fig. 60.18 (**a**–**d**) Ten years Post-operative photographs. (**a**) Frontal view showing restored symmetry. (**b**) Lateral view showing correct lip positioning, corrected vertical dimension, scar on left body of mandible. (**c**) Corrected occlusion. (**d**) Post-operative P.A. Waters view (Full face) showing adequate fixation of midfacial fractures at all the struts

10. Avoid MMF. Post-op X-ray (Fig. 60.18d) shows plating with wires, they were not removed as hardware used then was stainless steel so there was no issue of Eddy's current due to dissimilar metals.

60.13 Conclusion

The increasing number of RTA and related CMF injuries suggests the need for immediate attention from the concerned authorities, to enforce strict laws like mandatory use of seat belts and total head and face guard (that suit climatic conditions) rather than the conventional helmets. Restricting the use of mobile phones and head phones while driving may lead to decrease in the incidence of RTA. If RTA is considered an epidemic of modern times, then prevention is its vaccine. Increasing public awareness towards voluntary use of safety measures for their own safety rather than merely obeying the rules can reduce most of the cranio-maxillofacial injuries.

Panfacial trauma can appear complex and challenging to treat but is actually the conglomeration of treating individual fractures that are a common place in maxillofacial injuries (it would be wise to "simplify" the fracture in the minds' eye view and formulating a treatment plan). Adhering to a treatment protocol and treating each fracture as a unit, with adequate fixation, enable the surgeon to obtain good results. Development of a sequential and methodical treatment plan prior to surgery and adherence to the basic principles of maxillofacial trauma is vital in treatment of these patients.

61 Residual Deformities of the Maxillofacial Region

Samson Jimson

61.1 Introduction

A maxillofacial surgeon plays a vital role in not only restoring the structural form of the maxillofacial unit but also aims to restore the pre-traumatic functional status of the patient. Diagnosis, clinical evaluation with enhanced treatment planning and restoration of aesthetics and function is the key for any maxillofacial surgery. However, it is not always possible to achieve the most appropriate results in all cases. It is not uncommon to see failure or mediocre outcomes following maxillofacial trauma surgery. The outcome of the primary treatment may depend on factors such as the extent of the injury/defect, delay in diagnosis/management, improper treatment plan, lack of utilizing modern diagnostic/treatment planning utilities, poor execution of treatment plan and inexperience of the surgeon. These may lead to not expecting the eventful deformities and not coordinating with other specialists to yield the most standard and deserving treatment for the patient with restoration of both form and function [1–3].

Residual deformities are seen following primary treatment of trauma due to one more reason mentioned earlier. Correction of such residual deformities may be challenging to the surgeon but very often a life-changing experience for patients. It is the experience of the surgeon that helps to recognise the challenges ahead in restoring the form and function. Residual deformities are often evaluated by the extent of deformities following primary management. Apart from reasons that may pertain to the experience of the operating surgeon, pathobiology of the healing zone may also contribute to the residual deformities. A variety of such reasons contributes to both soft tissue and hard tissue defects in the maxillofacial unit. This chapter aims to discuss in detail the clinical evaluation, diagnosis, protocols, management and post-operative care of hard tissue deformities in oral and maxillofacial surgery with emphasis on current trends and future propositions.

61.1.1 Preventive Wound Management [4]

Wound management begins right after the soft tissue injury in the primary or acute stage.

Post-traumatic scarring can be reduced considering the following measures:

- Removal of foreign bodies/debris
- Reduce bacterial carriage by copious irrigation
- Judicious debridement to reduce the persistent scarring
- Management of the adjacent tissue with appropriate closure
- Tension free closure, minimising scar formation
- Wound care management by the use of agents that promote healing
- Prophylactic antibiotics in necessary conditions

Soft tissue injuries/scar revision/soft tissue and hard tissue reconstruction related to management of residual deformities have been dealt in detail in respective chapters of this book (refer Chaps. 36, 49, 86 and 88*). Wound care and management begin with preventive measures.*

61.1.2 Volume Issues in Deformities [3]

This section briefly discusses management of volume defects using tissue expanders. Volume issues are to be considered with all excision techniques. Loss of tissue volume due to trauma or contraction of the scar may lead to depression and

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_61

distortions that are more obvious than the original scar. Such loss of tissue may require volume replacement that can be achieved by other techniques. Surgical flaps may be commonly used to fill the tissues. Likewise, biological fillers can also be taken into consideration in managing depressed or irregular areas. Tissue debulking can be done whenever there is an excess of tissue volume.

Two methods of tissue transfer can be opted whenever there is loss of tissue: a free skin graft and a skin flap. A free skin graft of limited thickness involves the complete removal from the donor site and then placement on the recipient site for survival. This type of graft will not survive in avascular recipient sites. A skin flap with underlying subcutaneous tissue will carry its blood supply necessary for the survival of the flap. These skin flaps are further divided into local flaps or distant flaps (from distant sites). Single-stage transfer of flaps may be done with microvascular surgical techniques (Chart 61.1 shows types of soft tissue deformities with relation to the volume defects).

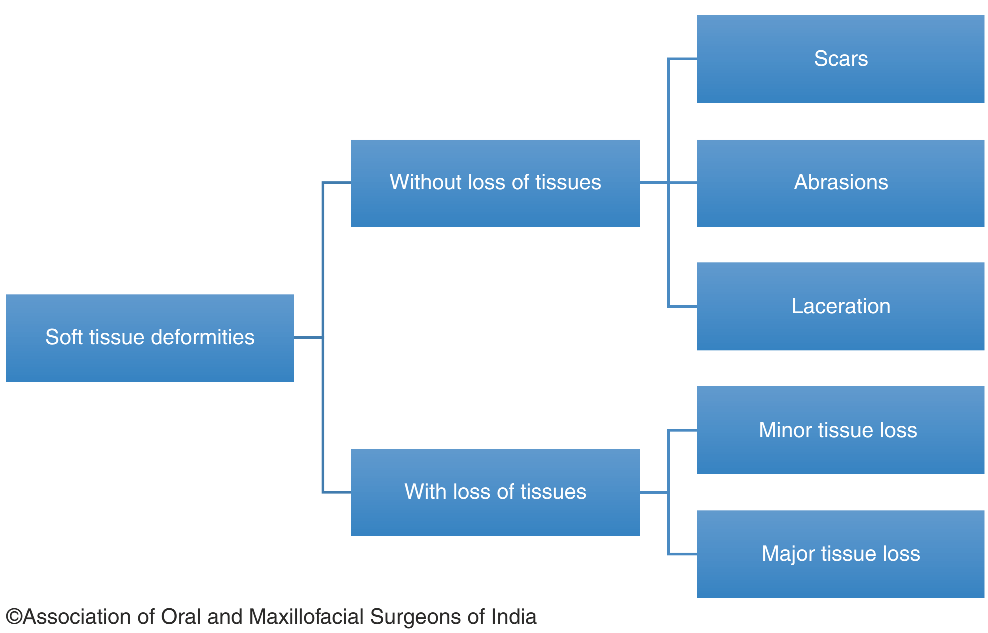
61.1.2.1 Minor Loss of Tissue [3]

- Local flaps should always be considered in case of minor loss of tissue. Facial tissue is naturally the first choice due to the colour and texture for replacement of tissue defects that are not too extensive. In such cases of local flaps, skin bordering the deformity should be raised and rotated into the defect, approximating the scar in a favourable position.
- Small scar defects may not yield a good result with split skin grafts, but full-thickness grafts can potentially give good aesthetic results in the repair of small defects.
- Lower eyelid scarring due to ectropion may be corrected using full-thickness graft (Wolfe's graft) that results in predictable function and aesthetics.

61.1.2.2 Major Loss of Tissue [3]

- Traumatic or gunshot injuries may result in a substantial loss of tissues. Majorly these injuries are associated with loss of soft tissue and skeletal structure.
- The replacement of tissue should involve necessary covering, lining and support to the bone or cartilage.
- Flaps used in all anatomical structures like the antrum, orbit, mouth and nose should have necessary lining epithelium; otherwise it will result in contraction of the tissues and exposure of underlying tissues.
- Complications like nasal airway stenosis, oral stenosis, microsomia and obliterated buccal/labial sulcus may occur.
- A split skin graft may be used in case of nasal or buccal defect.
- Double flap with both inner and outer aspects composed of full-thickness skin or subcutaneous tissue may help to increase the flexibility in case of a cheek flap. In such cases, the extent of fibrosis is decreased and thereby helps in increasing flexibility due to the underlying vascularity.
- *Nasal* lining may be provided by approximating the adjacent in-turned flaps of skin around the surrounding defects. A split skin graft should be preferred whenever such approximation is not possible. Hard tissue nasal deformities are discussed elsewhere.
- *Lip defects* may result in loss of larger tissue. Contraction due to lip re-suture may result in the loss of one-third of the available tissue. Local tissue flaps as full-thickness flaps should be considered ahead of tube pedicle flaps. Whenever permissible, it is better to take a full-thickness flap of the cheek or buccal mucosa, rotate it and form a lip and fill the subsequent secondary defect with tube pedicle.

Chart 61.1 Types of soft tissue residual deformities



- *Scar adhesions* of the sulcus or obliteration of sulci due to deficient tissues may predispose the difficulty in the construction of a functional and stable prosthesis. The fibrous scar tissue may be excised, or the sulci may be created with dissection followed by insertion of a free split skin graft.
- *Palate*: Substantial loss of tissue may involve the hard palate, soft palate or both areas. Generally, loss of tissue in the hard palate may be closed with an obturator. Scar tissue associated with the hard tissue defect may be managed by dividing the fibrous scar bands and restoring the residual tissues. Rotational flaps may also be used to close the defects. Tissues from additional sources may be used in the closure by using full-thickness flaps. Two-staged full-thickness flaps from the lateral third of the tongue are used, the base of which is divided after 3 weeks. In case of larger defects, myofascial temporalis flaps may be used with downward rotation, and following osteotomy of the zygomatic arch, it may be passed through a mucosal tunnel to reach the oral cavity. Both the flaps provide better results, but the advantage of the latter is being a single-staged technique [3].

61.1.3 Tissue Expanders [4–6]

Tissue expanders are the advised treatment technique when the loss of tissue or the scar surface areas are larger. It is indicated in revision or excision of scar where local or regional flaps may not be feasible to be used in the immediate reconstruction. Although commonly employed for tissue expansion in forehead and scalp, it may be beneficial for any areas with larger defects. Tissue expansion becomes an ideal choice in the scalp due to its inelasticity. It allows replacement of defects with adjacent surrounding tissue which is similar in colour, texture, adnexal structures and innervation (Fig. 61.1)

61.1.3.1 Properties of Tissue Expanders [4, 5, 7–9]

Silastic balloons with self-sealing valves which are used as tissue expanders are implanted beneath the skin.

- These tissue expanders are available in different shapes and sizes and can also be custom-made to fit an irregularly bordered defect.
- It is important to choose an expander of sufficient size to provide the necessary expansive force required for the need in tissue gain for reconstruction.
- The expander has to be 2.5 times that of the scar to be corrected while using a rectangular or crescent-shaped expander. On the other hand, the diameter of the base of the circular expander should be 2.5 times that of the scar to be replaced.
- The expanders must be implanted in a position where ideally a simple advancement, rotation or transposition flaps may be developed later.
- The goal is to have the adjacent healthy tissue expanded and not the scar itself. Hence, the proper placement of the tissue expander is vital.
- Scarred, atrophic areas or sites that have undergone prior radiation therapy are contraindicated.
- Sufficient expander volume must be available.

61.1.3.2 Biomechanical Properties

During the period of tissue expansion, a capsule is formed, and the epidermis is thickened and expanded. Increased mitotic activity is seen evidently using the microscope during the expansion. The dermal thickness, which decreases during the expansion phase, returns to normalcy in 2–3 years. Expanders may also result in decreased adjacent muscle thickness, but without any loss of function. The adipose cells may decrease in number, and subcutaneous thinning may also be seen. Viability of expander is maintained with increased angiogenesis. Bone remodelling may also take place beneath

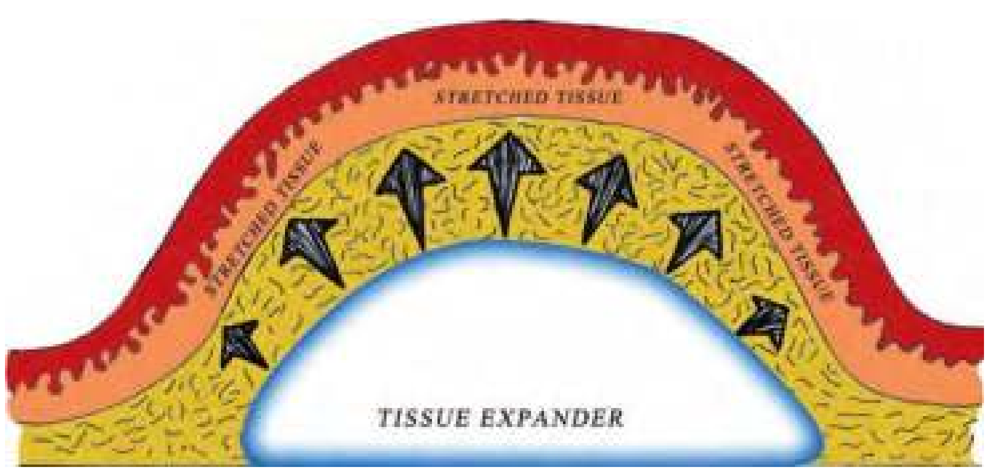


Fig. 61.1 Schematic representation of a tissue expander

the expander. The morphology and number of hair follicles are usually not affected, and hence this is a key in scalp expansion. Treatment duration can be reduced in areas where more than one expander can be placed. The gradual stretching of the tissue over the expanding subcutaneous tissue is called biological creep. Placement of the balloons and allowing a series of inflations and deflations to result in the stretching of the skin are the principles behind tissue expanders. This inherent nature of the skin to expand beyond its natural extensibility is referred to as mechanical creep [4, 10].

61.1.3.3 Technique

Expanders are implanted by making incisions at the junction of the scar and the healthy tissue. A pocket is made in an avascular fascial plane. Wound closure is done with layers over the expander. 10% volume of expander may be added at the time of surgery to minimise chances of hematoma formation around the expander. Necrosis of the overlying tissues may occur if any wrinkles are present over the surface of the expanders. If the site allows area for placement for more than one expander, it may reduce the overall treatment duration. Two weeks after placement, the expanders are inflated once or twice in a week. Patient discomfort or blanching over the surface of expander should be observed. Overexpansion of tissue is necessary as there will be a degree of contraction after removal of the expander. Likewise, bony contour changes usually regress without any intervention. The capsule of the expander is released along its margins but is left intact (Fig. 61.2). Generally, a waiting period of 2 weeks should be observed before proceeding to the next stage of the surgery/procedure. This allows the skin tension to reduce before the next stage of the surgery [4, 5].

Advantages

Local usage of tissue by expansion helps in the preservation of the sensation, vascularity and the adnexal structures. This aids well in both aesthetic and functional aspects.

Disadvantages

- Two operative procedures are usually required.
- Frequent inflation of the expanders.
- A temporarily visible deformity when the expander reaches its full inflation may not be socially acceptable by the patient.

Complications

- Pain
- Infection
- Implant failure
- Implant exposure
- Necrosis and tissue breakdown leading to exposure of the expander
- Bony erosion below the implant
- Decreased patient compliance and psychological stress for the patient as the expander increases in size creating a transient compromise in aesthetics

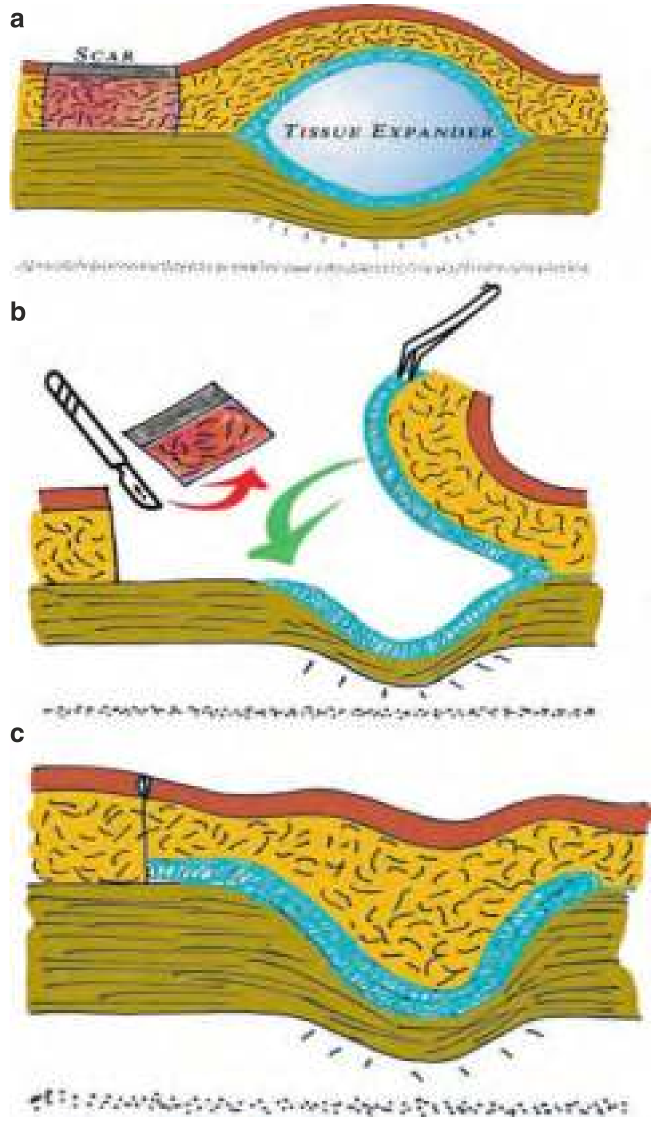

Fig. 61.2 Conventional method of tissue expander in management of scar tissue. (**a**) Expander placed near scar tissue and tissue expansion seen. (**b**) Adjacent scar tissue removed before closure. (**c**) Over-expanded tissue closed with adjacent scar tissue removed and the capsule is left intact with release along its margin

This chapter further discusses the use of grafts in residual deformities, management of hard tissue residual deformities and recent advances.

61.2 Grafts in Residual Deformity

Soft tissue and hard tissue defects are best managed by the use of grafts. Secondary or residual use of grafts and flaps is essential in restoring the hard tissue and soft tissue defects. The scope of this chapter briefly describes grafts used in residual deformities. This section also outlines the

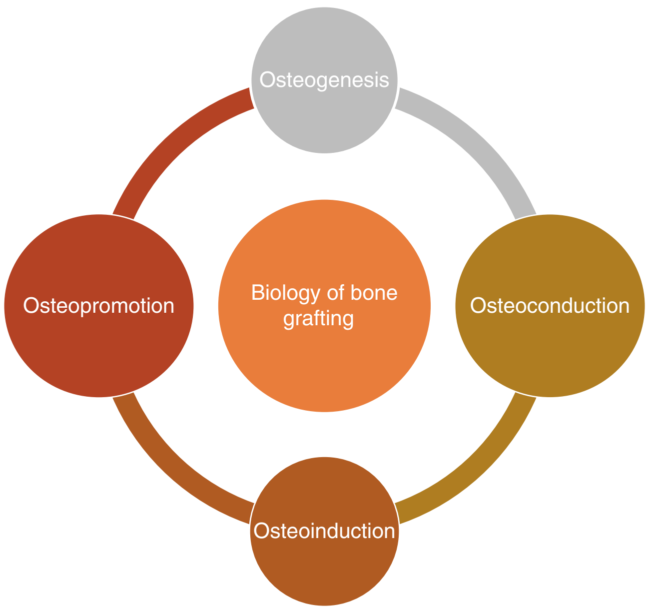

Chart 61.2 Essentials in biology of bone grafting

Table 61.1 Biology of bone grafting

Osteoconduction	Mechanism in which the graft substance serves as a scaffold for new bone growth aided by native bone. Osteoblasts from the source utilize the bone graft as a structural scaffold on which new bone generation takes place. A bone graft should be ideally osteoconductive. Ex: Calcium sulphate, calcium phosphate cements, ceramics, collagen, synthetic polymers
Osteoinduction	Mechanism involves stimulation of osteoprogenitor cells → differentiation into osteoblasts → formation of new bone. Ex: Bone morphogenic proteins. It is ideal to have grafts that are osteoconductive and osteoinductive in nature Ex: DBM (Demineralised Bone Graft), BMPs, growth factors, genetic therapy
Osteopromotion	Enhancing osteoconduction without osteoinductive properties. It promotes action and can't grow bone independently. Ex: Enamel matrix derivative enhances the osteoinductive property of demineralised freeze-dried bone allograft
Osteogenesis	Formation of new bone with the help of osteoblasts originating from the bone graft material. Ex: Bone marrow aspirate (BMA)

biology behind bone grafting and types of bone grafts (Chart 61.2).

61.2.1 Ideal Characteristics of Bone Graft Material [11]

- Biocompatible
- Promotes cell differentiation and proliferation
- Less risk of infection
- Non-toxic
- Non-immunogenic
- Maintains volume over time
- Balance in resorption rate and bone formation
- Ability to replace site with new bone growth

61.2.2 Biology of Bone Grafting

Biology of bone grafting includes the following rationale [12–17] (Table 61.1):
1. Osteoconduction
2. Osteoinduction
3. Osteopromotion
4. Osteogenesis

61.2.2.1 Types and Tissue Sources for Grafting (Table 61.2 and Chart 61.3)

Boyne's Ideal Characteristics of Bone Grafts [18]

- It should be easily and readily available and should not require additional surgical intervention in a second donor site.
- It should not stimulate any immunological response.
- It should stimulate rapid osteogenesis.
- It should enhance re-vascularisation and neo-angiogenesis.
- It should be highly osteoinductive.
- It should be osteoconductive in nature.
- It should not affect or impede bone growth.

Grafts play a major role in primary or secondary/residual management, eventually playing plays a vital role in reconstruction. Bone grafts in residual deformities are ideal to fill volume defects and also aid in reconstruction. Various types and sources of grafts have already been listed (Chart 61.3).

Table 61.2 Types of bone grafts

Type	Highlights
Autografts	• Bone grafting from the same individual • Bone harvesting from nonessential sites • Less risk of graft rejection • Osteoconductive, Osteoinductive and osteogenic • Requires an additional surgical site and risk of infection, pain and complications in the donor site • Gold standard and available in many forms
Allografts	• Bone grafting from another individual (Human donors). Bone is taken from cadavers. Although it can be from living donors, it is more likely to come from dead individuals • Properties may be limited due to preparation and sterilisation • Preparation removes risk of antigenicity • Limited risk of disease transmission • Osteoinductive • Gold standard and available in many forms
Synthetic variants	Artificial bone substitutes. Constitutes mineral to organic matrix ratio close to that of normal human bone. Grafts not taken from living donors
Xenografts	Grafts from species other than humans
Alloplastic grafts	• Strictly a synthetic bone substitute • Osteoconductive in nature • No risk of disease transmission • Unlimited graft options
Growth factors	Produced by recombinant DNA technology. Consists of human growth factors or morphogenic proteins

61.2.3 Bone Grafts in Hard Tissue Residual Deformities

61.2.3.1 Nasal Deformities [19]

- Bone grafts for nasal deformities can be readily obtained from cranial bone or iliac bone crest. Costochondral and tibial bone grafts have also been used earlier. Cartilage may be harvested from nasal septum. It may also be harvested from conchal bowl of the ear in case of septal bone loss. *Osteocartilaginous grafts are discussed in nasal reconstruction in detail.*
- Alloplastic materials used in nasal surgeries are silicone, Mersilene mesh, porous polyethylene, proplast, alloderm, etc. The usage depends on the type and size of defects and can be used alone or along with autogenous grafts.

61.2.3.2 Orbital Deformities [19]

- Autogenous bone grafts were earlier considered to be ideal for treatment of orbital floor deformities, but are currently replaced by alloplastic materials. Silastics are currently not considered due to reports of post-operative infection.

Most commonly used alloplastic materials in orbital reconstruction:

- Titanium mesh.
- High-density porous polyethylene implants (e.g. Medpore).

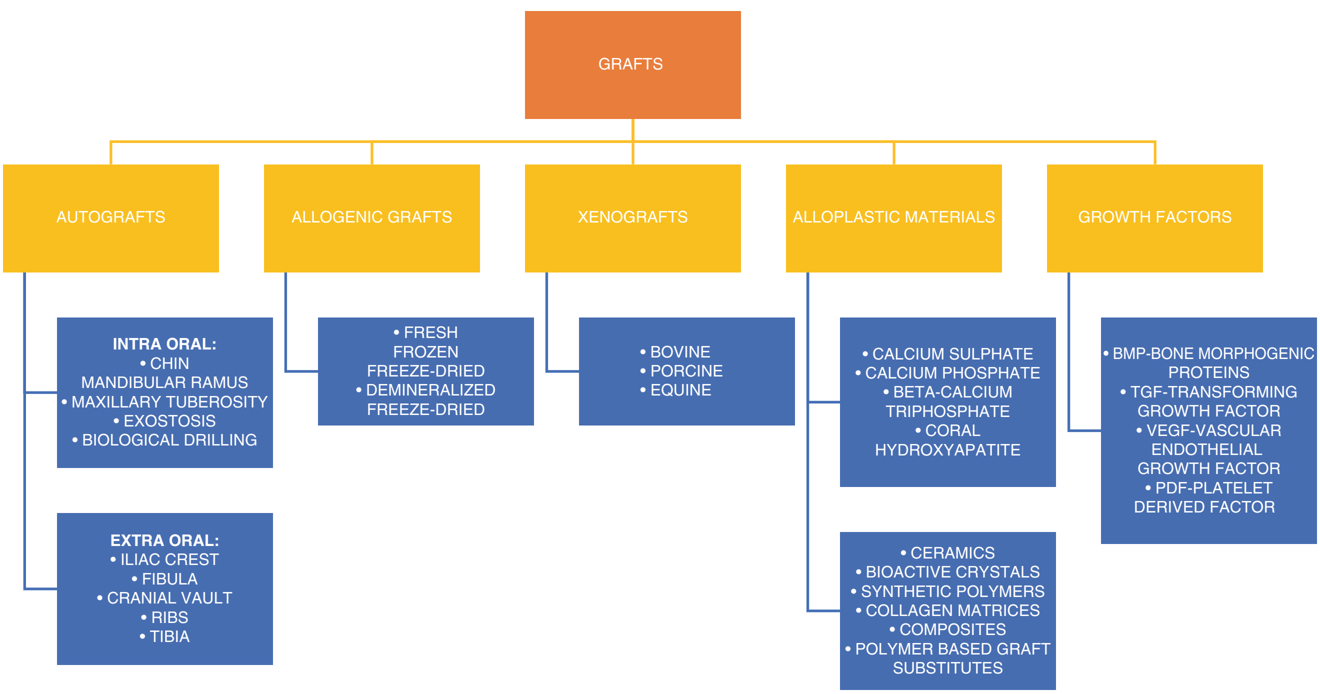

Chart 61.3 Sources of bone grafts

- Orbital floor implants are used by manual adaptation of implants according to the contour of the damaged site. However, custom designed implants with computer-guided surgical planning is best utilised in management of late deformities as there is time to assess, plan, design and custom manufacture the precise implants. Orbital titanium implants can also be manufactured by this method.

61.2.4 Alloplastic Materials [19–24]

Alloplastic materials have been used in surgeries since 1930s, and newer materials are available since then. Prime advantages of alloplastic materials are reduced donor site morbidity, easily usable, good patient compliance and shorter working time compared to autogenous grafts. Sources and types of graft materials are listed in Chart 61.3.

Goal of Alloplastic Materials
- *Biocompatible*
- *Resistant to infection*
- *Easy to use*
- *Cost effective*

Their role in maxillofacial reconstruction is still controversial. These porous alloplastic materials are high-density polyethylene implants that are very stable and flexible in nature and also help in new vascular and tissue growth within. This makes alloplasts an essential commodity in management of maxillofacial defects and also in reconstruction.

Alloplastic materials used in the region of defects for reconstruction are available in various forms like titanium mesh, porous polyethylene (Medpor) and PEEK (poly ether ether ketone) which can be customised as needed. *Medpore (stock)* can be manipulated and adapted in situ according to the defect. It is also possible to make *custom-made Medpore, silicone and PEEK* with the computer-aided designing. Even though they are known to produce good clinical outcomes, it may be predisposed to infection. Careful handling, understanding patient's history and surgical placement are essential to avoid any complications or to manage any failures. Medpore along with fat grafting may serve to restore the contour as well as the volume. These custom-made implants are widely used in management of defects and deformities as part of maxillofacial reconstruction. Applications of MEDPORE are chin augmentation procedures, correcting congenital deformities and improving aesthetic outcome in nasal, subnasal, paranasal, malar, orbital, and mandibular (angle and body) areas. It is essentially suited for midfacial contouring in patients treated for cleft. The use of these alloplastic materials ideally helps to establish three-dimensional anatomical harmony in correcting defects. Polyether ether ketone (PEEK) is another valuable alloplastic material that precedes with advantages similar to that of Medpore Custom-made patient-specific PEEK implants have proven to offer excellent facial rehabilitation. The durability and malleable property of PEEK make it a biomaterial of choice for maxillofacial surgeons with which complex maxillofacial defects following trauma or neoplastic can be corrected. Often, the use of alloplastic materials may be an adjunct or combined with prosthesis to further complete the facial rehabilitation process.

61.2.5 Use of Grafts in Associated Residual Structural Damages

Traumatic or iatrogenic reasons causing structural or residual damages are areas of concern during maxillofacial surgery. Important structural damages involving nerve tissues, salivary gland apparatus and nasolacrimal system should be identified and best managed during the primary surgery. If left untreated, secondary or delayed management leads to further complications. It is the skill of the surgeon to carefully carry out the surgery with no or minimal trauma to adjoining structures, and it is experience that will help to predict any relative functional damages and manage it accordingly.

Nerve Injuries: Injuries to the peripheral branches of the trigeminal nerve following maxillofacial trauma or surgery often result in sensory and functional problems. Spontaneous recovery of inferior alveolar nerve and infraorbital nerve after facial fractures depends on a number of factors like age, gender, fracture displacement, site, type of management and time interval between injury and management. Localisation and determination of the pattern of injury of trigeminal nerve are done by careful examination of the neurosensory dysfunction (NSD) of sensory dermatome of trigeminal nerve. It may be very difficult in establishing the exact cause in secondary NSD damages. Such residual defects due to injuries can be from nerve compression due to displaced old fracture segments, laceration due to fracture components, dislocated nerve from a displaced fracture, and compression due to soft tissue oedema or secondary ischemia. Injuries may also be related to crushing, avulsion and partial or total nerve transection [25–28].

Determining the exact aetiology of post-operative residual or secondary NSD damage is difficult, and the best way to manage is assessing the damage during the primary surgery. Accessing and operating the site for correction secondarily may itself cause further damage if not handled properly. Nerve grafts can be used in the management of such damages. It involves microsurgical repair of nerve that requires reconstruction of any continuity defect using an autogenous nerve graft (*donor site—sural or great auricular nerve*). Microsurgical repair helps in improving the clinical outcome in such conditions. Nerve allografts have proven to be successful in improving the neurosensory recovery. Allografts are further beneficial as it alleviates the donor site morbidity. Ichihara et al. suggest the use of alloplastic tubes in short span nerve defects as artificial nerve guides. However, studies need to ascertain their use in long span trigeminal nerve defects. Similar use of autogenous and allogenic grafts is applicable for facial nerve injury as well. The successful outcome of grafts depends on the length/size of the defect and patient factors like age/gender/nutritional status, and it is also important to address factors like previously irradiated sites [29–32].

Salivary Gland/Duct Injuries: Trauma, lacerations, deep injuries and iatrogenic injuries in the parotid region can result in injuries to the important related structures like the buccal branches of facial nerve, Stenson's duct and transverse facial artery and vein. Surgical and non-surgical management of injuries to the salivary gland or its duct is done to improve the clinical outcomes. Non-surgical management includes the use of anti-sialagogues, elastic bandages and reduced oral intake until the defect heals. Microsurgical repair may be done to preserve remaining ductal structures using autologous vein grafts. Reconstruction of the duct is done using autologous vein grafts like saphenous vein, antebrachial vein, facial vein, etc. Alloplastic Gore-Tex has been used, and the outcome was found to be similar to anastomosis in autologous vein grafts in parotid duct reconstruction. Gore-Tex tube carries advantages like decreased graft morbidity and shorter operation time. Timely correction of salivary ducts is important to avoid complications like sialocele, salivary fistula, etc. [33–38].

Nasolacrimal Duct Injury: It is important to reconstruct the nasolacrimal system if damage is seen following orbital or midface trauma. It is similar to other ductal and nerve management. The nasolacrimal duct system can be reconstructed with autogenous and allogenic grafts. Greater saphenous vein can be used as autogenic grafts in such cases. Buccal mucous membrane grafting also shows improved outcomes in removing obstructions in the ducts. Silicone stent intubation is also used in the repair of damaged nasolacrimal duct. Primary management is essential in this condition since delayed management may be difficult to carry out [39–41].

Future of Grafting

Future in grafting promises advances in gene therapy, tissue-engineering, and 3D scaffold. It has created greater perspective with the inclusion of growth factors, stem cells and biological scaffolds that will help in production of laboratory-engineered tissue substitutes in oral and maxillofacial surgery.

Three-dimensional (3D) computed tomography (CT) has brought major changes to visualisation, planning and treatment of maxillofacial defects ever since its introduction. The scanning and surgical planning software have advanced in such a way that a surgeon can meticulously plan a patient-specific protocol to carry out procedures effectively. Preformed and custom printed alloplastic has more accuracy, reduced operative time and a predictable outcome in management. However, conventional implants require intraoperative adaptations and longer duration of operation. All these have been possible with the advances in reconstructive surgeries with CAD-CAM (computer-aided design-computer-aided modelling) software. Such major advances will lead to further improvement in patient-specific implants (PSI) in the three-dimensional management of defects in reconstructive procedures [23, 24, 42, 43].

61.3 Hard Tissue Deformities

Deformities in the maxillofacial bones are due to a variety of causes like pathology, trauma, infection and congenital disabilities. Residual deformities are such defects that are observed even after the primary surgical management and need further cosmetic and functional intervention for an outcome. The size of the defects in the maxillofacial region may vary from small alveolar clefts and nasal deformities to maxilla-mandibulectomy-type defects. Restoration of the deformities to its closest healthy anatomical structure and their essential functioning are the primary goals of any re-intervention procedure.

Any defect (size, shape, position or amount) of the osseous structure can be replaced by reconstructive surgery. The aim is to replace it with the missing structure, i.e. the bone. Various types of bone grafts may be used for this purpose. Correction of soft tissue defects needs a complete understanding of the wound healing biology. Likewise, in hard tissue deformities, it is essential to know the bone physiology, immunology and surgical principles to make the reconstruction a successful procedure.

61.3.1 Patient Assessment

Although general rule implies to replace or reconstruct the lost osseous defect, it is important to evaluate every patient thoroughly before proceeding with any intervention. Analysis should include evaluation of hard tissue and associated soft tissues. When accompanied by soft tissue deformities, it is important to treat with caution considering the soft tissue changes over time as well [44].

61.3.2 Residual Mandibular Deformities [3, 45–50]

General Assessment Points for Mandibular Defects:

- Careful and complete clinical examination.
- Necessary radiographs to assess the amount of osseous defects.
- Site and size of the defect to be taken into detailed evaluation. Such evaluation is of utmost importance in mandibular osseous defects.

Causes for Post-traumatic Mandibular Deformities:

- Poor diagnosis
- Improper surgical methods—inadequate reduction and/or fixation
- Infection
- Healing disorders

Residual Deformities in Mandible:

- Causes like trauma, gunshot wounds and infection may result in loss of a portion of the mandible.
- Loss of tissues results in functional and aesthetic concerns. Small deformities may often go unnoticed.
- Loss of a portion of the alveolar process leading to loss of teeth is a less serious complication.
- Malunion of mandibular fractures can often result in serious consequences in occlusion among adults and children. More serious changes may affect the mandibular growth in children following condylar fractures.
- Loss of anterior attachment of the tongue due to tissue loss causes an airway hazard that needs to be corrected primarily.
- Loss of bone in mental region or large areas:
  - Difficulty in speech
  - Difficulty in swallowing
  - Drooling of saliva
  - Un-aesthetic appearance

61.3.2.1 Deformity in the Ascending Ramus of the Mandible

No treatment is often required if the occlusion is satisfactory. Complete fusion of the bony segments to the temporomandibular joints may occur following the destruction of the developing mandibular condyle after trauma or secondary infection. In this case, the destruction of the articular disc allows the contact between the bony fragments of ascending ramus and the glenoid fossa, finally resulting in ankylosis. When this occurs in children bilaterally, it shows reduction in lower third dimension resulting in appearance called “Bird Face deformity”. This usually results in aesthetic and airway concerns, and psychological disturbances. Airway disturbances should be viewed with greater importance. Ankylosis in adults will result in occlusal abnormalities and difficulty in enunciation of speech and communication. Sometimes pseudo-ankyloses may also be observed.

61.3.2.2 Surgical Options for Post-traumatic Residual Deformities

Post-traumatic deformities include *non-union, malunion/malocclusion and facial asymmetry*, and they may require secondary correction. These deformities can occur alone or in conjunction, sometimes as a sequel to a deformity.

61.3.2.3 Non-union [45–50]

They are fractures with arrested healing that requires further surgical treatment for correction. It is considered to be non-union when a fractured segment is mobile for 4 weeks without treatment or 8 weeks after surgical treatment.

Causes for Non –union	
• Soft tissue infection	• Improper reduction
• Large fracture gaps	• Delayed treatment
• Comminuted fractures	• Teeth in the line of fracture
• Severe atrophic fractures	• Smoking and alcohol abuse
• Osteomyelitis	• Poor treatment planning
• Movements	• Inadequate surgical skills
	• Poor patient compliance

Diagnostic considerations:

Clinical Examination:

- Identify persistent mandibular deformity.
- Tenderness at fracture site.
- Malunion in closed reduction techniques may be identified after release of maxillo-mandibular fixation.

Radiographic Findings:

Irregular radiolucency with mottled fracture ends.

Management:

- Extra-oral approach is the best option as it allows good visualisation. Transoral approaches may be considered in indicated cases.
- It is followed by the debridement for removal of any fibrous tissue, necrotic bone or failed hardware.
- Following this, adequate occlusion and maxillo-mandibular fixation is achieved. The fracture is reduced,

and then reconstruction plates are fixed with the help of screws away from the fracture.

- Considering less mineral (even though appearing normal) content in the site near the fracture, it is recommended to place screws no closer than 7–10mm.
- Autogenous bone grafting may be used to re-establish continuity of mandible in areas where the bone contact is inadequate.
- In younger patients and well-vascularised areas, union of small gaps is successful.

61.3.2.4 Malunion/Malocclusion: [46, 51, 52]

It can occur in any type of mandibular fracture when segments heal in improper alignment. Malunion is often due to inadequately established occlusion, inadequate anatomic reduction and poor adaptation of fixation plate.

Figs. 61.3, 61.4, 61.5, and 61.6 depicts malocclusion related management of deformities.

Diagnostic Considerations:
It is often diagnosed with malocclusion and more associated with rigid internal fixation. Dental models are used to study and plan the occlusion.

Management Considerations:

- Revisit of the surgical site may be necessary to correct the errors due to rigidity.
- Minor occlusal corrections can be done with orthodontic treatment.

Fig. 61.3 Malocclusion following trauma surgery with multiple loss of teeth in mandible and associated osteonecrosis. Fig. 61.5 Post-operative OPG

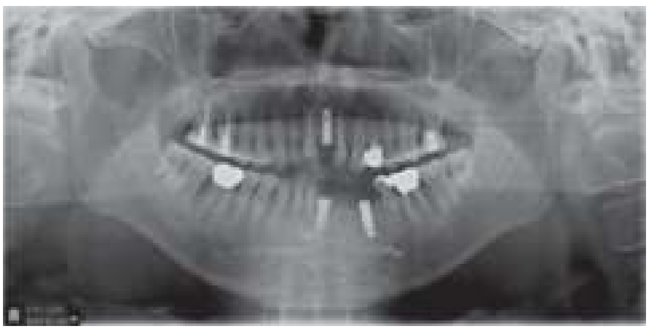

Fig. 61.6 Post-operative OPG after implant placement for dental rehabilitation

61.3.2.5 Early Malunions

- Surgical approach is similar to the primary treatment.
- Old hardware is removed → adequate occlusion achieved → with maxillo-mandibular fixation → fracture reduction if necessary → new fixation is done → new occlusion is verified with release of the fixation.

61.3.2.6 Late Malunions

- Surgical approach is determined based on type of osteotomy.
- Study models are used to study the occlusion and plan a mock surgery.
- Management includes osteotomies for proper establishment of anatomy and occlusion.
- Mandible is re-fractured → occlusion is achieved with the help of a surgical splint → maxillo-mandibular fixation is obtained → new rigid fixation → occlusion is verified after the release of maxillo-mandibular fixation.
- Bone grafts may be used to close gaps whenever necessary.

61.3.2.7 Malunions/Malocclusion and Condylar Fractures [53–56]

- Majority of condylar fractures when treated "closed" may develop malunion. However, condylar malunion may not always cause malocclusion.
- Quality of the functional rehabilitation of the mandible is an more important factor than the type of treatment (closed or open).

Diagnostic Considerations:
- Radiographs and malocclusion are key in examination.
- No treatment or previous unsuccessful treatment is a main reason for malocclusion following condylar fractures.
- Degree of mandibular ramus deformity is essential to determine the necessity for a re-surgery to correct malocclusion following condylar fracture.

Treatment Considerations:
- Unilateral or bilateral fractures.
- Time period between fracture and treatment of malocclusion.
- Availability of remaining stable dentition.

Management Considerations:
- *Minor occlusal discrepancies* may be treated with orthodontics, prosthetic rehabilitation, reconstruction and occlusal adjustments if indicated.
- *TMJ reconstruction* may be indicated—when the remaining ramus is short with multiple fragments and large movements are required to correct occlusion.
- *Orthognathic surgery* may be indicated in long-standing malocclusions.
- *Functional therapy* can be done up to 3 months for management of malocclusion.

61.3.2.8 Facial Asymmetry [46]

- Usually as a sequel to malunion, non-union and inadequate fixation.
- A number of clinical scenarios may present itself to facial asymmetry

Diagnostic Considerations:
- *Early stages*: Difficult to diagnose because of the swelling.
- Antero-posterior cephalometry or CT scans are confirmatory.
- Facial, dental and radiographic analyses are done.

Management Considerations:
- Treatment similar to malunions and malocclusions.
- In cases where the defect is diagnosed early, the mandible can be approached through the initial surgical wound, the hardware may be removed, mal union corrected and new fixation can be placed.
- Orthognathic surgeries in cases of established facial asymmetries. Surgical splints and model surgeries help in

surgical planning. Asymmetry is corrected, and new occlusion is verified with new fixation. The procedure similar to principle treatment. Additional osteotomy may be required depending on the type of original injury.

61.3.2.9 Principles of Mandibular Reconstruction [45, 57]

Reconstruction of larger defects of the mandible is discussed in Chap. 88.

Marx and Saunders listed the goals of mandibular reconstruction in order to consider a grafting procedure successful.

- *Restoration of continuity* is the key since the mandible is a bone with two articulating ends supported by muscles with opposing forces. Deviated mandibular segments need to be realigned not only to improve facial aesthetics but also to restore essential function movements.
- *Restoration of alveolar bone* is another essential aspect to aid in the functional rehabilitation of the patient. The process of mastication and the efficiency to masticate are possible only once the necessary alveolar bone height has been obtained. In patients with osseous defects, this helps in the placement of a prosthesis.
- *Restoration of osseous bulk* is vital to provide the required amount of osseous tissue to withstand forces and perform normal function. Fracture of the graft area may occur when the area is too thin, lacking the bulk to withstand functional forces directed towards the bone.

©Association of Oral and Maxillofacial Surgeons of India

Fig. 61.7 Highlighted (yellow) areas represent midface region

61.3.3 Midface Deformities [3, 58]

The midface is a critical zone of the maxillofacial region concerning both aesthetics and function. Midface includes structures like the maxilla, palate, orbit, cheek, upper lips, eyelid and nose. It is often an area that poses a significant challenge to a maxillofacial surgeon for reconstruction. Orbit is usually challenging to reconstruct in secondary setting mainly due to chances of scarring. Due to the difficulty in obtaining good results in primary surgery, the nose and auricle are best considered for correction in a secondary setting. Figure 61.7 shows areas of the midface.

Objectives in Correcting Midface Deformities [58]

- Restoration of midface projection
- Restoration of occlusion
- Providing support for the orbit
- Filling the volume of the orbit
- Restoration of palate competence
- Restoration of functional harmony

Along with the reconstruction of the hard tissue, it is important to correct associated soft tissue defects as well. Failure to correct the primary deformities may result in sequelae of defects of the associated soft tissues and end up in affecting the functional quality of life of the patients.

Indications to Correct Midface Defects [58]

- Untreated/avoided defects during primary reconstruction
- Poor result following primary reconstruction (partial or complete loss of flap, non-union of bone, oro-cutaneous fistula)
- Poor outcome in primary reconstruction due to poor planning
- Post-operative complications that may lead to hematoma and scarring

Diagnostic Workup: [58]

Treatment planning for midface changes requires careful planning and knowledge of previous treatments to achieve the best result.

- Evaluate general status of the patient (age, history of tobacco, alcohol abuse, nutritional status, and presence of co-morbidity)

- Accurate assessment of anatomic defects
- Assessment of quality of tissue involved, surrounding tissues and status of scar
- Availability of healthy surrounding tissue

During the workup, it is necessary to eliminate cases of unresectable conditions like distant metastasis or recurrence in oncology or non-traumatic cases.

Diagnostic Assessment: [58]
Assessment requires evaluation of surface or volume of missing tissues. Assessment should include evaluating defects in the bone, skin, musculature, innervation and mucosa (Chart 61.4).

Treatment Options: [3, 58]
Surgical correction in this region varies from prosthetic replacement to complex microvascular reconstructive surgeries.

Surgical Options:
- Local or regional flaps for small to moderate defects.
- Secondary free flaps: iliac crest flaps, fibula flaps, subscapular free flaps.
- Microvascular surgeries are primarily done in major defects.
- Microvascular flaps provide adequate and necessary amount of well-vascularised bone and/or soft tissue augmentation, thereby enabling a better 3D fitting flap and closure.

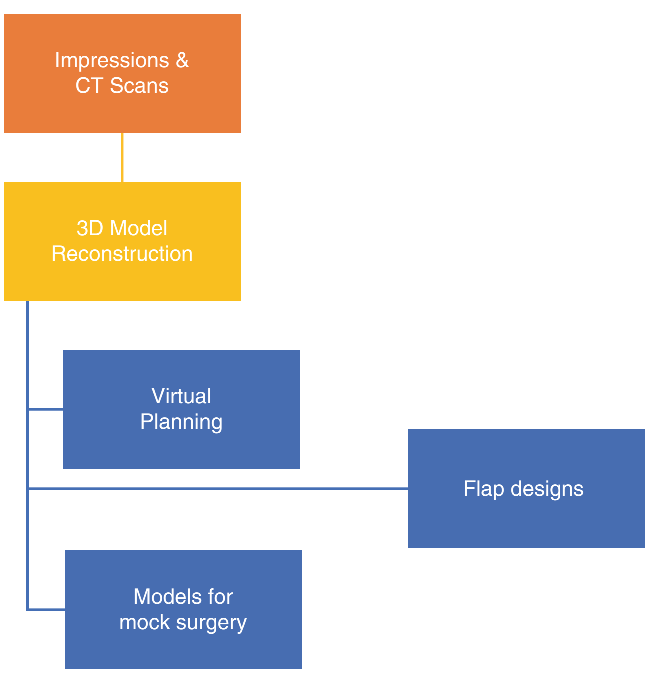

Chart 61.4 Diagnostic assessment

- Critical evaluation is to be done in previously irradiated or operated midfacial defects.

Current methods under development include tissue engineering for ideal regeneration of the tissues in head and neck defects. Facial transplantation has also paved newer paths in this field, but indications are restricted.

Other Non-surgical Options: [58]
Maxillofacial prosthesis:
- Palatal obturators in maxillectomy cases.
- Complex defects affecting structures like the nose, orbit and those which cannot be restored with flap reconstruction may be managed by maxillofacial prosthesis. Recent advancements include supporting the prosthesis with dental implants.

Ancillary Procedures: [3, 58–61]
- Additional supportive techniques may help to improve the outcome of a correction in midface re-operative procedures.
- CT images are useful in designing adequate fronto-orbital facial contours.
- Free bone grafts for facial contouring are indicated for upper midface defects. The bone grafts can be obtained from calvaria and synthetic implants—porous polyethylene, methyl methacrylate and titanium mesh. However, it is contraindicated in a previously irradiated area and in cases of oral cavity communication.
- Combination of titanium mesh and soft tissue may be helpful to provide support for the globe.
- *Liposuction* is an excellent alternative technique to fill certain residual defects following midface reconstruction. Microvascular flaps may help fill residual flattened areas.
- *Distraction osteogenesis*: Mainly indicated in mandibular repair, it is also used in the repair of minor maxillary bone defects which cannot be treated with bone flap reconstruction (refer Chap. 87).

Oral Rehabilitation:
- Implant-supported prosthesis with good osseointegration is often considered as the best option in oral rehabilitation. Peri-implant hygiene and osteointegration are important for the success of dental/zygomatic implants in oral rehabilitation procedures.
- Dental implants are most helpful for oral rehabilitation. Implants may be placed during the primary reconstructive procedure or preferably as a secondary procedure.
- Zygomatic implants may also be used when regular alveolar bone reconstruction is not possible.
- Implant placement in previously irradiated areas may not give the best results, and hence it is a contraindication.

61.3.4 Residual Maxillary Deformities [3, 58]

Goals in Correction of Maxillary Deformities
- Restoration of function
- Restoration of occlusion
- Restoration of original relationship between thirds of the face

Common Maxillary Deformities May Be Due to:
- Malpositioned maxillary fractures
- Undiagnosed fractures—untreated dislocated fractures
- Severely comminuted fractures with associated damages
- Untreated old fractures
- Edentulous displaced maxilla
- Post-traumatic hypertelorism

Essentials for Treatment Planning:
- Preoperative *photographs* (full face, profiles pictures, frontal and lateral views of occlusion, palate, floor of the mouth and other required projections).
- Detailed *clinical assessment* and treatment of other existing carious and inflammatory conditions of the oral cavity.
- *Models and radiographs*—OPG, lateral cephalometric X-rays
- Current imaging and planning techniques: CBCT helps in *3D virtual planning* to design flaps and to create 3D models for planning and mock surgery (61.5).

61.3.4.1 Immediate Repositioning of Maxilla and Midface Complex

Open Surgical Immediate Mobilisation Treatment: This is indicated in conditions where total mobilisation is not possible. These are cases that are treated after 6 weeks or more after trauma, or even years later, usually cases where partial or complete consolidation has already taken place. The principle of surgical treatment is often the same as in the treatment of primary maxillary and midface treatments.

Old Fracture Segments: Old fracture segments in the anterior maxilla can be corrected by techniques described by Wassmund (1935) and Wunderer (1962) in cases of protruded maxilla. It is key to observe any scars in the labial vestibule as that may affect the vasculature to the alveolar process. Wassmund's method should be preferred when a scar is present; otherwise, Wunderer's method may be followed in which maintenance of labial blood supply is essential. In contrast, Schuchardt K suggested a single-stage technique which involved an osteotomy of the lateral alveolar process and relocation to its original alveolar location [62–64].

61.3.4.2 Old Le Fort I and II Fractures [3]

Untreated Le Fort I Fractures: An incision may be made at a point horizontally through lateral and anterior maxillary sinus walls. Osteotomy is done to ensure that the plates are placed on both sides of the stable bone region. Line of osteotomy does not precisely follow the line of fracture.

Old Le Fort II Fractures [3]: If there's no cosmetic significance or less damage to the nasal region—similar procedure may be followed. Le Fort II osteotomy is indicated when the nose has sunken, and the midface is shortened.

In the above scenarios, Le Fort I and II osteotomies may be done when either occlusion needs to be restored or there is an aesthetic concern. Bone grafts may be used in the region of the bridge of the nose below the buttress and also between pterygoids and the maxillary tuberosity if possible (Figs. 61.8 and 61.9).

61.3.4.3 Displaced Edentulous Maxilla [3]

- *Minor displacements* may be corrected with osteotomies, only if the disturbance along the intermaxillary relationship in the sagittal plane is minimal. Otherwise, it is justifiable to treat with a prosthesis.
- *In case of severe displacements* of maxilla which results in the appearance of a skeletal Class III, the maxilla has to be surgically replaced to its original place with the help of bone grafts.

61.3.4.4 Old Le Fort III Fractures (Figs. 61.10 and 61.11)

Le Fort III osteotomy is indicated in old Le Fort III fractures when the deformities may be seen in the entire midface region with dislocations in orbital margins and zygoma. Unilateral osteotomy may be indicated when only one side of the face is affected. Occasionally in cases of comminuted fractures of the midface, a Le Fort I osteotomy may be needed to be done along with Le Fort III osteotomy procedure. This is essential to correct the occlusion in untreated midface fractures. It may be challenging to carry out a re-treatment for comminuted midface fractures. Segments may be stabilised separately considering the complex nature of the fracture. The procedure can be simplified by first mobilising the entire midface complex with Le Fort III osteotomy and then followed by Le Fort I osteotomy (Figs. 61.12, 61.13, 61.14, 61.15, and 61.16 shows surgical management of a mid face deformity by onlay grafting; All images 61.12–61.16 are from the same patient) (Figs. 61.17, 61.18, and 61.19 shows clinical images of management of post operative malocclusion; all images 61.17–61.19 are from the same patient).

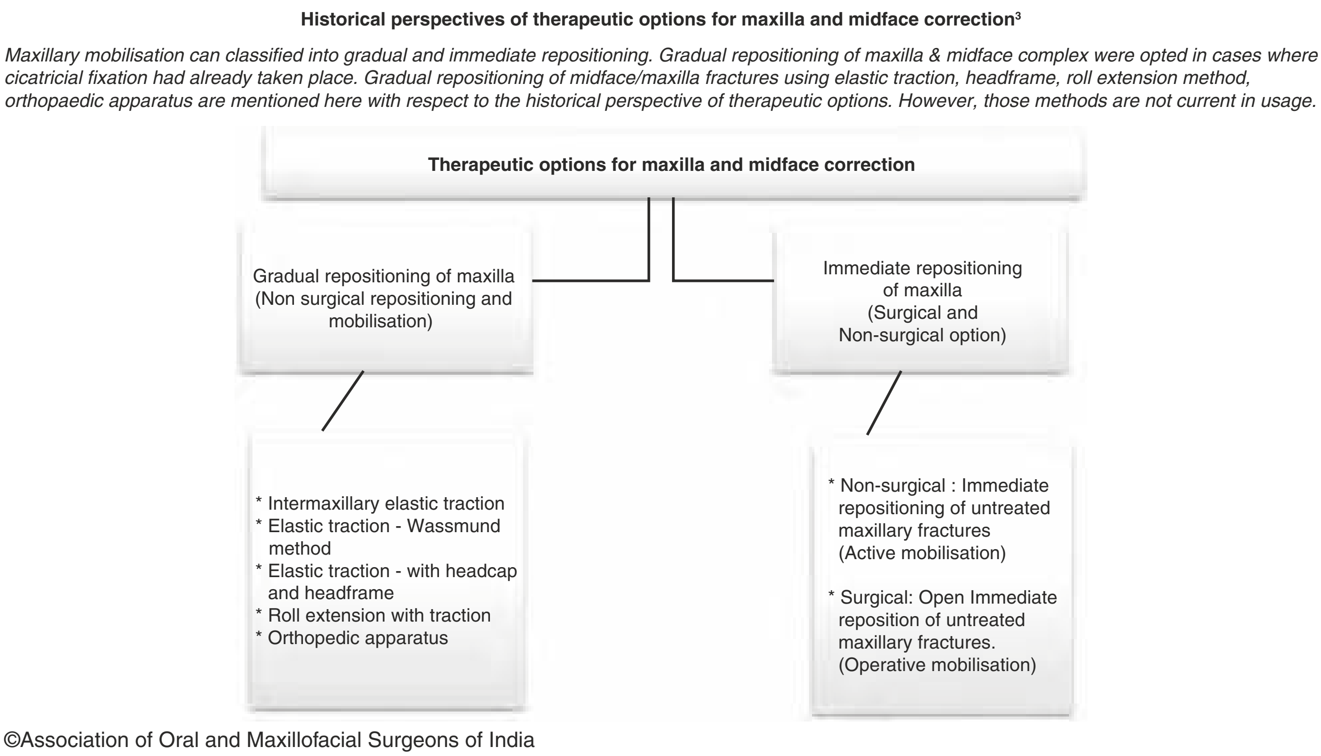

Chart 61.5 Historical perspectives of therapeutic options for maxilla and midface correction [3]

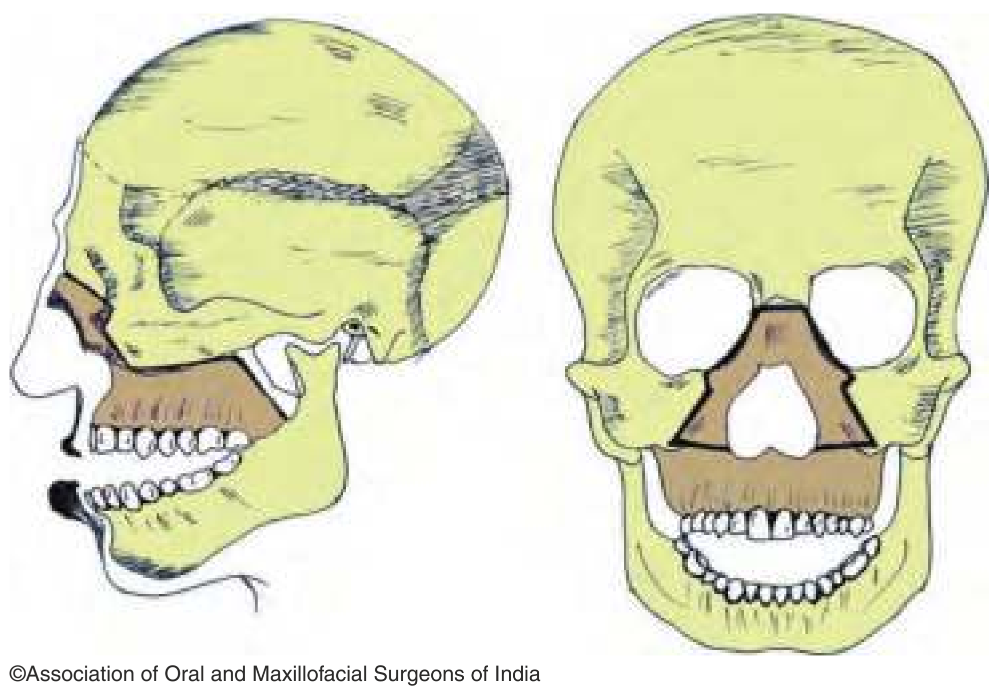

Fig. 61.8 Schematic diagram showing preoperative old untreated midface fractures

61.3.5 Post-traumatic Hypertelorism [3, 44, 65–71]

It is a complication that may arise in fractures of midface complex when there is a dislocation of one or both orbits. Treatment is similar to congenital hypertelorism, and procedure may follow as suggested by Tessier et al. (1967). Stereolithographic models are best used for treatment planning. Although Tessier developed the extra and intracranial approach to correct the deformity, it was further refined later by Tessier, Converse, Van der Meulen et al., Monasterio

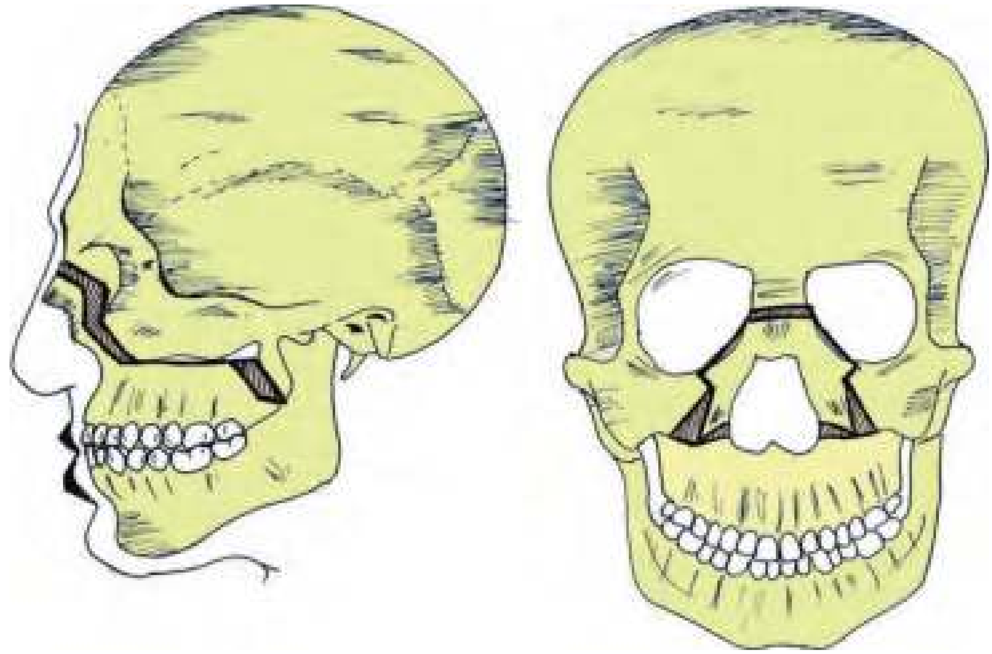

Fig. 61.9 Schematic diagram showing post-operative scenario following combined Le Fort 1 and Le fort II. Defects as a result of repositioning shaded as brown are areas to be filled with bone graft

et al. and Marchac et al. They were able to visualise the bony orbit in two parts with the outer square box containing the globe and the inner cone housing the optic nerve. It was established that if these two parts could be separated, the outer box can be moved without affecting the vision.

Goals of surgery for hypertelorism include:
- Correction of orbital dystopia
- Bringing the orbits closer together
- Creation of normal nose with adequate projection
- Narrowing of the nasal dorsum
- Correction of associated soft tissue defects over the nose, nasal clefts or even displaced eyebrows

61.3.6 Residual Zygomatic Deformities [3, 58]

Periorbital area is often a zone of interest in the midface region from a functional and aesthetic point of view. An imbalance in this region could result in aesthetic concern and altered vision. This can be due to malunion of the fracture of the zygomatic complex. Any untreated fracture for longer than *10 weeks* is considered to be an *old fracture* and results in malunion—a stage at which a procedure needs to be done to correct any deformity.

Clinical Signs and Symptoms
1. Facial asymmetry
2. Facial disharmony
3. Dislocated eyeball
4. Diplopia
5. Paraesthesia—infraorbital nerve
6. Limited movements of the mandible

Soft tissue damage like a torn lateral canthal ligament, malpositioned zygomatic bone, zygomatic arch or fragments of the orbital arm may result in an asymmetry of the lateral midface. Corrective surgeries may be required in case of a destroyed orbital bone as well. More often, patients visit the surgeon for aesthetic reasons. It may be often difficult to correct aesthetics when it involves post-traumatic deformities in the malar prominences (Table 61.3).

61.3.6.1 Associated Defects of the Orbital Zone [3]

- *Dislocated eyeball*: Usually occurs as a sequel to zygomatic fractures, and slight dislocation may be seen after primary treatment. Displaced orbital floor due to enlargement of the socket or the loss of the orbital content due to

soft tissue displacement or necrosis may result in enophthalmos and/or downward displacement of the globe.

- *Diplopia*: Usually due to severe dislocation of the eyeball, but severe diplopia may more likely occur as a consequence to trauma to the cranial nerves, scarring of the extraocular muscles or prolapse and entrapment of orbital soft tissue. Waiting period before re-treatment of diplopia neural and muscle damage is at least 12 months and 15 months, respectively, to observe if the diplopia subsides. Diplopia is differentiated into heterotropia and heterophoria. While sometimes heterophoria may not even need a correction, in certain cases of severe heterotropia, the patient is advised to maintain a titled head position to avoid any double vision. Sometimes double vision may persist even after the fracture has been corrected.
- *Paraesthesia of the distributing area* due to crushing or tearing of the nerve within the infraorbital canal or foramen. Recovery of the nerve by itself may take at least 1 year.
- *Limited mandibular movements* are caused due to a depressed zygoma impinging on the coronoid process of the mandible, restricting the free excursion of the coronoid process. Patient complains of difficulty to open the mouth, and some cases of difficulty to close the mouth may be due to an open mouth during the blow to the zygomatic complex.
- *Pseudoarthrosis* between the coronoid process and temporal process of the zygomatic bone may occur rarely in old untreated cases [72].

Indications for Surgery: [3]

- Aesthetically *unacceptable asymmetry of the orbital rims*. Pathological difference between the two malar prominences more than 5mm.
- *Diplopia* caused due to downward displacement (*more than 3mm*) of the eyeball due to orbital floor displacement and *not primarily due to neural or muscle damage.*

Table 61.3 Radiographic assessment for detecting malunion at fracture sites

Type of x-ray/ view	Use
Occipito-mental (Waters View)	To examine fronto-zygomatic suture, inferior orbital rim and maxillary sinus
Postero-anterior view	To examine orbital floor and rim
Vertico-submental	“Jug-handle” appearance. To view zygomatic arch
Tomograms	To examine orbital floor, space between coronoid process and zygomatic arch
CBCT	To obtain and study oblique images from the three-dimensional data for fracture detection, displacement evaluation, soft tissue herniation

- *Enophthalmos in combination* with displacement of the orbital floor.
- *Paraesthesia of the orbital nerve* after at least 12 months of post-surgical repositioning of bone fragments.
- *Depression of zygomatic arch* impinging the coronoid process that is radiographically evident in causing limited mandibular movement.

Surgical correction of traumatic zygomatic complex fractures is discussed in Chap. 56.

Treatment options: [3] (Chart 61.6) (Table 61.4)
Surgical approach is decided once the operative procedure has been finalised. Common approaches include [3]:

- Periorbital (Chart 61.7)
- Preauricular (Chart 61.7)
- Oral (Chart 61.8)
- Old facial scar

Complications: [3]

- Failed surgery due to insufficient fixation of the re-fractured site or failure due to the implanted materials.
- Untreated pre-existing chronic sinusitis may result in an orbital abscess or phlegmon.
- Serious complications that may lead to blindness.
  - Fracture of bone at the optic canal
  - Misplaced implant that may result in compression of nerve
- Retrobulbar haemorrhage

61.3.7 Secondary Orbital Reconstruction [5, 72, 73]

Post-traumatic secondary deformities include:

- Enophthalmos
- Dystopia

  Both deformities are difficult to correct.

Factors Responsible for Globe Malposition:

- Displaced or missing periorbital bone
- Orbital fat loss
- Contracture of scar

Factors Responsible for Enophthalmos:

- Pathological increase in bony orbit
- Dislocated zygomatic bone

Rotated and displaced zygomatic bone leads to separation of the structures from its normal articulation with the greater wing of the sphenoid and maxilla. A substantial increase in the volume of the orbital cavity is accompanied by fissures along the floor and lateral wall of the orbit. Also, naso-ethmoidal fractures can result in canthal distortion and mal-

Chart 61.6 Treatment options for residual zygomatic complex deformities

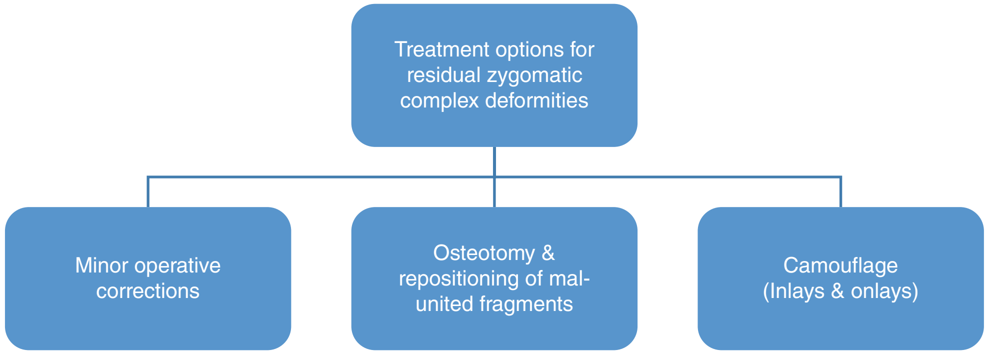

Chart 61.7 Treatment options for residual zygomatic complex deformities—Preauricular and periorbital approach

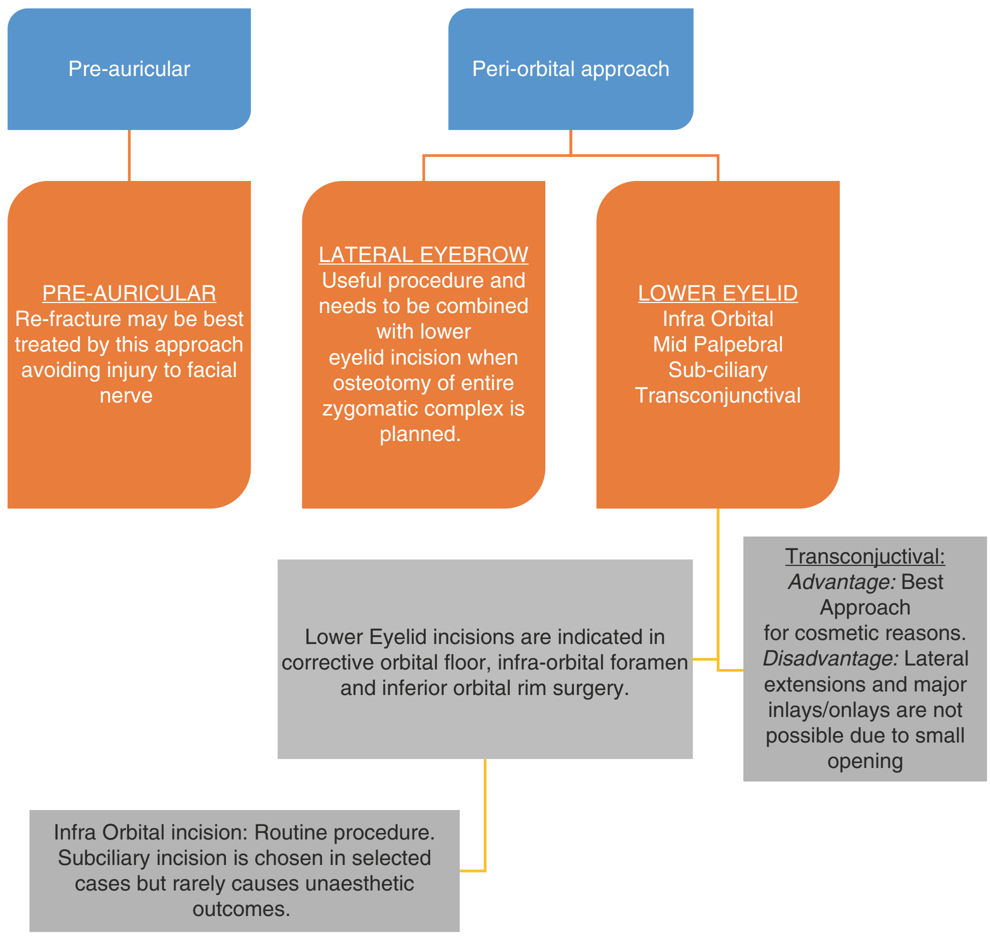

position. Telecanthus and canthal height distortion can be difficult to correct if there is a significant loss of soft and hard tissue.

Any excess or deficiency in the horizontal position of the globe is called dystopia and is easier to correct. Inferior displacement (horizontal displacement) is managed by augmenting the sub-periosteum of the anterior orbital wall, anterior to the axis of the globe. This technique helps to produce superior movement of the eyeball but does not correct enophthalmos even with the overall decrease in orbital volume [5].

Chart 61.8 Treatment options for residual zygomatic complex deformities–Oral approach

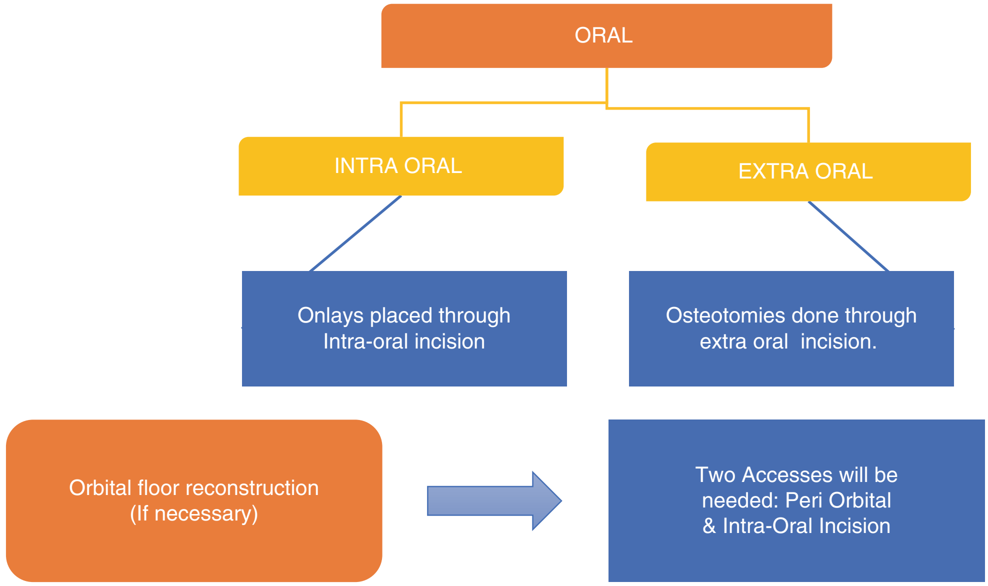

Table 61.4 Surgical options for zygomatic residual fractures [3]

Indications	Clinical presentation	Treatment
Removal or reposition of mal-united fragments	• Sequelae of old, mal-united and consolidated fracture of zygomatic complex	Corrective surgery considered
	• No disturbance to intercuspation and occlusion • No abnormal ophthalmic findings • Good overall symmetry and harmony of the face	No major osteotomy is indicated
	• Visible bony step at the orbital rim	*Surgically removed* through lower eyelid incision. During this, the orbital floor needs to be observed for any adhesions
Paraesthesia	• Persistent paraesthesia is an indication for surgery	*Infra orbital foramen* is widened to free the nerve When only paraesthesia is present—can be accessed through an intra oral approach When additional exploration of the infra orbital canal is required—lower eyelid incision is indicated
Depressed Zygomatic arch	• Hindering the coronoid process' free excursion	*Refracture, reposition and wire fixation* Surgical Approach: Curvilinear, pre-auricular and/or lateral eyebrow incision *Older surgical approach:* Removal of coronoid process
Complete Zygoma Dislocation	• Depressed malar prominence, caudally displaced eyeball and diplopia	• *Treated with osteotomy* • *Camouflage surgery* as a second option • Lateral eyebrow incision and infra-orbital incision to explore the zygomatic complex and detach from the frontozygomatic suture at the inferior orbital margin, inferior and lateral walls of the orbit, and the zygomatic arch (if necessary) • Reposition the segments • Fixation of the fragment is further assured by placing bone graft in the gap in lateral or inferior orbital rim • Orbital Floor is finally covered with lyophilised dura. Procedure is done to ensure good support to the malar bone and orbital floor
	• To prevent post-operative relapse after above surgery	*Over compensate* the pre-operative displacement to a certain extent
	• If downward displacement of globe is not completely resolved after the surgery.	*Free transplant of lyophilized dura could be an option*

Enophthalmos: [5]

Managing post-traumatic secondary enophthalmos involves reducing the volume of orbital cavity posterior to the globe axis. The three-dimensional anatomy of both external and internal structures of the bony orbit should be restored efficiently by refracturing and rearticulating the skeletal framework (including zygomatic bone).

- The zygomatic bone may be accessed by complete exposure using surgical techniques to free the bone and also to establish the correct alignment.
- The zygomaticofrontal suture and the zygomatic arch are exposed through the coronal flap, and facial and muscular connections including the masseter muscle are released.
- Inferior orbital rim and orbital floor are exposed through a lower eyelid incision. Upper lip gingivobuccal incision is done to uncover the zygomatico-maxillary articulation.
- Bony cuts mimicking zygomatic complex fracture are made with a reciprocating bone saw.
- The zygomatic bone is freed and then replaced into the new position with rigid fixation. Necessary bone grafting needs to be done to close the gaps and also to augment the orbital volume.
- The globe should be left slightly exophthalmic (1–2 mm). If an autologous bone is used in augmenting the orbital volume, this exophthalmos is left behind expecting resorption over the next few months. However, this may be difficult to achieve in cases of excessive scarring.
- Placement of the graft plays a very important role as improper placement of grafts, or displacement into the intramuscular cone can result in dysfunction of the extra-ocular muscles or damage/injure the optic nerve.
- Management of complication: Creating safe pockets for the graft by carefully dissecting off the periorbita from the underlying bone. The grafts may be placed external to the extraocular muscles if the periorbita had been disrupted from previous trauma.
- Enophthalmos and diplopia may worsen further due to scarring or displacement of the implant. However, post-operatively globe position may moderately improve and is often long-lasting [5, 72–74].

Complications in Correction of Enophthalmos: [12, 74]

- Worsening vision.
- Diplopia—may improve to certain degree.
- Dystopia.
- Persistent enophthalmos.
- Graft displacement/retrobulbar hematoma may result in changes in vision.
- Pressure from grafts posterior to the globe may result in retinal folds and ischemia.

Telecanthus: [74]

- Lateral displacement of the medial canthus is called telecanthus.
- Corrected using medial orbital osteotomy by positioning the tendon and the overlying soft tissue medially.
- Bone cuts that are made along the fracture lines (typical as in nasoethmoid complex fractures) help to free bone segment that inserts into the point of the tendon, followed by medially relocating the bone to its normal anatomical location.
- Rigid fixation of the bone is done to the surrounding bone over the maxilla and inferomedial forehead. Autologous bone grafts may be used to replace missing bone segments.

61.3.8 Nasal Deformities [3, 75]

Residual nasal deformities occur as a consequence of the displacement of bony and cartilaginous components of the nasal skeleton. The basic anatomy of the nasal skeleton includes the nasal bone and the cartilaginous part of the nasal septum. The frontal process forms the lateral walls, and the vomer forms the osseous part of the nasal septum. The nose is the most commonly traumatised area due to its prominent central location and its elevation from the frontal facial plane. However, secondary deformities to nasal trauma are not rare [3].

Reasons for secondary nasal deformities [75]	
• Inadequate diagnosis • Improper patient selection • Inadequate surgical skills • Improper surgical planning • Inadequate primary treatment • Delayed primary treatment • Inadequate post-operative stabilisation • Post-operative recurrent trauma	• Unstable bony and cartilaginous structures due to fracture • Poor nasal septal management—aggressive septal management • Poor nasal narrowing • Poor management of nasal tip/base surgery • Improper intranasal incisions (too many or incorrect) • Incorrect dorsal hump reduction

61.3.8.1 Potential Complications Associated with Nasal Deformities [3] (Chart 61.9)

Clinical Evaluation: [3, 75]

The patient needs to be aware and educated on the options for a secondary rhinoplasty to correct the residual nasal deformities as the pathology may concern the functional and cosmetic needs of the patient.

- The intensity of the trauma is relative to the type of deformity that may follow.
- Initial low intensity trauma → nasal tip may become malpositioned. There is an evident inward rotation of the lower portion and an upward-outward rotation of the upper portion. This results in a depressed supra tip and a small cephalic hump.
- Increased force → fracture of the bones, cartilage or the nasal dorsum
- Incomplete fracture → late deviation

Preoperative Examination: [3]
- Identify the aesthetic and functional concerns of the patient
- External examination of the nose and the face as a whole
  – Deformity
  – Symmetry
- Internal examination with endoscope and speculum
- Airway examination
- Radiological examination to aid in diagnosis

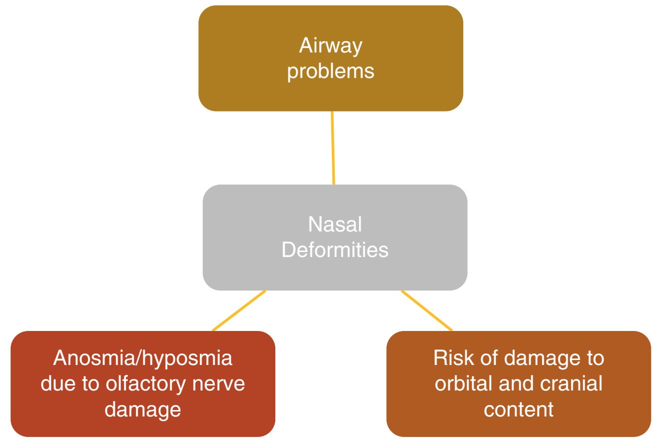
Morphological Considerations: [3]
- Profile:
  – Shape/contour
  – Prominence of the nasal bridge
- Symmetrical position: Position and relation with the naso-orbital angles
- Degree of angulation and contour of frontal and the nasal margins at nasofrontal angle
- Evaluation of naso-labial angle

It is important to evaluate the injury as it may be related to [3]
- Exterior framework
- Posterior ethmoidal maxillary bony base
- Superior fronto-ethmoidal complex

Residual deformities may fall in the following groups and are discussed in brief
- Deformities of the nasal bridge or nasomaxillary region.
- Deformities of the naso-orbital angle or naso-ethmoidal region.
- Deformities associated with nasofrontal angle.
- Complex deformities involving the naso-ethmoido-frontal complex.

61.3.8.2 Deformities of the Nasal Bridge or Nasomaxillary Region [3]

Deformities involving the nasal bridge and lateral walls of the nose not extending into the frontal or orbital regions.



©Association of Oral and Maxillofacial Surgeons of India

Chart 61.9 Potential complications associated with nasal deformities

Pathogenesis:
- Fractures of → nasal bone, frontal process of the maxilla, septal cartilage → untreated and/or inadequately treated fractures, displaced fragment → resorption associated with fibrous union/malunion with excess callus formation.
- Malunion depends on the direction and point of contact of the blow of the original injury.
- Residual callus and subsequent deformity will be evident following fracture of bony or cartilaginous structures or both tissues.
- Force directed from the lateral aspect → deviation of the bridge and lateral wall to the opposite side.
- Force → antero-posterior plane → depression of the nasal bridge and crushing of associated supporting posterior bony elements.
- Blow from the lateral aspect → displacement or bent/twisted nature of the nasal septum → one surface of the septum is therefore outwardly bent → airway obstruction.
- Impact → antero-posterior or sagittal plane → telescoped or folded septum → reduces nasal patency → obstruction of airway

Clinical Features:
- Obvious external deformity—aesthetic concern for the patient.
- Nose deviated towards one side or crushed inwards or both deformities together.
- Deviation → curvature of the septum.
- When seen from the front, the bridge and the dorsum of the nose may appear to be in a straight line, but the tip and the base of the septum are deviated, also leading to deformation of the nasal orifice.

Nose:
- Convex on one side (*or*) upper half/lower half—convex, another half—concave.
- Tip of nose may often be straight but is angulated when the cartilaginous dorsum is displaced.
- Profile—straight or depressed along the entire length/depression confined to nasal prominence (upper or lower half).
- Malunion of septal component—deformity leading to alteration in patency of the nasal airway.
- Narrowing of patency—Unilateral or bilateral → ultimately leads to obstruction.
- Nasal disturbances—Important to evaluate with age, occupation, pre-existing illness or any pulmonary pathology.
- Nasal airway disturbance → may lead to complications of airway tract and paranasal sinuses.
- Depression of nose—depression along the entire nasal crest or depression involving only the lower half.

Surgical Approach for nasal deviation:
- Intranasal approach for aesthetic rhinoplasty—this avoids any external cutaneous scars.
- Dissection is done by Separating or freeing the external investing tissues → elevation of mucous membrane that lines the nasal fossae.
- Dissection includes separation of underlying soft tissues and separation of mucosa.
- Bony and cartilaginous structures freed from the external and internal harvesting tissues.
- This is followed by chondrotomies and osteotomies.
- Chondrotomies are done to mobilise the septal cartilage.
- Osteotomies are done to reduce the displacement of the nasal bridge and dorsum – lateral and median osteotomy.
- Immobilisation aids in maintaining the fragments in position during the union. Careful immobilisation is done internally and externally.

61.3.8.3 Depression of Nose [3] (Saddle-Shaped Deformity)

Treatment differs based on extent of the deformity along the nasal crest (entire length or lower half).
- This deformity is best treated with placement of a bone graft in the region of depression of the bone.
- Intranasal: Best indicated surgical approach but less nasal exposure is a disadvantage.
- Vertical columella incision: Gives good exposure but may leave scars.
- A combined incision with both internal and external incision gives best exposure and leaves a less obvious transnasal scar in the anterior one-third of columella. This is almost invisible in the upright position due to its presence in a "dead angle".
- Surgical steps involve preparation of bony bed at receptor site and preparation of bone graft for placement.
- Stabilisation of bone graft by firm fixation in median, vertical and sagittal planes. Ensure the maintenance of columnar support.
- Sutures placed with adequate immobilisation.

61.3.8.4 Depression of Lower Half of Nasal Crest [3]

Two types of concepts are followed in treatment of such deformities:
- Reduce false or relative prominence by resection of upper half of the nasal crest. Nasal profile is converted to being straight. This might increase the width of the upper half of the nasal crest for which osteotomy of lateral walls may be essential. This concept is to be applied when adequate nasal bone is available to produce a healthy and aesthetic profile.
- The other concept involves the placement of a cartilaginous graft to cover the depression. Fixation may however be difficult in this scenario.

61.3.8.5 Naso-Orbital Deformities [3]

Deformities not only involving the nasal pyramid but also affecting the ethmoid and maxillary components.

Pathogenesis:
- Severe impact → nasal complex → results in extension of fracture lines and displacement of associated components.
- Deformities may extend into the frontal process of the maxilla and the two orbital plates of ethmoid bone (which support the nasal bones).
- Due to the complex anatomy of this region, various combinations in deformities, fracture pattern, injury and pathology may be seen.

Anatomical Characteristics: [3]
Frontal process of the maxilla—
- Determines the morphology of nasal pyramid.
- Determines the orbito-nasal angle
- Forms the lacrimal fossa (anterior part)
- Serves as a point of insertion for the medial palpebral ligament in the anterior crest

  Ethmoid bone—
- Determines the formation of lacrimal canal on lateral aspects.
- Continues posteriorly as the orbital plate which forms the medial wall of the orbit.
- Contributes to the formation of the posterior part of the nasal septum.

Clinical Features:
Nasal crest—

- Deviated or often depressed → consequent lateral displacement or antero-posterior crushing of the nasal bones.

Orbito-nasal angle—
- Reduced/obliterated/displaced outwards

Widening of bridge—
- Due to displacement of frontal processes of the maxillae outwards and backwards
- Due to malunion of a comminuted type of fracture.

Displacement of medial canthus—
- External displacement may produce telecanthus.
- Anterior displacement will further increase in obliteration of the orbito-nasal angle.
- Inferior dystopia—vertical displacement deranges the symmetry of two medial canthi.
- Dystopias are due to the bony fragments impinging on the tissues and causing rupture of the medial canthal ligament, avulsion of the ligament and displacement of frontal process of maxilla which houses the medial canthal ligament.

Lacrimal passages—
- The lacrimal canal is blocked due to discontinuity in nasolacrimal apparatus. Bony fragments of comminuted fractures may cause tearing of the lacrimal sac. This may result in epiphora.
- Epiphora → watering of eyes — → dacryocystitis.

Nasal airway patency problems due to —
- Deviation of posterior part of nasal septum.
- Blockage caused by nasal septum may further be accentuated by displacement of anterior cartilaginous part of the nasal septum.

Essentials in Correcting the Deformity:
- Repair the base of the nose.
- Repair the naso-orbital angle.
- Restore the lacrimal passages.
- Nasal reconstruction must be carried out while correcting the above mentioned during the same procedure.

61.3.8.6 Surgical Management

Key Points in Treatment:
- Reconstitution of the nasal base is the basic procedure in reconstruction of the nasal pyramid. It has to be supported by a solid base.
- Base has to be aesthetically appealing, smooth, regular and well proportioned.
- Reconstitution of the naso-orbital angle is essential.
- Symmetrical placement of the two medial canthi is necessary. Any asymmetry can affect the appearance of the nose.
- Approach to the lacrimal passages may be obtained by dividing the medial canthal ligament that can be reattached later.
- Quality of repair is subsequently affected in cases of infected lacrimal passages.
- Any deviation of the nasal septum negatively influences nasal reconstruction.

61.3.8.7 Nasofrontal Deformities [3]

Deformities due to secondary post-traumatic lesions involving not only the nasal pyramid but also the nasal base and area of the frontal bone. Concentration of injuries at the nasofrontal angle is proportionate to the degree of violence encountered, thereby resulting in fractures and displacement of tissues.

Nasofrontal angle profile is affected by
- Frontal region (median)
- Paranasal region (inferior)
- Secondary malunited callus

Pathogenesis:

- Trauma → nasal spine of frontal bone→ displacement of nasal spine involving middle part of the inferior wall or floor of the sinus
- Trauma → anterior wall of sinus → fracture extending into the anterior wall of sinus or posteriorly communicating with the posterior wall

Lesions on anterior wall—
- When isolated and not involving the other walls → has only aesthetic significance
- Malunited depressed fracture → hollow midline → significant reduction of the nasofrontal angle

Lesions of inferior wall—
- Depression → hollow midline → reduction in nasofrontal angle → has a cosmetic influence and also affects patency of frontonasal duct →blockage of canal → blockage of outflow tract
- Lateral aspect of lesions → involving medial portion of orbital roof → deformed naso-orbital angle → subsequent risk of spread of the infection

Lesions of posterior wall—
- Injury in this zone affects the brain and the meninges.
- Fracture → unhealed fissures → spread of infection to the meninges.
- Deformity in the continuity of bone → herniation of the brain and meninges.
- Sharp bony defect → penetrates the meninges → CSF rhinorrhoea.

Associated lesions—
- When more than one wall is involved → increased deformity of the nasofrontal angle → complications in sinus drainage, brain and meninges
- Resorption of fractured margins → loss of continuity in the anterior or posterior walls → deformed nasofrontal angle

Clinical Features:

- Profile is altered—depression and deviation of nasal bones → unaesthetic profile of the frontonasal angle.
- Greater degree of depression is relative to the retrusion or displacement of middle frontal segment posteriorly, extending above the orbits as far as the bridge of nose.
- Resorption or loss of bony tissue → protrusion of tissue between bony margins → meningocele → increased prominence.
  Associated pathological changes—
- Osteitis in fracture zone
- Improper drainage → persistence of infection
- Meningitis
- CSF rhinorrhoea
- Brain abscess

Essentials in Surgical Management:

- Morphological and functional defects should be corrected to avoid any vital injury in the future.
- In case of depression of the nasal crest and deformities involving only the anterior wall of sinus, onlay bone graft is essential to augment the defect.
- Grossly deranged sinus must be treated first and then followed by nasal reconstruction.
- Grafting is not enough when deformities involve the inferior wall/floor and/or posterior wall as it carries the risk of damaging the sinus, brain and meninges.

The principles of the management of nasofrontal deformities in delayed conditions are similar to managing post-traumatic nasofrontal deformities but should be done with caution and must address associated complications seen at the stage of delayed management. In case of nasofrontal deformities, it is important to address post-traumatic dehiscence of frontal sinus wall in delayed management cases. Certain degree of bone loss due to resorption is seen during the post-traumatic phase, and this may increase when the management is delayed. Hence, in such cases it is important to be cautious in resection of minimal tissue of the posterior wall, and it needs to be carefully performed. Reconstruction of the anterior wall with bone grafts may be done, also including the orbital roof and the ethmoidal region if necessary [3].

61.3.8.8 Naso-Fronto-Ethmoidal Deformities [3]

Deformities involving the nasal bony mass are caused due to greater degree of force. The impact may extend as far as the ethmoid bone which forms the upper wall/roof in the posterior part.

Pathogenesis:

- Fractures lines extending from the front, passing behind and across the nasal spine and extending into the cribriform plate
- Displacement due to fracture → affects the passage of olfactory nerve → further lacerates the dura mater → cerebrospinal fluid leakage or CSF rhinorrhoea

Clinical Features:

- Clinically, it may be similar to the deformities involving nasofrontal fractures. A mere extension into the cribriform plate does not increase the severity of the deformity. Features may differ based on the involvement of anterior wall.
- Anosmia—loss of smell sensation.
- If the meningeal tear is not sealed immediately → CSF rhinorrhoea.
- The meningeal tear is always predisposed with long-term risk of leak (even after the leakage has dried) due to lack in quality of scar tissue and increased permeability of the malunited callus.

Essentials in Management of Naso-Fronto-Ethmoidal Deformities:

- Surgery may be carried out by combined neurosurgical and maxillofacial teams.
- Meningeal tear repair can be managed by trans-ethmoidal (low level) approach. However, trans-frontal approach is considered to be safer and effective.
- Sinus-associated lesions should be managed along with nasal reconstruction procedure.
- *The principles of the management of naso-fronto-ethmoidal deformities in delayed conditions are similar to managing post-traumatic naso-fronto-ethmoidal deformities or naso-orbito-ethomoidal complex fractures but should be done with caution, addressing associated complications seen at the stage of delayed management.*

61.3.8.9 Delayed Management of Orbital Hypertelorism and Naso-Orbito-Ethmoidal (NOE) Fractures [73, 75–77]

Acute trauma in the naso-orbito-ethomoidal region could result in chronic orbital and naso-orbital deformities. It is important to be aware of the acute injury to correct the deformity that will be established later. Secondary late corrections in cases of severe orbital hypertelorism may be very difficult to correct. The severity of orbital hypertelorism can be assessed with the help of Tessier score.

Traumatic orbital hypertelorism due to NOE complex fractures

Goals of management:

- Symmetrical restoration of medial canthal anatomy
- Maintenance of physiologic function of the lacrimal system
- Avoid frontal sinus-related complications
- Restoration of globe position and volume

Surgical Management:

- Coronal approach gives the most predictable access and visualisation for the surgeon.
- Frontal sinus should also be evaluated and operated at this stage.
- Reconstruction should be considered in the following order starting first with cranial base, frontal region and outer orbital zone, followed by fixation of the orbital rim and frontonasal buttress. Grafts and plates may be used to restore the nasal dorsum and nasal projection.
- It is then followed by repositioning and fixation of the mini-plate in the medial orbital wall and medial canthal tendon. Mesh and trans-nasal wiring may be used for repositioning the displaced medial canthal tendon.
- It is important to establish a good frontonasal angle and nasal projection to have good aesthetic outcome. Deformity could result in poor aesthetics when there is poor frontonasal angle and poor nasal projection along with orbital hypertelorism.

61.3.8.10 Secondary or Delayed Management of Orbital Hypertelorism Associated with NOE Complex Fractures [75–77]

- Goal is to restore the normal interorbital distance.
- Acute management of chronic long-standing deformities is essential. It is very difficult to correct severe orbital hypertelorism, especially in cases which includes intracranial osteotomies. Such cases are associated with increased post-operative morbidities. Subcranial osteotomies may be opted in milder cases.
- Aesthetic and functional outcomes in late correction may not be satisfying, and hence the best strategy is to repair the deformities as early as possible following the first injury and hence not delay the treatment.

61.3.8.11 Conclusion

- Repair and reconstruction of nasal deformities are often challenging and technique sensitive for the surgical team (maxillofacial and neurosurgical). It is emotionally and psychologically challenging for the patients as well. Hence, it is essential to identify the pitfalls and carefully carry out the surgical treatment plan. Sometimes, further revision may be necessary even with the best planned surgical procedures. Therefore, it is important for the surgeon and the patient to understand the limitations of the available surgical techniques.

61.4 Post-oncological Deformities

Management of Post-oncological Deformities:

Post-oncological deformities here refer to the soft tissue and hard tissue defects that may be encountered following a primary treatment. Unlike a primary cosmetic therapy, predicting the result of an oncological treatment is often more technique sensitive and should be considerate in establishing the overall physical and mental well-being of the patient. Management of deformities should also aim at a comprehensive functional, aesthetic and social well-being of the patient.

Reconstruction of soft tissue and hard tissue structures following trauma or oncological surgical therapy is primarily essential. Correction of the residual deformities should be carried out along with the principles of reconstructive management.

Reconstruction generally includes the following steps in management [78]:

- Healing by secondary intention
- Primary closure
- Grafting—split or full-thickness graft
- Composite grafts
- Local grafts
- Regional pedicle grating
- Free tissue transfer

We have already discussed in detail the use of above methods in management of traumatic residual deformities in this chapter.

Recurrences, untreated tumours and metastasis which are considered to be residual in nature after primary management are not considered under management of post-oncological deformities. It is important for the surgeons to be more accurate with the surgical margins when surgically operating malignancies. Any re-surgical procedure for recurrence or deformities is often challenging due to factors like previously irradiated areas, previously operated surgical field, under nourished status due to the pre-existing malignant condition and also due minimal surgical options for such patients.

Residual deformities associated with post-oncosurgery results in external facial disfigurement/defects, intra-oral defects and also changes that may affect certain functions. These deformities are often relative to structures which were primarily involved and their corresponding functional deformities. Deformities occurring following surgical treatment of head and neck oncology usually require reconstruction procedures as the complete removal of tumours with margins may involve increased loss of soft or hard tissues.

61.4.1 Lip Deformities [79–83]

Post-oncosurgical defects of the lip are often seen with loss of tissues. Management of such defects is usually considered according to the size of the defects. Secondary deformities of the lower lip after reconstruction are described in (Table 61.5), and they need to be treated accordingly with cosmetic surgeries. *Lip reconstruction is discussed in soft Tissue reconstruction chap.* 86.

Table 61.5 Secondary deformities of lower lip following reconstruction

Type of Flap	Deformities	Complications
Abbe	Relative Microsomia Trap Door deformity due to thickened scar	Vermillon notching Lip asymmetry Scarring beyond submental crease
Estlander	Commissure violation and may require commissuroplasty	
Karpandzic	Microstomia Inversion vermillion Flat mentolabial junction	Dysthesia or Anesthesia of lip
Gillies fan	Oral incompetence may result	
Bernard burrow	Adynamic reconstruction	Post-operative drooling

61.4.2 Management of Intra-oral Defects Involving Floor of the Mouth and Alveolar Ridge Tumours

Defects in these regions are relative to the size of tissues lost and may be corrected with augmentation and reconstruction procedures.

- *Correction of small intra-oral defects is best done with* primary closure in the buccal and tongue region, but scar contracture is seen with grafting. Closure by secondary intention can be done in alveolar and hard palate defects where the scar contracture is insignificant [84].
- *Correction of large intra-oral defects using* free flaps is considered ideal in reconstruction procedures [84–86].
- *Advanced large defects* may be seen in cases which require large resection of tissues, as in cases of advanced tumours which may include cortical or segmental mandibulectomy, composite resections, and glossectomy (total/sub-total) procedure. These defects may also involve the lip or skin of the lower third of the face when tumour extends anteriorly [86]. Hemi- or partial loss of mandible may result in severe functional or psychological morbidity for the patients. The loss of anterior mandible results in a defect called as "Andy-Gump" deformity [87]. En bloc resection is best reconstructed with regional free tissue transfer or free flaps. Bony defects are managed with osteocutaneous free flap or with free tissue transfer.

61.4.3 Management of Defects of Oropharynx

Oropharyngeal defects are managed with primary closure, skin grafts, local pedicle flaps and microvascular-free flaps. Current goals in reconstruction include restoration of the function and closure of defects as well.

61.4.3.1 Management of Soft Palate Defects [88]

- Soft palate defects cause *velopharyngeal incompetency* resulting in inability to seal the oropharyngeal and nasopharyngeal cavity during speech and deglutition.
- *Rhinolalia aperta* is caused due to small soft palate defects leading to change in resonance of voice as a result of air escape due to incompetent velum.
- *Smaller defects* are best closed primarily or along with a split-thickness skin graft.
- *Radial forearm flaps* are used in cases following surgical ablation of *soft palate and tonsillar defects*.

- *Large or extensive palatomaxillary defects* are managed with obturator prosthesis or with vascularised osteocutaneous free flaps.

61.4.3.2 Management of Tongue Defects [89, 90]

Tongue defects are usually difficult to treat and reconstruct. Management of tongue defects primarily involves improving the functional outcome.

- *Small defects* are managed with primary closure.
- *Large defects* are treated with myocutaneous flaps (rectus or pectoral major flaps and fasciocutaneous flaps)

61.4.3.3 Management of Posterior Pharyngeal Wall [90]

- Primary closure with/without split thickness skin graft is used for closure of small defects. Free flap reconstruction is necessary for large defects.

61.4.4 Deformities Associated with Intra-oral Disfigurement [91–98]

The primary goal in surgical management of oral tumours is to gain surgical access for assessment and visualisation of margins and anatomic relations for resecting the tumours. Surgical margins are vital in establishing a tumour-free zone. Although it is important to have a follow-up on recurrence of tumours and metastasis, it is the complex nature of the oral cavity and head and neck anatomy that requires careful yet skilful management of the adjacent normal tissues by proper closure and post-operative management.

The goal earlier was to achieve access to the tumours, but now it also involves incisions that will facilitate an aesthetic access to the pathology. Increased incidence of dehiscence and unaesthetic scar formation are common in neck incisions (with trifurcation extensions) that do not lie along the natural skin creases. Irradiated areas may cause worsening of scar appearance, or even superficial necrosis may occur. Inadequate, delayed and infected tracheostomy may also result in an unaesthetic tracheostomy scar formation. Prevention of unaesthetic scars can be done by careful tissue handling. It is also essential to protect the skin from additional trauma due to traction, tension or electrocautery. Flaps with adequate vascularity further help to minimise the chances of unaesthetic scars. Following access through the lip to certain tumours in the oral cavity, the site requires to be exactly oriented and aligned with the vermilion lip border, as well as interdigitating orbicularis oris muscle, re-orienting lip skin and oral mucosa to replicate lip competence, aesthetics and function [92–97].

Even though reconstruction of maxillectomy defects is an option, maxillary defects can also be corrected with prosthetic obturators. Maxillary obturator provides adequate structural support to preserve speech, swallowing and essential mastication. Clinically, a good obturator can be fabricated only by the skills of a good prosthodontist [98].

It is important to evaluate any history that may contribute to poor wound healing and also lead to post-operative wound dehiscence and compromised flap vascularity resulting in improper scarring.

61.4.5 Deformities Associated with Healing Tissues [91, 92, 99, 100]

Surgical procedure involving the upper aerodigestive tract through neck incision may lead to fistula formation as a result of salivary leakage.

The formation of fistulas is contributed majorly due to:

- Incision design
- Tumour type
- Tumour stage
- Improper surgical site management
- History of operative site
- Physical and nutritional status of patient

Biological Factors that Contribute to Fistula Formation:

- Effect of radiation on surgical wound closure: Radiation dose and timing play an important role in delayed wound healing, formation of fistula and dehiscence.
- Low oxygen tension: Proportional to flap vascularity and viability.
- Vascularity: Decreased blood supply affects the wound healing property.

Signs and Symptoms of Fistulas:

- Occurs post-surgery as early as 1 week and somewhere between 3 and 4weeks in late cases of fistula formation. Persistent fistulas are present for more than 1 month.
- Low-grade fever.
- Inflamed and indurated areas of skin that facilitate the drainage.

Management:

- Early assessment of fistula can help to explore the surgical wound and aid in directing saliva from vital structures.
- Site may be explored, irrigated and closed. This is followed by antimicrobial therapy and nutritional support.
- Persistent fistulas are managed with excision of the fistulous tract with closure of oral mucosa and/or skin.

- Hardware failure due to infection can be managed with local debridement, removal/replacement of existing failed hardware and closure with local and regional flaps.
- Management can be combined with anti-cholinergic medications to decrease salivary flow if necessary and only if indicated.

61.4.6 Functional Deformities Associated with Oro-Oncological Surgery

Surgical cancer resection may cause the following functional defects [101]:
- Difficulty in speech, swallowing and chewing
- Difficulty in masticatory function and nutrition
- Neurological complications

61.4.6.1 Spinal Accessory Nerve

Iatrogenic injury may cause “shoulder syndrome”, for which physical therapy may help to improve the functional outcome. Pain, weakness of muscles, restrained shoulder movement, deformity of the upper extremity and inability to abduct upper extremity above 90degress occur due to denervation of trapezius muscle [91, 92, 102, 103].

61.4.6.2 Phrenic Nerve

Iatrogenic damage causes paralysis of ipsilateral diaphragm. It may even result in long-term pulmonary complications. Such damage can be prevented by limiting surgical dissection to the layer superficial to pre-vertebral fascia and thereby prevent injury to nerve [92, 101, 104].

61.4.6.3 Hypoglossal Nerve and lingual Nerve [92, 101, 104]

- Iatrogenic damage to both the nerves is possible during head and neck dissection. This is aggravated with damage to lingual nerve during excision of tongue and floor of the mouth. Hypoglossal and lingual nerves are often preserved unless there is extensive neural invasion of the tumour.
- Hypoglossal nerve dysfunction/damage causes deviation of tongue to ipsilateral side of injury, tongue biting, dysarthria and difficulty in mastication and deglutition. Bilateral nerve injury may result in upper airway obstruction when the patient is in supine position. Atrophy of tongue muscles may also be observed.
- Damage to lingual nerve may cause ipsilateral loss of sensation, further impacting mastication, speech and swallowing. Injury to tongue during speech and mastication may also be observed.
- Rehabilitation by physical therapy is often useful for improving the speech and swallowing.

61.4.6.4 Vagus Nerve, Recurrent Laryngeal Nerve and Superior Laryngeal Nerve [91]

- Injury to these nerves may occur during dissection around the carotid sheath.
- Injury to recurrent laryngeal nerve causes unilateral vocal cord paralysis. The damage is usually compensated by the intact contralateral vocal cord. Mild hoarseness is experienced by the patient. Upper airway obstruction is seen with bilateral injury.
- Injury to branches of superior laryngeal nerve occurs due to dissection around the superior thyroid branch of external carotid artery. The following changes may be associated:
- Minor swallowing difficulty
- Decreased sensation in laryngeal inlet
- Decrease in tensor capability of true vocal cord
- Fatigue
- Decreased ability to reach high phonated/pitched sounds

Management usually begins with accurate diagnosis of the neurological origin. It is best to prevent such injuries with careful dissection.

61.4.6.5 Sympathetic Trunk [92, 101, 104]

Damage or disruption to the sympathetic trunk can result in ipsilateral Horner’s syndrome. Careful evaluation is necessary to diagnose Horner’s syndrome due to damage of nerve fibres, and it involves the following:
- Blepharoptosis (drooping of upper eyelid)
- Miosis or pupillary constriction
- Lack of perspiration of forehead skin
- Enophthalmos
- Vascular dilation (ipsilateral to injury)

61.4.6.6 Marginal Mandibular Branch of Facial Nerve [92, 105]

Injury to This Nerve Causes:
- Altered mobility of corner of the mouth as a result of disruption in innervation to orbicular oris and depressor anguli oris.
- Inability to control lower lip movements during liquid consumption.
- Functional and cosmetic disturbances are seen.

Management:
Careful design and incision considering the anatomic location of the nerve during flap elevation help to prevent

iatrogenic injuries and resultant deformities. It may take several months for neurosensory recovery when the neurologic injury is due to traction and not due to severance.

61.5 Recent Advances

61.5.1 Endoscopy in Residual Deformitites [106, 107]

Recent trend in oral surgery includes the use of an endoscope to facilitate oral and maxillofacial procedures. Endoscopy techniques can be used in diagnosis and for treatment with minimal complications in many oral and maxillofacial surgical procedures like TMJ disorders, pathologies of jaw, nasal deformities, trauma and aesthetic procedures. The techniques and applications of endoscopy in oral and maxillofacial surgery are explained in detail elsewhere in this book. The advantages and applications of endoscopy-assisted maxillofacial surgical procedures make its usage a favourite option for maxillofacial surgeons. Minimal complications, good success rates and its efficiency make endoscopy-assisted procedures a viable option.

The following are the best-known applications of endoscopy currently in oral and maxillofacial surgery:

- Trauma
- Orthognathic deformities
- Obstructive salivary gland pathology
- Maxillary sinus surgery
- Trigeminal nerve injury
- Temporomandibular disorders
- Nasal deformities
- Trauma

Endoscopy-assisted minimally invasive technique is used in traumatic deformities like the following:

Orbital Floor Fracture: Requires trans antral approach. Care should be taken to protect the intraorbital contents like musculature, periorbita and optic nerve. Intraoperative conditions may necessitate the need for an additional periorbital approach during the surgery.

Mandibular Angle Fracture: Here, endoscopy can be used to fix the mandible with the superior and inferior plate with the best approximation possible. Endoscopic reduction helps in complete visualisation of the entire fracture line with inclusion of the inferior border. Management with endoscopy-assisted surgery also reduces the risk of facial nerve injury. A single transbuccal trocar technique is used for positioning and fixation of the plates with easy visualisation of the fracture line. Some surgeons prefer a locking cannula for the precise placement of the fixation hardware. Endoscope is then used to confirm proper fixation and reduction, and it is then closed. Endoscope also aids in appropriate documentation of the procedure.

Sub-condylar Fractures: (Refer Chap. 54 on endoscopic approach for treatment of condylar fractures of mandible) Endoscopy can be applied in management of sub-condylar fractures by open technique, reducing risks of scars, fistula formation and facial nerve injury. Extra-oral and transoral approach may also be used. Although the procedure is technique sensitive, it is proposed with advantages of improved visualisation, magnified field of view, less trauma to tissues, less bleeding, better patient compliance, good reduction and decreased post-operative complications.

Frontal Sinus Fractures: Endoscopy in the management of frontal sinus fractures helps to avoid large incisions and its associated complications like alopecia, paraesthesia, scarring, nerve injury, etc. It helps in better visualisation of sinus wall fractures, nasofrontal duct and the posterior wall of sinus.

- The use of *endoscopy in orthognathic surgery* helps to visualise aspects of the osteotomy so as to improve the efficiency of the surgical outcome.
- Best application of endoscopy in salivary gland pathologies is the usage of sialoendoscopy in the diagnosis and treatment of salivary gland/ductal pathologies in a non-invasive manner.
- TMJ arthroscopy is another area that has gained greater attention.
- Endoscopy is also best utilised in removal of foreign bodies from the cranio-maxillofacial region as it allows visualisation of anatomical structures without extensive incisions.

Endoscopy in nasal deformities: is a developing concept, and there has been an increase in its extensive usage in sinus endoscopic surgeries. The use of endoscope in correction of septal deformities like deviation, aids in better visualisation of the target site and reduced time of the procedure. The primary advantages are improved field of view, reduced morbidity, decreased post-operative swelling and more accuracy in surgical procedure. Endoscopy in nasal corrections is very essential in cases that have gone for prior septal cartilage resection, reducing the need for repeated incisions or extent of dissection. Studies also suggest lesser post-operative symptoms in endoscopic-assisted nasal septal corrective surgeries [107].

61.6 Conclusion

Careful planning, eminent skills and excellent knowledge of the clinical anatomy are of utmost importance in carrying out secondary corrective procedures in treating residual deformities following trauma or oncological procedures. It is the skill of the surgeon to predict the functional and aesthetic outcome of the treatment so as to facilitate a proper treatment planning. It is also the role of the surgeon to educate the patient about the condition and options available for the correction, to provide the best possible outcome. It is recommended that surgeons use available imaging techniques (routine X-rays, CT scans, CBCT, etc.) in their treatment plans and also make best usage of the current trends in 3D models and visual planning software in treatment planning. The use of CAD/CAM-designed patient-specific alloplastic (e.g. Medpore, PEEK) implants should be considered in surgical management. Treatment plan should often accommodate recommendations from other specialities that may be a part of the surgical team.

Both soft tissue and hard tissue deformities should be dealt together in a well-planned manner to provide the patient with an acceptable aesthetic outcome and functional rehabilitation. Likewise, mastication and prosthetic rehabilitation can be aided by dental and zygomatic implants. Most often correction of residual deformities may go together with reconstruction of the lost structures. It becomes essential to carry out the entire treatment phase in a well-planned manner to provide the patient with a final, socially and psychologically acceptable outcome with or without post-operative physical therapy. Surgeons are also recommended to be updated about endoscopy-assisted surgeries and transoral robotic surgeries to further enhance the quality of outcome of the treatment.

Temporomandibular Joint Disorders

Myofascial Pain Dysfunction Syndrome

62

Mirza Farhatullah Baig and Yashoda Ashok

62.1 Introduction

There is an accepted concept of triple complex involving both joints and intact dentition forming an integrated system which is carefully monitored by an arthrokinetic reflex muscular activity to ensure a controlled and stable pattern of painless mandibular movement. A disturbance in the co-ordinated activity of this musculature arising from malocclusion often accentuated by psychological factors inducing neuromuscular tension forms the basis for majority of problems involving temporomandibular joint (TMJ) dysfunction.

There is a large pool of evidence that clearly shows that mind and body are not independently functioning entities but closely interrelated in all aspects of pain direction, detection and perception. TMJ disorders is an umbrella term referring to a classification of musculoskeletal disorders impacting the masticatory muscles and/or the TMJ and is usually subdivided into three main categories. Box 62.1 enumerates the three categories of musculoskeletal disorders, often clubbed as TMJ disorders.

Box 62.1 Subcategories of TMJ Disorders (TMDs)

1. Myofascial pain disorder
2. TMJ disc interference disorders
3. TMJ degenerative diseases

It has always been a challenging job for the clinician to manage temporomandibular disorder (TMD) as it is a conundrum wrapped in enigma.

Management of TMD is controversial because science takes a back seat. We need scientific studies especially randomised clinical trials to overcome this problem. Matching the diagnosis to the treatment is still the most problematic aspect of TMD practice. The solution lies in making an accurate diagnosis to match an appropriate method of treatment.

62.2 Definitions

The definitions for TMJ pain are not universally used. Three currently accepted definitions of TMJ pain are:

1. Temporomandibular pain and dysfunction syndrome (International Association for the Study of Pain: Merskey and Bogduk [1])
   (a) Aching in the muscles of mastication often associated with restricted jaw movements and popping sounds
2. Oromandibular dysfunction [2] (International Headache Society: Oleson 1988)
   (a) Temporomandibular joint sounds on movement
   (b) Limited or jerky jaw movements
   (c) Pain during jaw function
   (d) Lock jaw on opening
   (e) Gnashing of teeth (bruxism)
   (f) Miscellaneous parafunction (tongue, lips or cheek biting)
3. Facial arthromyalgia [3]
   (a) Chronic or intermittent pain of TMJ and of its associated musculature

62.2.1 Evolving Terminologies

Over many years, functional disorders of the masticatory system have been referred by many terms contributing to the confusion regarding aetiologic mechanisms and manifestations in this area.

In 1934 James Costen [4], an otolaryngologist, described a set of symptoms focused around the ear and temporomandibular joint (TMJ) leading to the earliest nomenclature of Costen syndrome. Costen believed these symptoms were due to the backward displacement of condyle after overclosure of the bite. Auriculotemporal nerve is found behind the tympanic bone which prevents nerve compression. Hence this theory was rejected.

Schwartz [5] (1959) described myofascial pain dysfunction syndrome (MPDS) characterised by clicking, muscle tenderness, pain in the TMJ region and restricted mouth opening. Following this, much later the term TMJ disturbances became popular, and then, in 1959, Shore [6] introduced the term TMJ dysfunction syndrome. Later Ramfjord and Ash [7] brought forth the term functional TMJ disturbances. To establish a connect with the aetiology, terms such as occluso-mandibular disturbance and myoarthropathy of the TMJ [8] were introduced. When pain and associated muscle involvement became the focus, terminologies such as pain-dysfunction syndrome [9], myofascial pain-dysfunction syndrome [10] and TM pain-dysfunction syndrome [11] arose.

Currently it has been established that these terms attempt to describe conditions with symptoms not always isolated to the TMJ, and for the need of a broader, umbrella term to classify these conditions, some authors believe that the title craniomandibular disorders [12] should be used. Finally, the term which has gained large-scale acceptance was suggested by Bell [13]—“temporomandibular joint disorders”.

62.2.2 Current Definition

Myofascial pain dysfunction syndrome (MPDS) is a well-known term that is used in many other branches of medical science [14–16]. But in the last few decades, this term has been employed to describe orofacial chronic pain [17–19] often abbreviated in the literature as MPDS.

Presently, myofascial pain can be defined as “a regional myogenous pain condition characterised by local areas of firm, hypersensitive bands of muscle tissue known as trigger points” [20] alternatively called myofascial trigger point pain. The presence of central excitatory effects is a defining characteristic of this myalgic disorder. The presence of referred pain is common, often resembling a tension-type headache.

62.3 Etiopathogenesis and Proposed Mechanisms

A number of mechanisms have been put forth to explain myofascial pain, even though currently a holistic understanding of aetiologies remains elusive (Fig. 62.1):

1. Continuous source of input leading to deep pain [21, 22]
2. Heightened emotional stress [21, 23]
3. Sleep disturbances [21, 24]

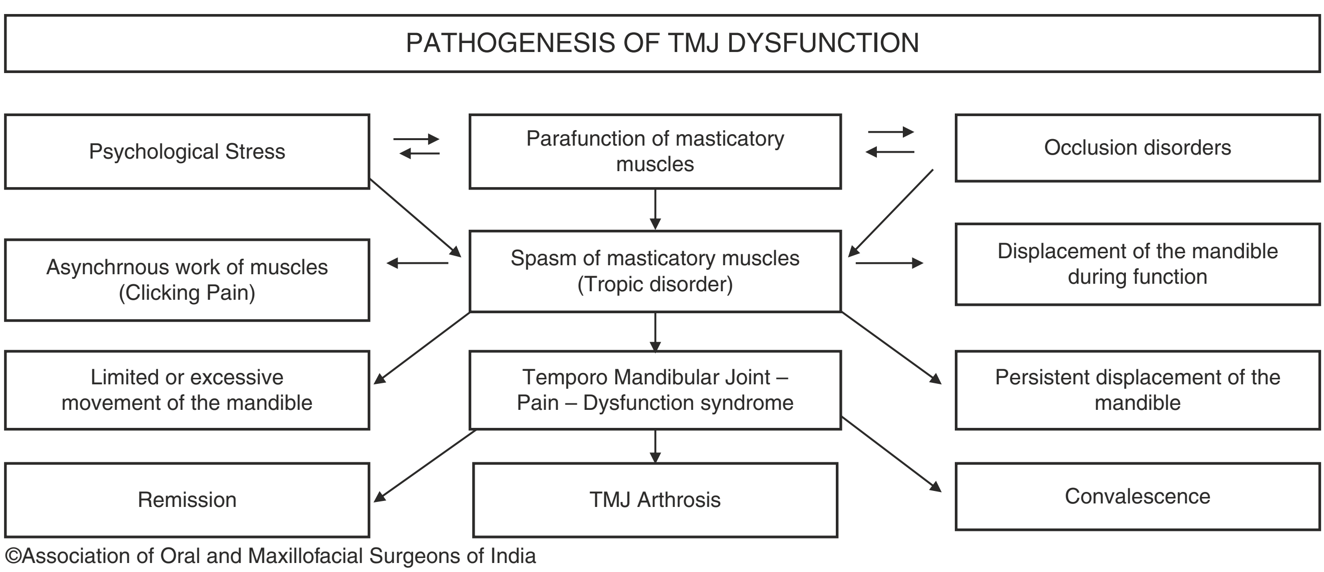

Fig. 62.1 Pathogenesis of TMJ dysfunction

4. Local factors that govern muscle health, namely, habits, posture and muscle strains
5. Systemic factors like nutritional deficiencies [21], poor physical status, chronic fatigue and viral infections [21]

62.4 Patient History and Clinical Characteristics

The patient's main complaint is often directed towards the site of referred pain and rarely the exact source of pain (the trigger points). The clinician may accidentally direct treatment towards the secondary sites of pain resulting in failure to treat the actual cause of the pain, thereby leading to unsuccessful treatment. History taking must specifically include incidences of repetitive muscle trauma, improper postural habits, presence of occlusal parafunction and mental and emotional stress.

On clinical examination, the patient will display decreased range and speed of mandibular movement which usually correlates to the location and intensity of trigger point pain. The pain is commonly described as a dull ache or pressure which can be throbbing and severe. The masticatory muscles are tender on palpation with identifiable trigger points on palpation [25].

Trigger points are described as firm knots within muscles which are more tender on palpation than the surrounding muscle tissue. The pain that is generated is usually within and beyond the muscle and may occasionally elicit referred pain to a distant site and even an autonomic response.

Temporary inactivation can be tried through a trigger point anaesthetic injection, vapocoolant sprays, transcutaneous electrical nerve stimulation (TENS), etc. [26] which are used by certain practitioners to temporarily inactivate trigger points.

From a clinical standpoint, if the muscle is tender to palpation and none of the other masticatory muscle disorders better describe the patient's condition, the suggested diagnosis is myofascial pain.

62.5 Examination

- Questions concerning pain and restricted mandibular movements and TMJ sounds
  - Visual examination of the head and neck.
  - Palpation of the head and neck—This includes palpation of the individual masticatory muscles for tenderness (Figs. 62.2a, b and 62.3).
  - Listening to TMJ sounds and joint palpation (Fig. 62.4).

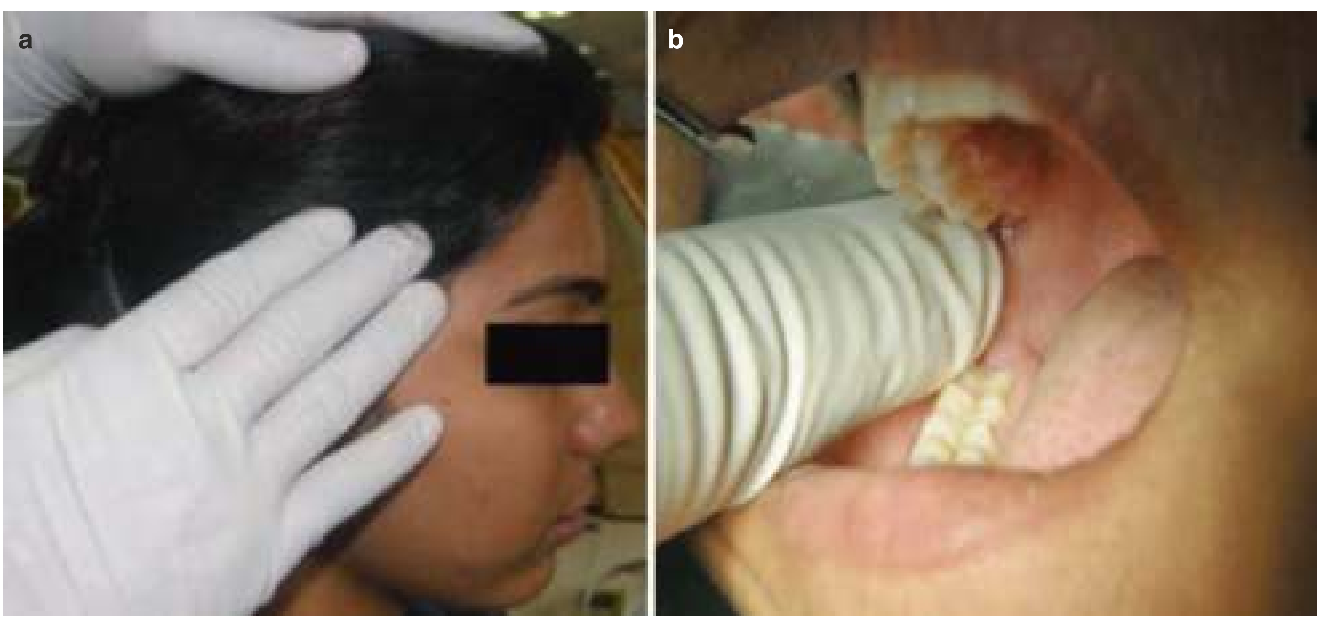

Fig. 62.2 (**a**, **b**) Palpation of temporalis

Fig. 62.3 Palpation of masseter

- Mandibular movements—For range of motion and deviation.
- Radiographs and other imaging techniques—An OPG (Fig. 62.5) may be easily available in most clinical set-ups. Dental cone beam CTs (Fig. 62.6) offer the advantage of lowered radiation dose with reasonable hard tissue detailing, articular surface erosions and joint space dimensions. MRIs are useful for imaging soft tissues such as the articular disc and joint ligaments (Fig. 62.7a, b).
- General oral examination.
- Occlusion.

62.5.1 Imaging Techniques

Pain in relation to the TM joint and masticatory muscles are among the commonest complaints of patients with TMD. MPDS is unique in that the contributing factors are neurogenic, psychogenic and musculoskeletal in nature. This greatly limits the role of conventional imaging modalities in clinching the diagnosis of MPDS.

OPG and CT are useful in imaging bony articular surfaces for erosions and changes in the joint spaces. MRI is excellent for imaging the disc, capsule and TM joint ligaments. However the usefulness of these imaging techniques appears restricted to ruling out other contributing factors to the patients' pain such as internal derangement and osteo-degenerative disorders. These features may often overlap with myofascial pain, often adding to confusion in diagnosis.

Fig. 62.4 Palpation of temporomandibular joint

A thorough clinical examination is the most reliable way to arrive at a diagnosis of MPDS with imaging investigations assisting in ruling out other causative factors. Figures 62.5, 62.6 and 62.7 demonstrate some of the conventional methods of imaging the TM joint and associated structures with relevant findings.

62.6 Psychological Assessment

It is mandatory to do psychological assessment or screening of the patient for history of anxiety, depression and pain-related disability.

62.7 Pathophysiology of TMJ Pain

Pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage [27] (*International Association for the Study of Pain 1979*).

Inflammatory Pain Intra-articular tissue damage in association with disc displacement results in local TMJ pain. In addition, it can elicit reflex spasm of masticatory muscles resulting in pain from regions other than TMJ.

Arthrogenous Pain The patient can point to the worst spot with one finger in the TMJ region. The pain is relieved by giving auriculotemporal nerve (ATN) block.

Myogenous Pain Not relieved by block and diffuse in nature over the muscle.

Fig. 62.5 OPG showing bony articular surfaces of TMJ

Fig. 62.6 CBCT shows erosions and craters in the head of the condyle and increased joint space

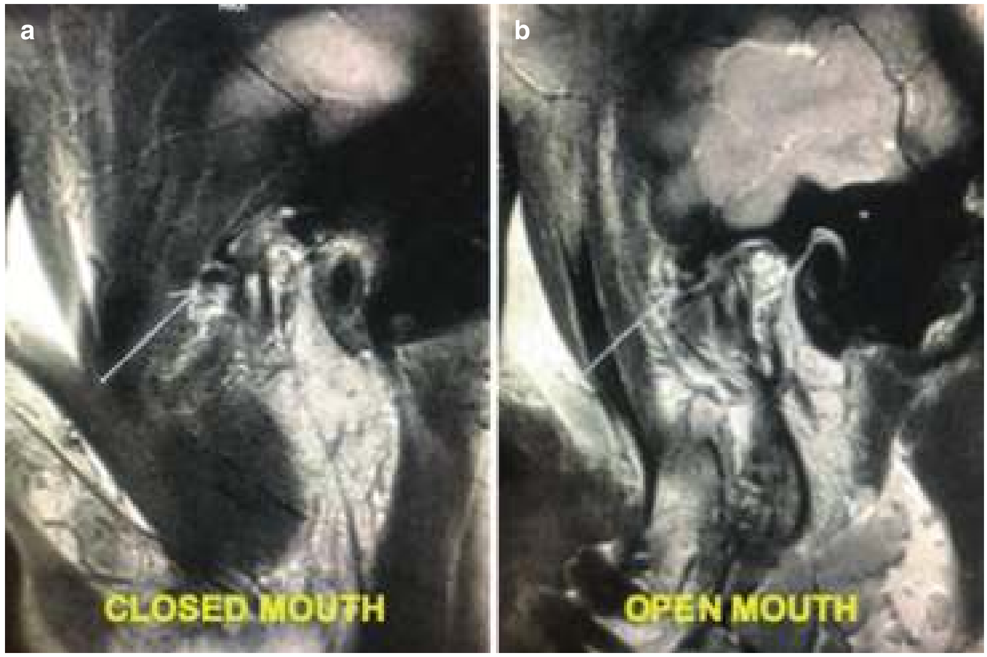

Fig. 62.7 (**a**, **b**) MRI showing disc displacement without reduction in open and closed positions

62.8 Role of Parafunctional Habits

62.8.1 Bruxism

- Bruxism is defined as an oral habit of involuntary rhythmic non-functional gnashing or clenching of teeth outside of masticatory movements of the mandible [28]—"tooth grinding neurosis".
- Associated with REM, commonly seen in patients with high trait anxiety or increased depressive symptoms.
- This sustained muscle contraction leads to non-serous inflammatory reaction in masticatory muscles, subsequent fatigue and pain.
- Signs of bruxism: Fig. 62.8a–c
  – Attrition of teeth
  – Scalloping of the tongue
  – Cheek ridging—linea alba

A complete process of risk evaluation and assessment helps to highlight the problematic causative factors. These may include central and peripheral causes as shown in Table 62.1.

62.9 Clinical Signs of MPDS

- Pain in TMJ region
- Clicking/popping noise
- Restriction of mouth opening
- Deviation of mandibular midline to the affected side on mouth opening before clicking
- Restricted laterotrusive jaw movements to the contralateral side (Fig. 62.9a)
- Unrestricted laterotrusive jaw movements to the affected side (Fig. 62.9b, Table 62.2)

62.9.1 Clinical Test

To diagnose clicking caused by disc displacement with reduction:

- Patient is instructed to occlude the teeth firmly together.
- Patient is instructed to open the mouth until jaw clicking occurs indicating that the disc/condyle relationship is now reduced into normal position.
- No clicking sound is heard after placing the spacer (Fig. 62.10a, b).

62.10 Principles of Management

62.10.1 Role of Evidence-Based Management

The varying manifestation of myofascial pain (MFP) can range from single muscle involvement to complex cases involving multiple sites of pain and numerous contributing

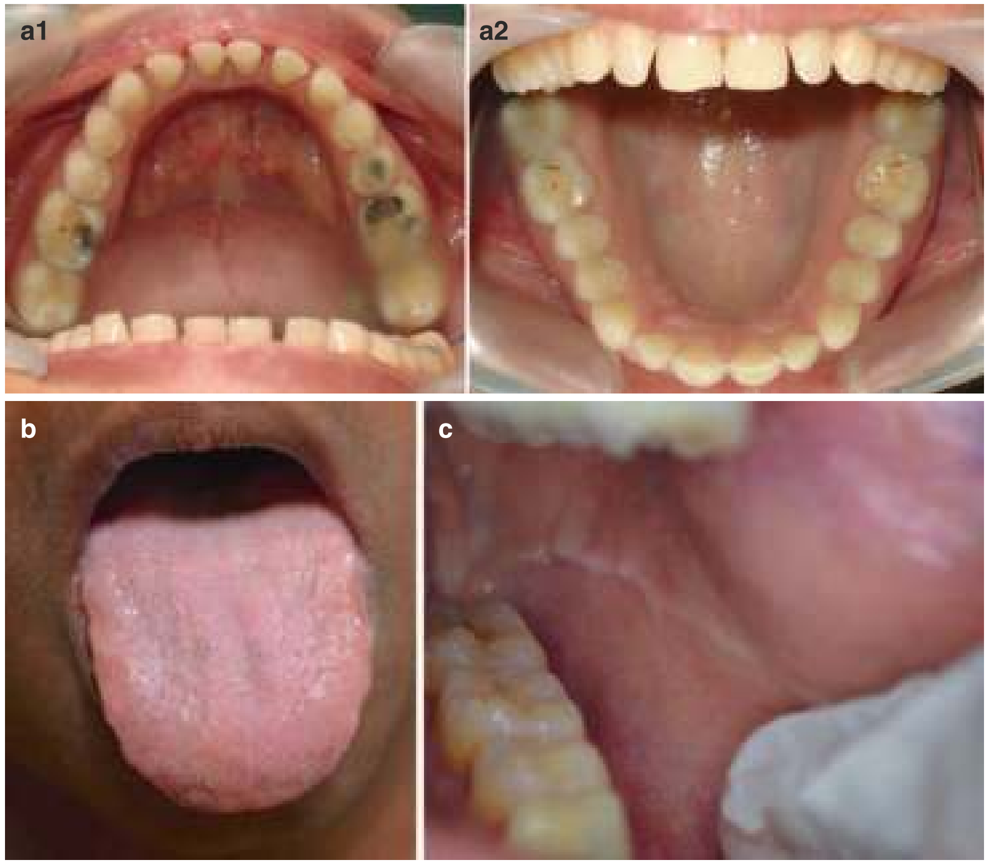

Fig. 62.8 (**a**) Attrition of teeth from bruxism. (**b**) Scalloping of tongue margins (**c**) Linea alba

Table 62.1 Central and peripheral causes of MPDS

Central causes	Peripheral causes
Stress	Adverse postural issues
Anxiety	Repetitive localised strain in the form of occlusal parafunction
Depression	

factors. The challenge in management consists of educating patients about the lifestyle factors that contribute to MFP, the persistence of which tends to result in treatment failure. Studies by Fricton and Aronoff [29, 30] et al. indicate that patients with MFP visit multiple practitioners in their quest for relief and are often treated with multiple modalities in a disorganised manner without experiencing improvement other than on a temporary basis.

62.10.2 Formulating a Comprehensive Problem List

Patient must be encouraged to adopt therapeutic lifestyle changes such as diet modification, exercise, proper sleep habits, social support and coping mechanisms which may contribute to more holistic and long-lasting positive outcomes.

62.10.3 Role of Interdisciplinary Management for the Complex Patient

Patients exhibiting multiple and often overlapping risk factors are best approached via an interdisciplinary involvement that uses a team of specialists to address the varied nuances

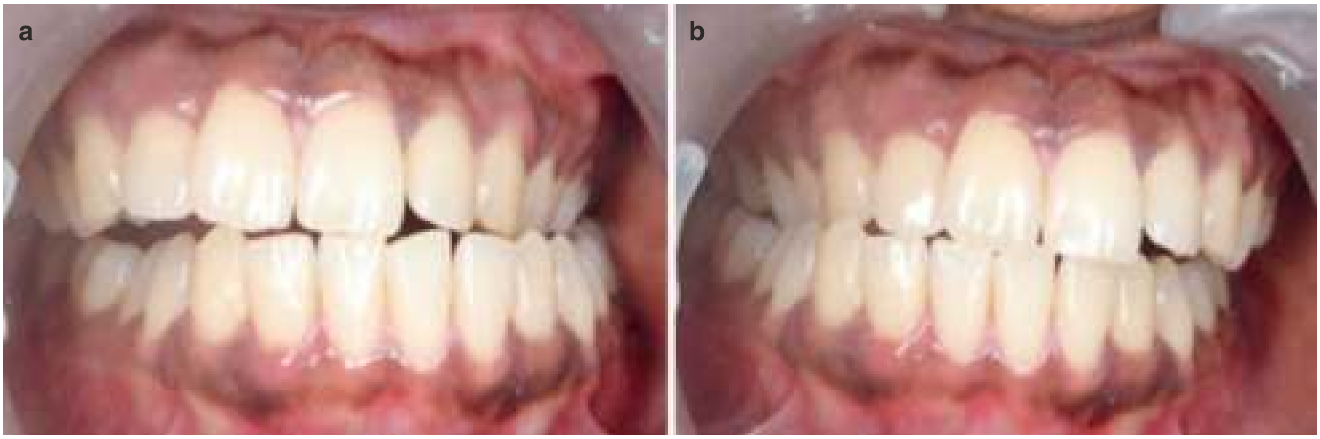

Fig. 62.9 (**a**) Restricted laterotrusive jaw movements—contralateral side (**b**) Unrestricted laterotrusive jaw movements—affected side

Table 62.2 Causes of clicking

Causes of clicking
1. Disc displacement with reduction
2. Hypermobility of the condyle
3. Loose intra-articular bodies like arthroliths, intra-articular fracture fragments of the articular surface [29]
4. Thickening of the soft tissue on the slope of articular eminence

of the problem in an organised manner. In both simple and complex cases, the clinician needs to isolate the individual problem area and arrive at a customised solution best suited to the patient.

62.10.4 The Role of Occlusal Splint: Termination of the Cycle of Habitual Pain

Chronic pain is a learnt pattern that arises from repetition and is generated by the CNS. This habitual pattern must be arrested before attempting to treat MPDS. Treatment of MPDS is dependent on breaking the repetitive pattern generated by the central nervous system. Nociceptive responses are carried from peripheries into the central nervous system (CNS) through myelinated (type A-delta) or unmyelinated (type C) nerve fibres [31]. Dental malocclusion as a causative factor for MPDS has been found in literature since most treatment modalities hint at occlusal alteration one way or another. In a study by Laskin et al. [32], the authors remarked that many aspects of MPDS are yet to be explored; many have agreed that rapid improvement of symptoms is noticed with splint therapy. Splint therapy is an effective method of isolating occlusion as the causative factor as the interposition of a splint can immediately and dramatically break the pain pattern generated by the CNS. It is however necessary that splint therapy be initiated by skilled practitioners.

Soft splints are constructed of polyvinyl worn at night. It may act as a habit breaker.

The anterior bite plane or Lucia Jig is recommended for short-term use and is to be worn at night. Stabilisation splints help to disocclude the jaws, thereby restoring normal joint space with prolonged wear. These are also used to correct disc dislocations in internal derangement. The anterior repositioning splint allows the patient to close the mandible in a forward direction; however, this has not yielded successful results in many circumstances.

The gnathological splint was designed based on Roth's philosophy of correction of centric relation-centric occlusion discrepancies. It is a permissive type of hard splint made of heat cure clear acrylic fabricated using a semi-adjustable articulator (SAM 3, AD2, PANADENT articulators). It is usually worn full time in maxillary or mandibular arch. The splint is designed on the concepts of gnathology to correct the centric relation-centric occlusion (CR-CO) discrepancies, which are a sequence of progressive disc derangements.

A few important factors to be considered prior to splint fabrication include diagnosis and institution of therapy by skilled clinicians, and alteration of occlusion results in

Fig. 62.10 Diagnosis of clicking sound in the TMJ. (**a**) Patient in closed mouth position, with anterior disc displacement (shown by TMJ superimposition) and (**b**) Condyle translating over the displaced disc (TMJ superimposition), to produce clicking sound

changes in masticatory behaviour which in turn alters neuromuscular activity and learnt patterns of pain generation. Regular follow-up is essential after splint usage. This helps to identify any complications as a result of splint therapy which might mandate stoppage of splint therapy altogether [33, 34]. The specific type of splint and duration of treatment must be carefully titrated for individual patients. Overuse of the right splint can also result in worsening of the condition by creating open bites, intrusion of teeth and loss of occlusal contact and worsening of MPDS symptoms [35–37].

62.10.5 Occlusal Adjustments

Wang et al. advocated elimination of premature contacts using occlusal adjustment as one of the most crucial methods for breaking the neuromuscular cycle in MPDS [38]. A thorough occlusal analysis has consistently been an instrumental diagnostic criterion to resolve MPDS symptoms.

62.11 Modalities of Management of MPDS

Because of the prolonged and occasionally varied treatment phases in the management of myofascial pain, the healthcare provider must develop a long-term association with the patient and direct the goals towards fostering a positive attitude towards therapy and commitment to long-term change [39, 40].

62.11.1 Muscle Exercises

Muscle exercises are the most effective for muscle rehabilitation. Active muscle stretching combined with passive exercises diminishes the sensitivity of trigger points. Postural exercises reduce trigger point reactivation, while strengthening exercises serve to enhance circulation and suppleness of the muscles. Determination of the muscular range of motion is the preliminary requirement prior to prescribing physiotherapy.

Postural exercises function to teach the patient to adopt a more neutral and relaxed body position, thereby ameliorating fatigue from undue stress on a set of muscles. Interincisal mouth opening is an effective indicator of muscle range of motion, and limited mouth opening is indicative of tender points in the masticatory muscles. Adverse postures such as jaw thrust and forward head position must also be discouraged.

Correctional exercises include:

1. Placement of the tip of the tongue on the roof of the mouth with the teeth parted.
2. Instruction in proper posture for daily activities like sitting, standing and lifting of objects.
3. Encourage sleeping on the side or back. This is effective for patients who complain of muscle stiffness upon awakening.
4. Incorporate a form of aerobic exercise into the daily routine to improve mood, circulation, strength and muscle endurance [41].

62.11.2 Muscle Treatments

There are various techniques for muscle stimulation.

Non-invasive methods of trigger point (TrPs) inactivation include

- massages,
- acupressure therapy
- and ultrasound application which act as non-invasive mechanisms of disruption.

Relaxation measures include

- moist heat applications,
- ice packs,
- Fluori-Methane sprays
- and diathermy which alter muscle and skin temperature.

Electrical current stimulation through

- transcutaneous electrical nerve stimulation (TENS),
- electro-acupuncture
- and direct current application stimulates the muscles and TrPs.

Methods of chemical and mechanical alteration of TrPs are achieved by:

- acupuncture and
- TrP injections with local anaesthetic,
- saline
- and corticosteroids.

Spray and stretch technique: Local muscle vapocoolant spray application alongside passive stretching renders instant pain relief [21, 42]. Failure of this technique has been attributed to:

(a) Inadequate achievement of full muscle dimension due to bone or joint abnormalities, muscular contractures or the patient's inability to voluntarily relax
(b) Incorrect technique of spraying
(c) Failure to attenuate causative factors

62.11.3 Trigger Point (TrP) Injections

Pain reduction, improvement in range of motion, better exercise tolerance and generalised enhancement of circulation in muscles are some of the positive effects of trigger point injections as documented by Cifala et al. [43] and Jaeger and colleagues [44].

Trigger point injections act by physical disruption of the trigger point from needle entry, and the pain relief may be seen to last from the anaesthetic duration to several months. Saline injections and "dry needling" have also been reported with varying degrees of success. Dry needling, frequently known as myofascial trigger point dry needling, is an alternative medicine practice comparable to acupuncture. It is carried out by physical therapists where permissible by state laws. The use of a combination of sub-anaesthetic doses of local anaesthetic agents has also been found to be successful. The results of a double-blind controlled trial by Simons et al. [45] suggested 3% chloroprocaine and 5% procaine (without vasoconstrictors) to be effective.

Corticosteroid in combination with a local anaesthetic administered as a local intramuscular injection was first practised in the early 1950s. Though there haven't been randomised trials to prove the efficacy of the same, Gray and colleagues suggested that locally delivered corticosteroids mitigate pain and improve function in patients with MPDS [46].

62.11.4 Trigger Points

These are areas of taut, inflamed muscle bands that elicit pain on palpation. Pain of this origin is usually referred to other sites in the local region. Figure 62.11a–e demonstrates the various muscles of the head and neck and the related trigger points elicited in MPDS.

62.11.5 Bite Adjustment

Despite many MPDS cases being treated from an occlusion-related standpoint, literature has shown dental occlusion or partial and total edentulism to be weakly correlated as causative or maintenance factors of TMPDS [47, 48].

Therapies ranging from occlusal adjustments on natural teeth to extensive prosthetic dental rehabilitation have been reported. Other treatments include oral appliances and orthodontics. Marbach [49] et al. demonstrated that missing teeth, malocclusion and night-time bruxism in control group patients did not correlate with facial pain and vice versa.

62.12 Intraoral Appliance Therapy *(Refer to suggested reading at the end of the chapter)*

Stabilisation appliances are well accepted, but the clinician must ensure that they are not ill-fitting, bulky, etc., so it is imperative to adjust them for patient comfort and better compliance. Regular reviews and inspection for soft tissue ulceration, dental pain, oral malodours, speech impairment, caries, tooth mobility and occlusal alterations must be carried out.

Splints: Box 62.2 enumerates the broad classification of splints conventionally used in the management of MPDS.

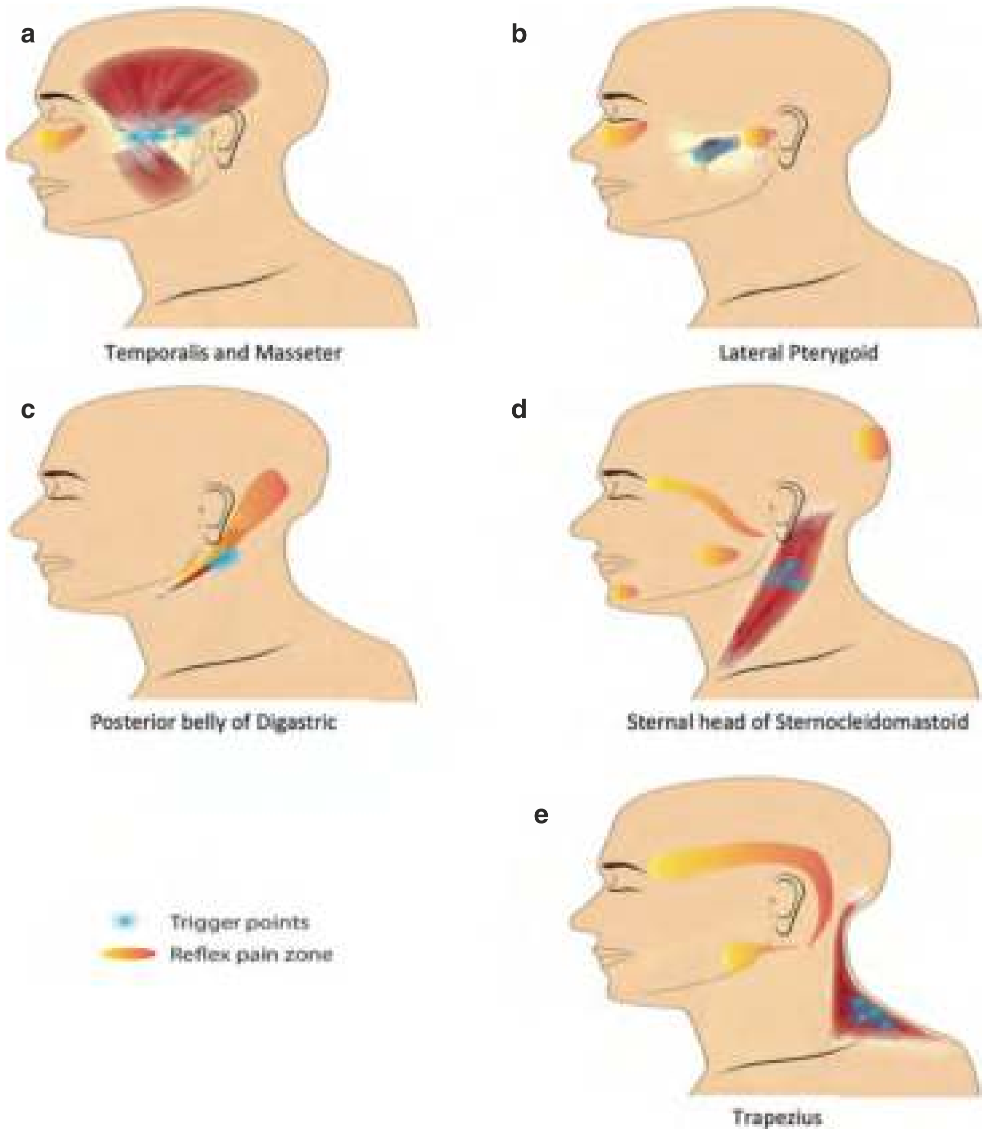

Fig. 62.11 Trigger points (blue) in chewing muscles, neck muscles and reflex pain zone (yellow-orange): (**a**) Masseter and temporalis. (**b**) Lateral pterygoid. (**c**) Posterior belly of digastric. (**d**) Sternocleidomastoid (**e**) Trapezius

Soft Bite Guard: Splint is constructed of polyvinyl worn at night. It may act as a habit breaker and also serves to protect the occlusal surfaces of the teeth (Fig. 62.12).

The Anterior Bite Plane or Lucia Jig (Fig. 62.13): For short-term use to be worn at night.

Stabilisation Splint: It is a hard splint made of acrylic for the restoration of occlusion (Fig. 62.14). It minimises abnormal muscle activity and restores neuromuscular balance.

Gnathological Splint: A specialised splint based on Roth's philosophy: To correct centric occlusal-centric relation discrepancies (Fig. 62.15a, b).

62.12.1 Pharmacotherapy

Multiple different pharmacologic therapies have found application in MPDS.

62.12.1.1 Non-steroidal Anti-inflammatory Drugs (NSAIDs)

In the case of TMPDS, few controlled trials exist that indicate daily use of NSAIDs offers little benefit when compared to the well-known occurrence of side effects as reported by Dionne et al. [50]. Singer and colleagues concluded that a 4-week trial of ibuprofen 1500 mg per day was no more effective than a placebo [51]. Patients report short-term relief with high doses of NSAIDs; however, long-term therapy with NSAIDs is not encouraged.

62.12.1.2 Opioids and Narcotic Analgesics

With the use of opioid and narcotic analgesics comes the problems of physical dependence, addiction and drug tolerance. There is a lack of controlled studies in literature to guide the clinician regarding the same which restricts the use of these drugs specifically to recalcitrant cases. Patient selection is critical when instituting opioid therapy, and success of therapy is usually measured by reports of reduction in pain intensity, return to quality of life and achievement of a stable dose.

Oral opioids are, namely, sustained release morphine, meperidine and butalbital in combination with aspirin and caffeine. Transdermal fentanyl is effective in some cases.

Box 62.2 Splints Used in the Management of MPDS (Refer to suggested reading at the end of the chapter)

Types of splint:

1. Permissive/muscle deprogrammers, e.g. stabilization splints, gnathological splint—Roth philosophy
2. Non-permissive/directive, e.g. anterior repositioning splint

Fig. 62.14 Stabilisation splints (hard split)

Fig. 62.15 (**a**) Gnathological splint (intraoral) (**b**) Gnathological splint (in vitro)

62.12.1.3 Antidepressants

Antidepressant drugs are frequently used in the management of a number of pain conditions, including MPDS. Studies indicate that these drugs behave independent to their role as antidepressants since they are effective at low doses (on average 23.6 mg for pain relief as opposed to a mean of 129 mg for depression) [52].

Amitriptyline and imipramine have been widely researched for their antidepressant and pain control properties. Dosage is initiated at 10 mg during bedtime and, if needed, is raised in 10 mg increments up to 30–40 mg. Analgesic effects are noted to occur within a few days. Side effects include sedation, constipation and dry mouth. TMPDS case reports have shown anecdotal evidence suggestive of agitation arising from selective serotonin reuptake inhibitors. Citalopram, a Selective Serotonin Reuptake Inhibitor (SSRI), had comparable effects to a placebo in the treatment of fibromyalgia [53]. Earlier sources of literature have also highlighted the efficacy of monoamine oxidase inhibitor drugs (phenelzine, tranylcypromine) in the treatment of orofacial pain conditions [54].

62.12.1.4 Muscle Relaxants

In the short term, diazepam and related muscle relaxants bring about relief from painful muscle spasms but are effective only for a short-term basis.

Benzodiazepines are associated with development of tolerance when used for a long period of time among other side effects. Varying degrees of relief have been reported with relatively low (diazepam, 5 mg bid; clonazepam, 0.5 mg bid or tid) doses, and usually an increase in dosage is not mandated.

62.12.2 Supportive Therapy

62.12.2.1 Ultrasound and Electrogalvanic Stimulation

Painful trigger points have been demonstrated to be managed effectively with therapeutic modalities such as ultrasound application and electrogalvanic stimulation (EG) [55]. Ultrasound causes localised muscle relaxation by producing heat deep within the fibres corresponding to the trigger points [56]. Low-voltage EG stimulation is used to stimulate muscles in a phased and rhythmic manner. This results in muscle relaxation and reduced muscle hyperactivity [57, 58]. These techniques are generally considered conservative and are extremely useful in mild to moderate cases of MPDS.

Box 62.3 outlines the prognosis and some of the important pearls to be borne in mind by the clinician attempting to treat MPDS.

Box 62.3 Clinical Pearls for Successful Outcomes and Prognosis of MPDS

Successful outcomes and prognosis of MPDS are dependent on the following factors:

- Accurate diagnosis—It is essential to isolate MPDS from a host of conditions that may mimic symptoms such as internal derangement, migraines and cluster headaches.
- Appropriate case selection—This necessitates the correct identification of the disease phase and institution of appropriate treatment measures.
- Clinician factors—Experience and patient rapport.
- Patient factors—Compliance, understanding, expectations.
- Multidisciplinary team approach—Effective communication between maxillofacial, orthodontic, orthopaedic and physiotherapy colleagues can ensure holistic management of the patient's condition.

Table 62.3 Summary of MPDS stages and authors' recommendation for management

Phase	Treatment approach
I (Fatigue and spasm causing pain and dysfunction)	• Avoidance of clenching and grinding • Soft diet • NSAIDs and muscle relaxants—ibuprofen, Valium
II (Unsuccessful phase I)	• Medications are continued • Splints (bite appliances) are introduced to prevent muscle overuse, including bruxism • Encourage to wear night and day • Medications discontinued if relief is obtained
III (Unsuccessful phase II)	• Physical therapy of muscles • Ultrasound
IV (Unsuccessful phase III)	• Psychological counselling • Referral to multidisciplinary centres • Surgery for recalcitrant cases

62.13 Treatment Summary

The management of MPDS can be summarised as follows (Table 62.3). (Refer also to Chap. 63 - Internal Derangements of the Temporomandibular Joint)

62.14 Recent Advances

Newer management methods that have emerged in the recent years for treatment of MPDS include botulinum toxin injections as well as cold and soft laser therapy.

62.14.1 Botulinum Toxin Injections

Botulinum toxin injection enhances vascularity by augmenting the blood flow to the affected muscles and releases the taut muscle fibres caused by abnormally contracting muscles [59]. It has also been reported to increase endogenous endorphin secretion by way of needle insertion into trigger points [60, 61]. However, studies reveal that 3–10% of patients develop neutralising antibodies with long-term adverse effects that include muscular atrophy [62].

The injection solution is prepared by dissolving 100 IU of botulinum toxin into 1.0 mL of sterile saline solution (0.9%) at room temperature to be done immediately before injection. An insulin syringe with a hypodermic needle may be used for administering the injection. Small increments of this solution may be injected into trigger points in different muscles. (refer Chap. 33 for more details)

62.14.2 Cold and Soft Lasers

Cold laser therapy or low-level laser therapy (LLLT) has been shown to play a substantial role in the treatment of generalised musculofascial disorders and facial pain relief [63–66]. After a thorough clinical examination of the patient that must reveal clearly the affected muscles, a treatment cycle is formulated which usually consists of low-level laser application like Ga-Al-As (Endolaser) of wavelength 780 mm for 4–6 weeks.

Theories put forth to explain pain reduction via low-level laser therapy include hyperpolarisation of neuronal cell membranes and resultant elevation of pain threshold alongside an increase in the secretion of morphine-like substances such as encephalin and endorphin which have an analgesic and anti-inflammatory effect [11].

Since trigger points are known to be of inflammatory nature [6], it can be concluded that laser application alleviates oedema, inflammation and pain by inhibiting inflammatory components such as prostaglandin (PGE2), prostacyclins, histamine and kinin.

62.15 Summary and Conclusion

It would be appropriate to conclude that successful outcomes and prognosis of MPDS are dependent on accurate diagnosis, appropriate case selection and above all an interdisciplinary involvement that uses a team of specialists to address the various nuances of the problems in an organised manner.

The clinician needs to isolate the individual problem area and arrive at a customised solution best suited for the patient.

The following salient points must be borne in mind by the reader on completion of the chapter on MPDS as shown in Box 62.4.

Box 62.4 Summary of Important Points

- Myofascial pain dysfunction syndrome is mainly a pain disorder related to muscles and fasciae, distinct from TMJ disc interference disorders and temporomandibular degenerative diseases.
- Myofascial pain can be defined as "A myogenous pain condition characterised by Local areas of firm, hypersensitive bands of muscle tissue known as trigger points".
- Bruxism and other parafunctional habits lead to sustained muscle contraction and eventually non-serous inflammatory reaction in masticatory muscles, muscle fatigue and pain.
- Splint therapy as interposition can dramatically break the pain pattern. "Lucia Jig" or anterior bite plane recommended for short-term use helps to disocclude the posterior teeth, thereby relieving muscle fatigue and pain caused by sustained muscle contraction due to clenching.
- Non-invasive method of muscle treatment includes inactivation massage, ice packs and Fluori-Methane sprays.
- Trigger point (TrP) injections with local anaesthetic, saline and steroids mitigate pain and improve function.
- Anti-depressants like amitriptyline in small doses (10 mg) at bedtime along with "Lucia Jig" for short-term use give good pain control results.

62.16 Case Scenarios

Case 1: (Fig. 62.16a–c)

A 29-year-old female patient complained of pain in the head and jaw for the past 2 years and underwent medical treatment for the same with little relief. On examination, muscles of mastication were sore and there was difficulty in manipulation of the jaw, and the patient showed a deep bite (Fig. 62.16a). CBCT showed increased joint space and MRI showed normal imaging. Having diagnosed with MPDS, the patient was advised gnathological splint (Fig. 62.16b) for full-time wear. The symptoms improved over 6–8 months. Post splint therapy, the bite was considerably opened (Fig. 62.16c), relieving pressure on the joint structures, and the patient was forwarded for orthodontic settling.

Case 2: (Fig. 62.17a–c)

A 48-year-old female patient complained of pain in the head and neck for the past 1 year. All the symptoms started with dental procedures which lasted long. On examination there was severe muscle spasm with tenderness in muscles of mastication and difficulty in opening mouth due to muscle spasm, and deviation on mouth opening was also seen. Intraorally, she had a deep anterior bite which was almost closed in relation to 11, 21, 31, 41 (Fig. 62.17a). CBCT and MRI showed normal imaging, and hence she was advised a gnathological splint (Fig. 62.17b) for her myofascial pain and to open the bite. The symptoms improved over 3–5 months of full-time wear, the bite was significantly opened and the patient was referred for orthodontic settling of the bite.

Case 3: (Fig. 62.18a–c)

A 21-year-old female patient who was a dental student reported with clicking sounds and pain on both sides of the lower jaw and severe teeth grinding at night for the past 6

Fig. 62.16 (**a**) Anterior deep bite with spacing in the lower anteriors. (**b**) Gnathological splint in place. (**c**) Post splint therapy correction of deep bite prior to orthodontic settling

Fig. 62.17 (**a**) Pretreatment occlusion showing anterior deep bite. (**b**) Gnathological splint in place. (**c**) Post splint therapy

Fig. 62.18 (**a**) Palpation of tender points on the temporalis and masseter muscles. (**b**) The Lucia Jig. (**c**) Patient wearing the Lucia Jig

months. The patient was clinically examined, severe tenderness was elicited on palpating the masseters and temporalis bilaterally (Fig. 62.18a), and intraoral signs of enamel wear from attrition were apparent. Imaging of the TMJ via MRI showed a normal study. She was advised to wear a Lucia Jig (Fig. 62.18b, c) for 3 months in order to disocclude the posterior teeth. In addition, she was prescribed amitriptyline (10 mg) once a day at night which she took for the same period. On follow-up after 3 months, she had complete relief from the pain and reported complete cessation of the parafunctional habit.

Acknowledgement The authors would like to acknowledge the invaluable contributions of a few who helped make this chapter a rewarding endeavour. We would like to thank Dr Elavenil P for her tireless efforts towards shaping important nuances of this chapter for the textbook. Dr Faisal Tajir and Dr Arvind Muhthukrishnan are sincerely appreciated for their timely contribution of clinical photographs and case scenarios included herein. The authors would like to extend heartfelt thanks to Dr Vidya Devi for the illustrations in this chapter.

Disclosure Authors have no financial conflicts to disclose.

63 Internal Derangements of the Temporomandibular Joint

Gary Warburton

63.1 Introduction

The term “internal derangement” has been used for more than a century in surgical and orthopedic literature to describe conditions that interfere with normal joint function [1, 2]. In the knee, the term internal derangement is broadly used to describe a torn, ruptured, or deranged meniscus of the knee, a partial or complete cruciate rupture, with or without injury to the capsular ligament of the knee, resulting in ongoing or intermittent signs and symptoms such as pain, instability, or abnormal mobility. Alterations in the disc, condyle-fossa relationships in the temporomandibular joint (TMJ) were suspected as early as 1887 by Sir Astley Cooper and published by Annandale in the Lancet “on displacement of the inter-articular cartilage of the lower jaw, and its treatment by operation” [3]. The term internal derangement was adopted and used to describe disturbances between the articulating components of the TMJ, alluding to the damage to the internal structures and dysfunction of the joint associated with changes in the position of the disc [4, 5].

In the TMJ literature, the term has evolved to be synonymous with disc displacement. In the 1970s and 1980s, TMJ internal derangement was perceived as a mechanical problem and resulted in attempts to reposition or replace the disc. In 1979, McCarty and Farrar stressed on the relevance of disc displacement as a major disorder of the TMJ [5]. It was believed that a displaced or abnormal disc was a progressive problem that led to degenerative joint disease and as a result importance was given to repositioning the displaced disc. Conservative therapy was done by mandibular manipulations and oral appliances, and surgical repositioning was performed for patients who had persistent symptoms. A commonly performed surgical procedure was repositioning of the disc, and if the disc was perforated or beyond repair, even discectomy was performed. Various materials and tissues were used for disc replacement (cartilage, dermis, muscle fascia, fat, silastic, and Proplast-Teflon). However, the use of Proplast-Teflon resulted in severe destruction of the articular surfaces due to foreign body giant cell reactions [6–8].

Over the past few decades, there has been a conceptual shift from internal derangement and disc displacement being a primary diagnosis toward our current understanding that disc displacement/internal derangement is an endpoint and a manifestation of a process in which there is damage to articular tissues and biomechanical failure from a specific cause that must be identified if treatment is to be successful.

Clinical and basic science research has led us to the conclusion that internal derangement represents a variety of stages of biomechanical failure of the joint tissues, resulting from different causes.Wilkes staging system (Table 63.1) categorizes the extent of joint damage in internal derangement without being specific for the underlying cause that is responsible for the failure of the joint tissues. With this limitation in mind, Wilkes classification [9] is still useful today in communicating severity and guiding treatment.

The realization in the 1990s that arthroplasty with disc repositioning or discectomy often leads to degenerative joint disease and fibrosis, coupled with the fact that the disc repositioning was not reliably maintained, caused a major change in surgical management. Arthroscopic surgery of the TMJ was shown to be an effective alternative to arthroplasty. Arthroscopy was a reliable procedure to reduce the pain and to improve the maximal incisal opening without causing a change in position of the disc [10–15]. The role of disc displacement and disc position in symptomatic patients has been further questioned due to the fact that MRI studies have documented disc displacement in 32–38% of asymptomatic patients and volunteers [16, 17]. We now know that the abnormally positioned disc is not the primary cause on pain and dysfunction for many

Table 63.1 Wilkes classification

Stage I Early	Painless clicking Anterior disc displacement with reduction
Stage II Early intermediate	Clicking with intermittent pain and locking Anterior disc displacement with reduction
Stage III Intermediate	Pain, joint tenderness, frequent and prolonged locking, restricted motion, No degenerative changes Anterior disc displacement with or without reduction
Stage IV Intermediate-late	Chronic pain, restricted motion, no clicking, degenerative bony changes Adhesions Anterior disc displacement without reduction
Stage V Late	Variable pain, painful function, reduced function, crepitus, advanced degenerative bony changes, gross disc deformity and/or perforation Advanced adhesions Anterior disc displacement without reduction

patients as the majority of patients with displaced discs are asymptomatic through the process of adaptation.

Arthrocentesis was subsequently introduced as another effective yet minimally invasive means of treating patients with symptomatic internal derangement [18–22]. Arthroscopy and arthrocentesis allowed sampling synovial fluid and has been of tremendous value in our understanding of the biochemical mediators and cytokines responsible for inflammation, cartilage degeneration, and destruction of joint tissue leading to internal derangement [23–26].

Diagnostic criteria for temporomandibular disorders (TMD) for research and clinical purposes were recently updated in 2014 [27] and include internal derangement or disc displacement which is presented as:

- Disc displacement with reduction
- Disc displacement with reduction with intermittent locking
- Disc displacement without reduction with limited opening
- Disc displacement without reduction without limited opening

Normal disc position, displacement with reduction, and displacement without reduction are depicted in Fig. 63.1.

63.2 Epidemiology

Internal derangement of the TMJ is a relatively common problem. Farrar estimated that up to 25% of the population has TMJ internal derangement [28]. Epidemiologic studies have shown that TMJ clicking is detectable in up to 31% of the population, and crepitus is detectable in up to 40% of the population on auscultation, with a higher prevalence among women.

MRI studies have documented disc displacement in 32–38% of *asymptomatic* patients and volunteers [15, 16]. The mean age for TMJ disorders is 34 with 90% of patients falling within 15–45 years of age range. Agerberg et al. studied 637 people aged 18–65 and found an incidence of 21% clicking in men and 28% in women, while crepitus was noted in 26% of men and 40% of women [29]. Disc displacement occurs most commonly in the anterior or anteromedial direction, which is the most common direction of displacement followed by lateral and rarely posterior displacement accounting for only 0.7% of displacements [30].

63.3 Etiology

Internal derangement is an endpoint and a manifestation of a process in which there is damage to articular tissues and biomechanical failure from a specific cause that must be identified if treatment is to be successful. The broad etiologic categories resulting in internal derangement are:

- Macrotrauma—major impact to jaw, e.g., sports injury, assault
- Microtrauma—parafunctional habits (clenching and bruxism)
- Systemic arthropathy—rheumatoid, SLE, psoriatic arthritis, HLA B27, infective, etc.

An alternative framework regarding etiology is:

- A normal joint subjected to overload (trauma or parafunction)
- An abnormal joint subjected to normal load (rheumatoid, SLE or psoriatic arthritis, osteochondroma, chondromatosis)

The majority of patients fall into the normal joint subjected to overload etiologic category and in particular due to parafunctional habits of clenching or bruxism during the day or at night.

Historically occlusion has been considered a primary etiologic factor, but this has now been refuted in current evidence-based literature [31, 32].

63.4 Anatomy and Function Relevant to Internal Derangement

The TMJ is a hinging and sliding synovial joint (ginglymoarthrodial joint) and forms the articulation between the mandibular condyle and the temporal bone. The articular surfaces

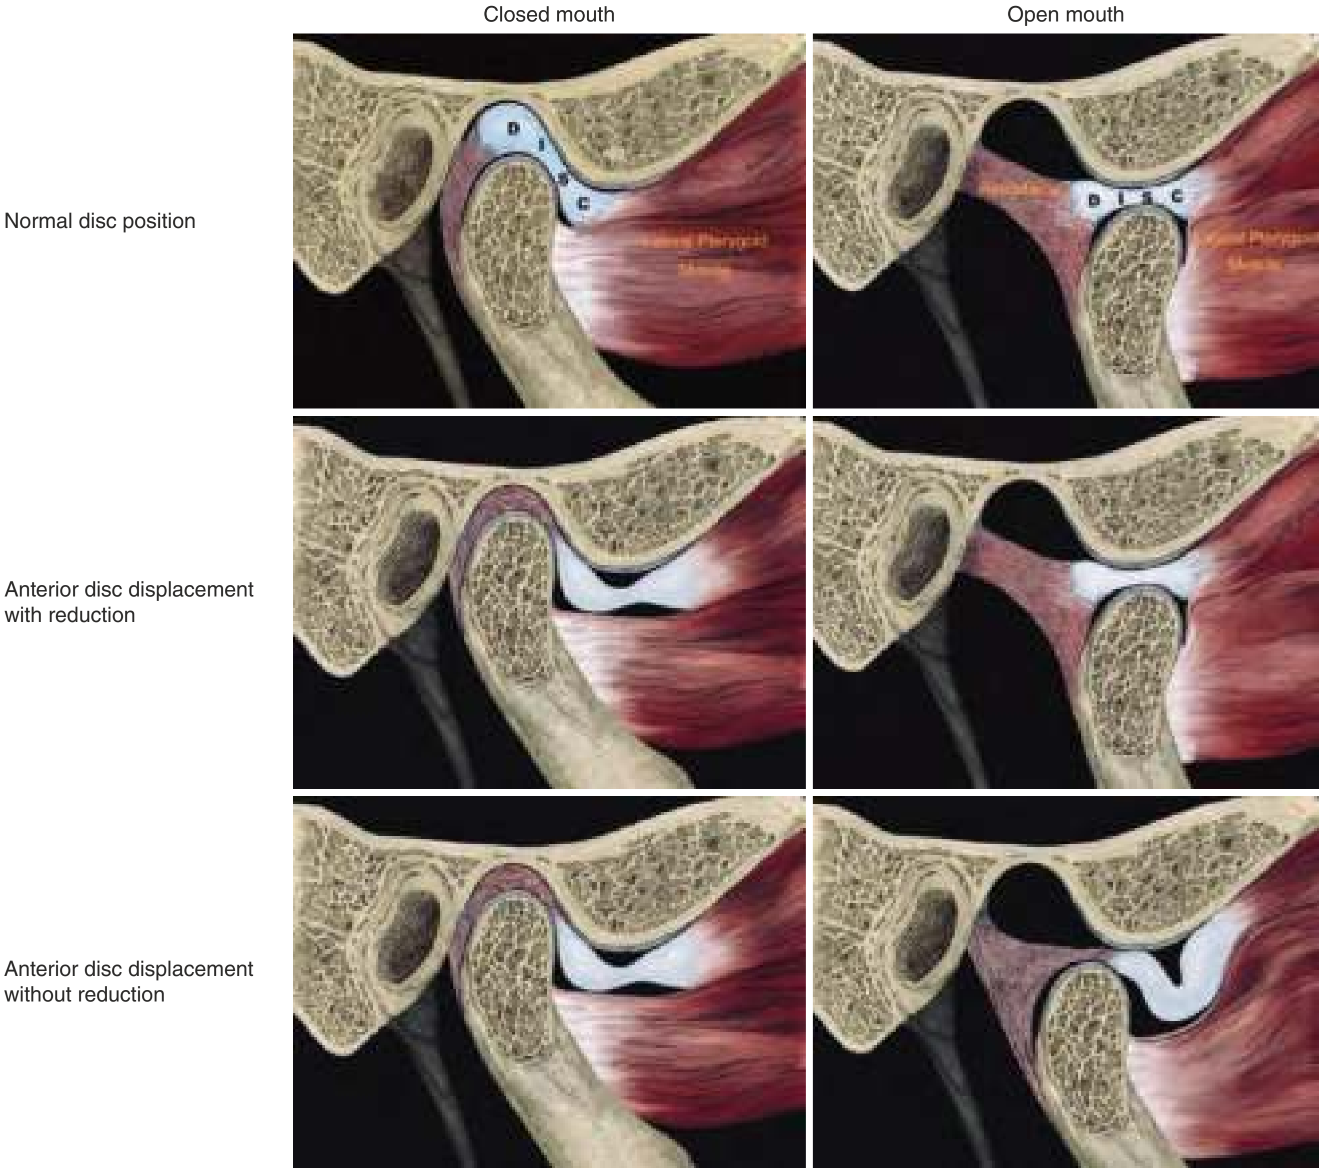

Fig. 63.1 Normal and displaced disc positions, with and without reduction (modified with the permission of Dr. Robert Talley)

are covered with fibrocartilage, while most other synovial joints are composed of hyaline cartilage. Fibrocartilage is composed of fibrochondrocytes, fibroblast-like cells, type I collagen, and proteoglycans. Fibrocartilage is less susceptible to degeneration and also has a greater repair capacity compared to hyaline cartilage [33]. The articular disc or meniscus that is interposed between the mandibular condyle and articular eminence of the temporal bone is also a fibrocartilaginous structure in the shape of a biconcave elliptical disc. It has a thicker posterior and anterior band with a thinner intermediate zone in between (Fig. 63.2). From a lateral viewpoint in the closed mouth position when the condyle is seated in the glenoid fossa, the posterior band is normally positioned at the 12 o'clock position from a point in the center of the condyle. As the condyle rotates and translates forward beneath the disc during mouth opening, the disc comes to lie above the condyle (this has been termed "roofing"). The disc itself is an avascular structure and that has no innervation. The metabolic and nutritional requirements of the avascular disc are provided by the surrounding synovial fluid through a process known as weeping lubrication (whereby a small amount of synovial fluid is forced into and out of the disc during the compressive forces generated by joint function and loading of the disc). The disc is anchored to the medial and lateral poles of the condyle by the collateral (discal) ligaments (Fig. 63.3).

Figure 63.4 shows the attachments of the disc in a sagittal view. The posterior attachment of the disc is the retrodiscal

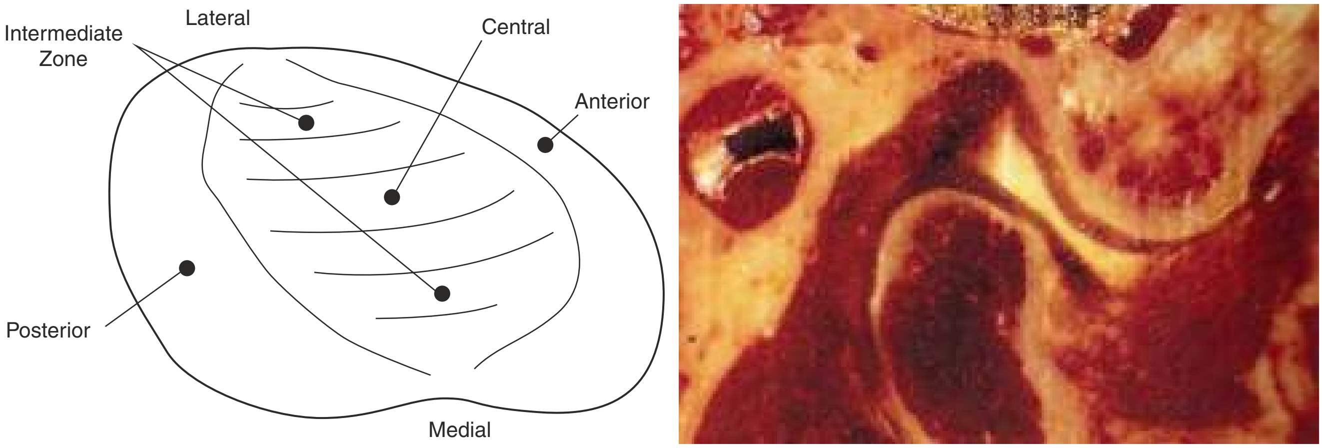

Fig. 63.2 Articular disc or meniscus (normal position) (Also see normal disc position in open mouth and closed position in Fig. 63.1)

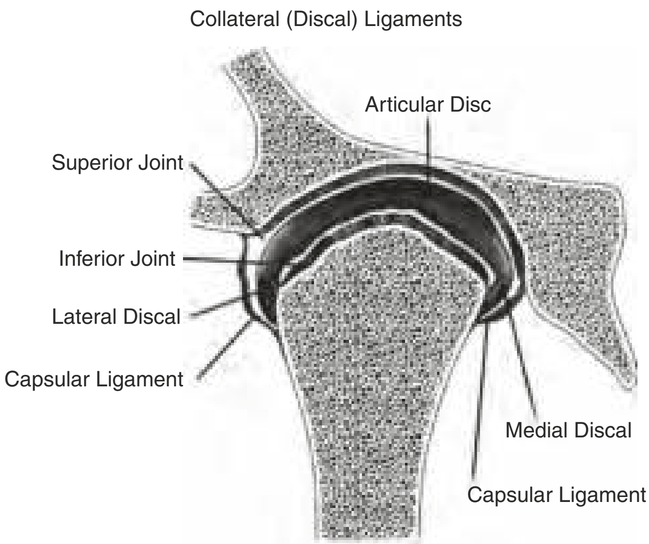

Fig. 63.3 Coronal view of the medial and lateral collateral (discal) ligaments

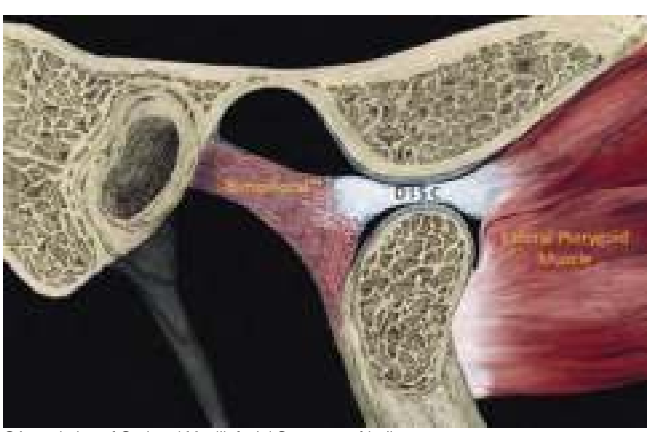

Fig. 63.4 Attachments of the disc in a sagittal view (modified with the permission of Dr. Robert Talley)

tissue. The retrodiscal tissue is a bilaminar structure with a superior lamina, inferior lamina, and intervening loose connective tissue that is very vascular and well-innervated. The retrodiscal attachment connects the disc to the tympanic plate of the temporal bone by the superior lamina, which is composed of connective tissue and elastic fibers. These elastic fibers condense to form a prominence recognized arthroscopically as the posterior oblique protuberance/band. The inferior lamina is composed of collagen fibers and inserts into the condylar neck. The disc and retrodiscal tissue together divide the TMJ into upper and lower joint spaces which are filled with synovial fluid. The anterior attachment of the disc is to the temporal bone, the anterior condylar neck, and the upper head of the lateral pterygoid muscle, while the medial and lateral attachments are to the capsular ligaments as well as the collateral ligaments. All the joint surfaces are covered with synovial lining except the disc itself, glenoid fossa, articular eminence, and condylar head.

It is the collateral (discal) ligaments along with the superior and inferior lamina of the retrodiscal tissue that are disrupted and elongated when the disc is displaced anteriorly in internal derangement.

The glenoid fossa of the temporal bone lies immediately beneath the middle cranial fossa (Fig. 63.5a, b). From both arthroscopic and open surgical standpoints, one must recognize that the bony roof of the fossa is extremely thin. An autopsy study revealed that the glenoid fossa was only 0.2–1.5 mm thick in normal joints and 0.5–2.0 mm thick in joints with disc displacement [34]. Care must be taken not to perforate the thin roof of the fossa during arthroscopic and open TMJ surgical procedures.

The TMJ is innervated by the trigeminal nerve, predominantly through the auriculotemporal branch of the mandibular division which passes behind the condylar neck and penetrates the capsule to enter the joint. However, some innervation also comes from the deep temporal and masseteric branches.

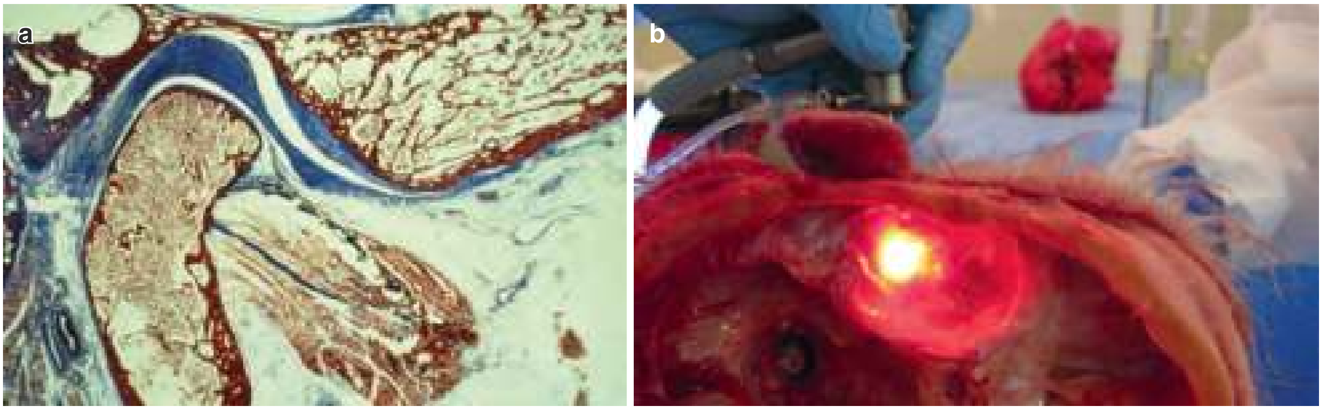

Fig. 63.5 (**a**) Sagittal section through TMJ and glenoid fossa. (**b**) Cadaveric specimen viewed from the middle cranial fossa (brain removed) with an arthroscope in the left TMJ. Both demonstrate the thin roof of the glenoid fossa

63.5 Clinical Features and Diagnosis

The most common presenting complaints in patients with TMJ internal derangement include:

Pain
Joint noises (click or crepitation)
Loss of function
Occasionally a change in occlusion

The loss of function may be due to limited mouth opening (closed lock in anterior disc displacement without reduction), a mechanically obstructive click, or dietary compromise secondary to pain.

63.5.1 Patient History

A good clinical history is essential for accurate diagnosis of any TMJ disorder including internal derangement. Questions including onset and evolution of the problem may reveal a classical story of a clicking or "popping" joint, indicating a disc displacement with reduction, or a story in which a patient with a history of a clicking joint notices that the click suddenly disappears and at the same time develops limited mouth opening and pain indicative of progression to disc displacement without reduction. Questions regarding initiating factors are helpful in identifying the underlying etiology (trauma or parafunction). Patient reports of pain increasing with stress or pain present on waking from sleep are strongly suggestive of parafunctional habits.

Other questions should include details of prior treatment attempts and specific questions regarding pain:

Location
Radiation
Severity
Timing (intermittent or constant)
Duration and frequency of episodes
Exacerbating factors
Relieving factors
Associated symptoms (headache, tinnitus, etc.)

The answers to these pain questions may suggest pain originating from the joint when the pain is localized over the preauricular area, compared to muscular pain when it is more widespread, a critical differentiation in determining appropriate management. Problems with other joints such as pain or laxity may suggest systemic arthritis or even conditions such as Ehlers-Danlos syndrome.

63.5.2 Patient Examination (Fig. 63.6a–c)

Should include examination of the muscles of mastication, TMJ, range of mandibular motion, and intraoral examination to evaluate occlusion and signs of parafunction (buccal mucosal ridging at the level of the occlusal plane, scalloping of the lateral border of the tongue, tooth wear, and fractured teeth or restorations).

When examining each pair of muscles, one should evaluate for tenderness, trigger points, muscle mass, and tone. If the patient reports pain on palpation (indicating myalgia), it is helpful to determine if the pain is localized to the point of palpation (local myalgia), spreading beyond the point of palpation but within the muscle boundary (myofascial pain), or radiates outside the muscle boundary (myofascial pain with referral).

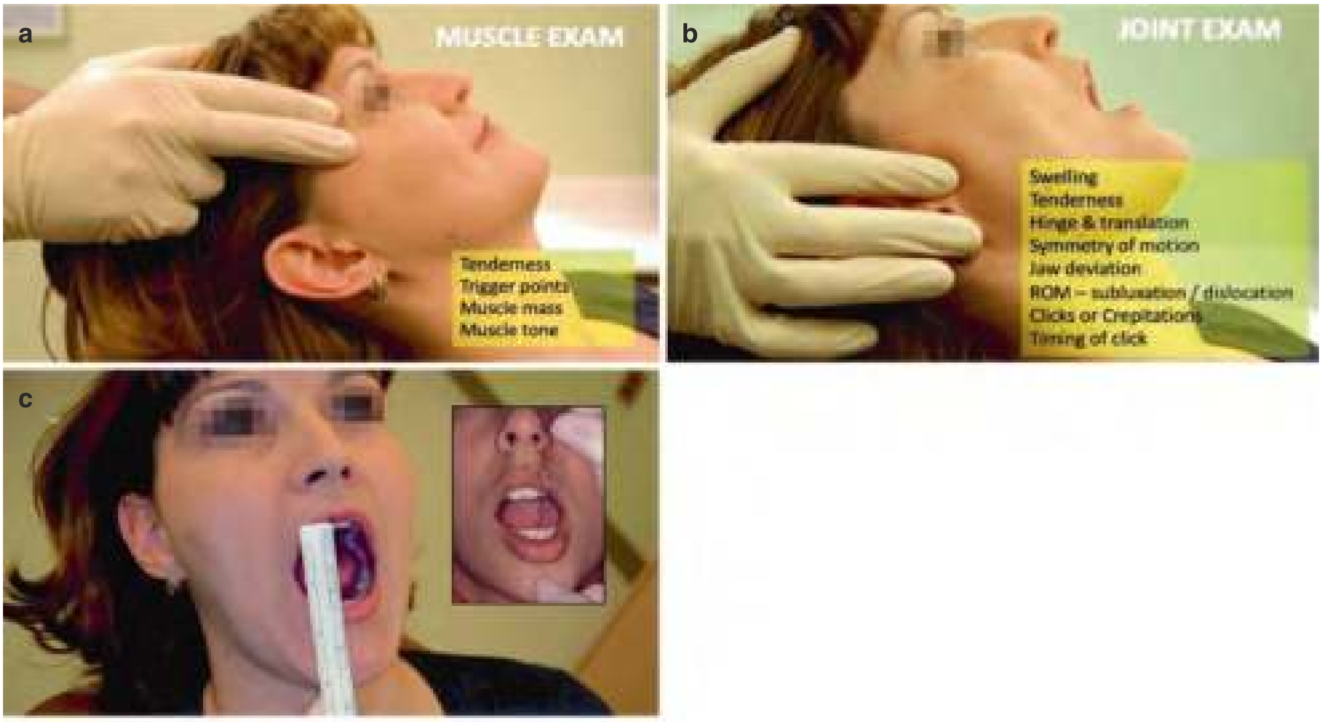

Fig. 63.6 (**a**–**c**) Examination of muscles, joint, and range of motion

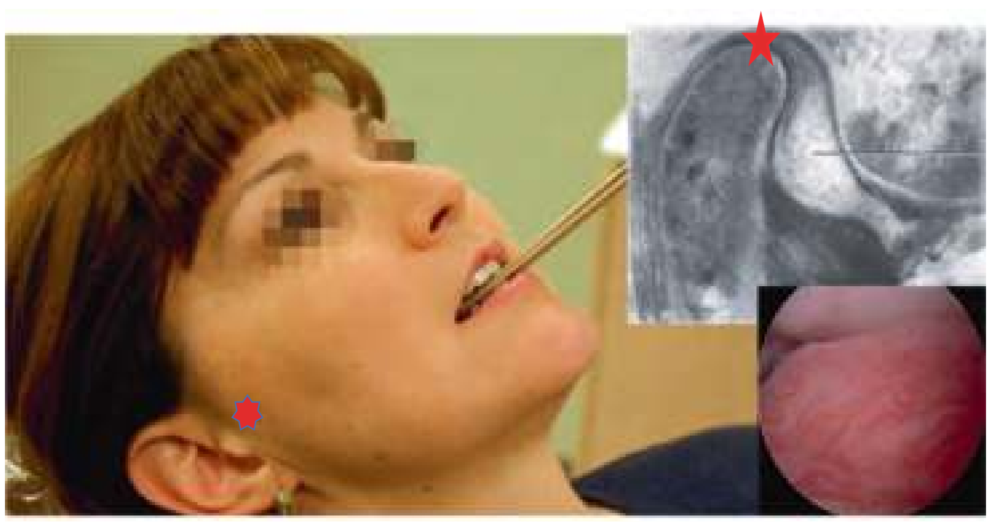
Fig. 63.7 Anterior disc displacement and retrodiscitis (as seen in the inset arthroscopic image) with a positive direct pressure loading test of the right TMJ = biting on tongue blades between left canines loads the right TMJ, and pain is reported in the right TMJ



When examining the joint, one should evaluate for tenderness, swelling, range of motion (hinge and translation), symmetry of motion or deviations, subluxation/dislocation, clicks, and crepitation. Joint noises may be audible or palpable, but some may only be detected by auscultation. Timing of any opening click provides clinical information on the extent of disc displacement before reduction. A very early click on condylar translation suggests minimal anterior disc displacement before reduction, while a late click suggests greater anterior displacement of the disc. If the disc is anteriorly displaced, there may be significant retrodiscitis due to the condyle functioning on the retrodiscal tissue rather than the disc itself (Fig. 63.7). If the patient is asked to bite on two wooden tongue blades between the canine teeth and they report pain localized to the contralateral TMJ that is now being loaded, this is pathognomonic for retrodiscitis and is known as a positive direct pressure loading test. Crepitations often indicate perforation, usually in the retrodiscal tissues, and may occur due to long-term function on the retrodiscal tissue or trauma.

63.5.3 Radiographic Evaluation

While plain radiographs and CT scans are useful for evaluating bony changes, MRI scans are best suited for evaluating disc position and displacement and have a diagnostic accuracy of at least 90% [35]. MRI should be ordered with both T1 and T2 images in the open and closed mouth positions (Fig. 63.8a–c); often additional imaging sequences are helpful such as fat suppressed or STIR sequences which help to show edema in tissues that contain fat. This can be helpful in evaluating edema in the cancellous bone of the condylar head. Using MRI, one can assess the bone of the condyle, fossa, and eminence (looking for sclerosis, erosions, flattening, osteophytes, and breaks in cortical continuity), the disc

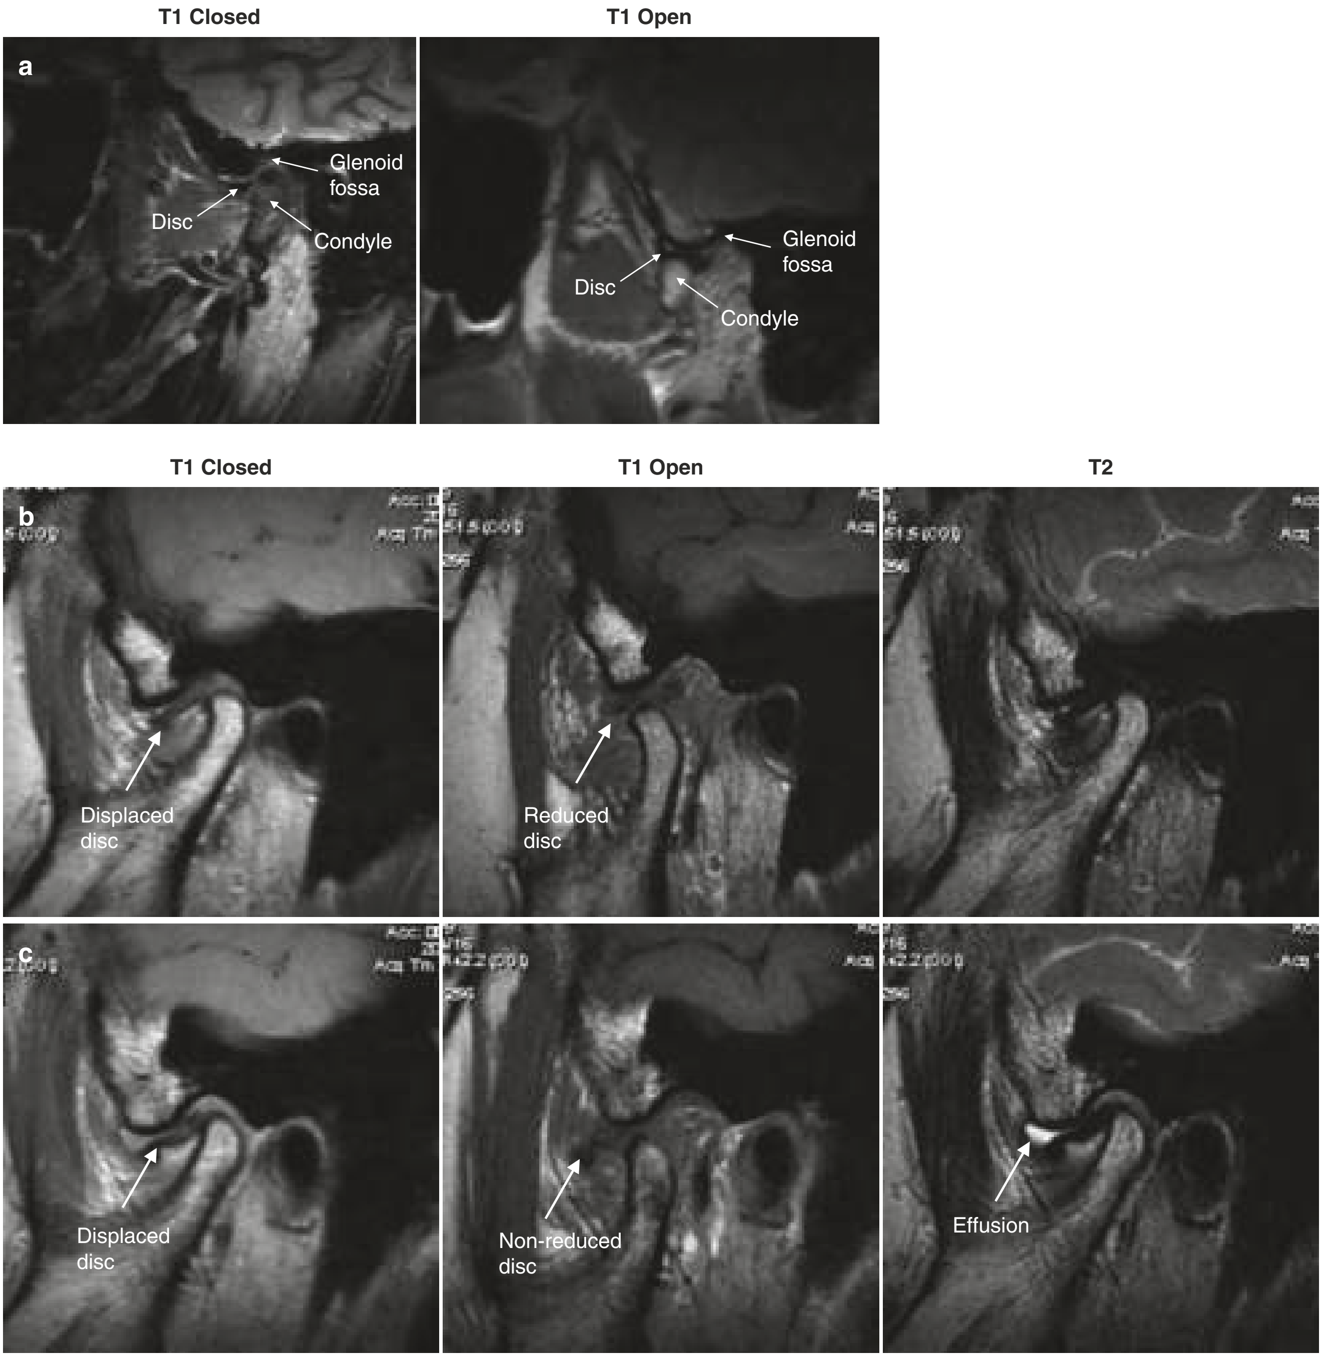


Fig. 63.8 (**a**–**c**) MRI scan—T1 and T2 images in closed and open mouth positions. (**a**) Normal disc position. (**b**) Anterior disc displacement with reduction. (**c**) Anterior disc displacement without reduction and superior joint space effusion

(looking at its position, density, shape, size, and continuity in cases of perforation), effusions which are easily seen on T2 sequences, and finally for collapse of the joint space. The sagittal closed and open mouth images determine if the disc is displaced and whether or not it reduces on opening.

63.5.4 Serology

Is helpful in the diagnosis of primary inflammatory arthritis (Table 63.2). Rheumatoid factors (RFs) occur in 60–80% of patients with rheumatoid arthritis (RA) [36]. While they are sensitive, their diagnostic utility is limited by their relatively poor specificity, since they are also found in 5–10% of healthy individuals, 20–30% of people with SLE, virtually all patients with mixed cryoglobulinemia (usually caused by hepatitis C virus infections), and those with many other inflammatory conditions. Higher titers of RFs (at least three times the upper limit of normal) have somewhat greater specificity for RA. The prevalence of RF positivity in healthy individuals rises with age. More recently, other antibody markers have been utilized. Anti-cyclic citrullinated peptide (anti-CCP) antibodies have a similar sensitivity to RF for RA but have a much higher specificity (95–98%). Anti-CCP antibodies are also present early in the disease, and their presence often correlates with more severe forms of RA, making them better prognostic indicators [37]. HLA-B27 is associated with seronegative spondyloarthropathies, psoriatic and reactive arthritis [38].

Table 63.2 Serology in primary inflammatory arthritis

Serology	• Rheumatoid factor → Rheumatoid arthritis
	• HLA B-27 → Reactive arthritis, ankylosing spondylitis, juvenile reactive arthritis
	• ANA → Autoimmune D/O (e.g. rheumatoid arthritis, systemic lupus erythematosus)
	• Anti-citrullinated protein antibody ACCP → Aid in dx of RA and its prognosis

63.5.5 Diagnostic Local Anesthetic Block

In complex cases where history and examination fail to clearly confirm pain originating from the joint itself, or in cases that have undergone previous surgeries on the TMJ, or in chronic pain patients, an auriculotemporal nerve block and injection of local anesthetic into the superior joint space is very helpful and can demonstrate the amount of pain originating from the joint. The author uses 3% mepivacaine injected using a dental syringe (Fig. 63.9a–c). With the patient in occlusion, the needle is inserted and advanced to contact the posterior condylar neck where half the carpule is injected as an auriculotemporal nerve block. The patient then opens their mouth, and the needle is advanced superiorly to contact the posterior slope of the articular eminence, and the remaining anesthetic is deposited into the superior joint space. The patients pain score before is compared to the pain score 10–15 min after injection. Any portion of pain that has resolved is most likely originating from the joint. This is helpful in determining if surgery is indicated and also in providing realistic postoperative pain expectations for the surgical patient.

63.6 Treatment of Internal Derangement

Treatment for internal derangement can be divided into nonsurgical and surgical options, but the general treatment goals are the same:

Decrease joint overload
Decrease pain
Reduce inflammation
Improvement in the range of motion
Restore function
Causative factors to be identified and controlled

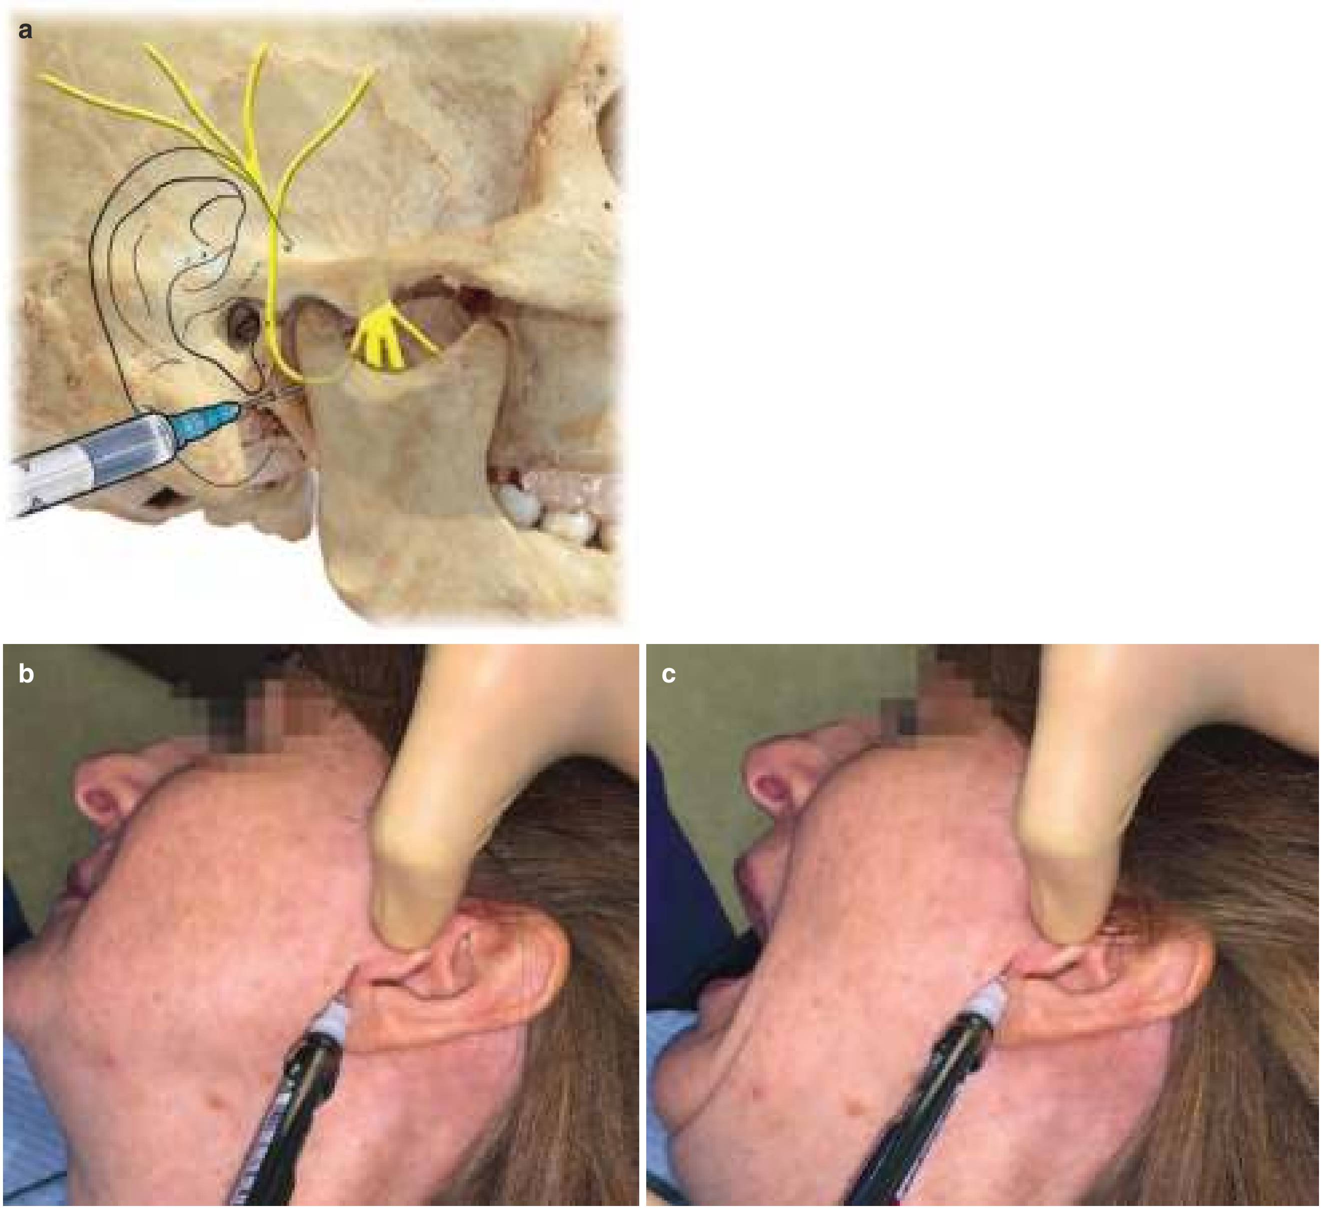

Fig. 63.9 (**a**–**c**) Diagnostic auriculotemporal nerve block and TMJ injection

Clinical research [39–41] into the natural progression of TMJ internal derangement has shown:

- Without any treatment, improvement is seen in many patients.
- On an average, about 1 year is required for the resolution of symptoms , but this time is variable.
- About 25–33% of patients do not improve.
- Older patients and those with MRI evidence of more advanced disease (osteoarthritis and advanced internal derangement) are at higher risk for not improving spontaneously.

63.6.1 Nonsurgical Treatment

Nonsurgical options include:

Patient education
Soft diet
Occlusal appliance/orthotic devices
Parafunctional habit awareness
Biofeedback
Nonsteroidal anti-inflammatory medication
Muscle relaxants
Botulinum toxin
Physical therapy

Occasionally, psychology referral and counselling are indicated in certain patients.

Patient education is of great value. A simple explanation of the mechanics causing a clicking joint with internal derangement with the information that around 30% of the population have internal derangement can be very reassuring and put a patient's mind at ease. Furthermore, educating the patient in habit awareness to avoid daytime clenching is a key element in the long-term success of any nonsurgical or surgical treatment (Table 63.3).

Orthotic devices or occlusal appliances may help to reduce nighttime parafunctional habits. However, our understanding of orthotic devices has changed significantly over time. In the late 1930s and 1940s, temporomandibular joint disorders (TMD) used to be seen as problems related to occlusal or skeletal disharmony. Costen was an otolaryngologist who in 1934 first suggested the link between occlusion, TMJ disorders, and ear symptoms based on his observations in 11 patients [42]. This evolved into orthotics and occlusal therapies being used for the treatment of TMJ disorders in the 1940s and 1950s. However, a significant paradigm shift has occurred as the classic dental and skeletal etiologic theories have been challenged and refuted by studies conducted around the world, and a biopsychosocial medical model of orthopedics, pain phenomenology, and behavioral factors has gradually replaced them. As a result, the conceptual basis for occlusal appliances/orthotic use has significantly changed over the years. Occlusal appliances/orthotics were initially conceived and used based on these old dental and skeletal etiologies and were thought to produce occlusal disengagement, relax jaw musculature, restore vertical dimension of occlusion, unload the joint(s), or reposition the condyle and or disc. Even today, these are often described as deprogrammers or jaw-repositioning devices that can establish ideal craniomandibular relationships wile relieving pain and restoring function. Until the 1960s, there were no well-controlled, well-designed, systematic studies evaluating the treatment of TMD. Instead, there were a number of anecdotal reports claiming success with various mechano-dental treatments, including various designs of oral appliance or orthotic [43, 44]. As the evidence-based literature has evolved, these reports have been refuted. Lundh [45] divided patients with symptomatic TMJ disc displacement into two treatment groups: one group with no treatment and one group with an occlusal appliance/orthotic and compared outcomes. After 12 months, pain had resolved in around 33% of patients in both groups. 40% of patients reported increased pain in the occlusal appliance/orthotic group compared to 16% in the no treatment group. Truelove [46] evaluated 200 patients with anterior disc displacement with reduction, arthralgia, and myalgia who were randomly assigned into three treatment groups: group 1 had basic nonsurgical treatment (education, self-care, hot/cold packs, and passive stretching), group 2 had hard flat plane occlusal appliance/orthotic, and group 3 had soft splint. Outcomes were evaluated after 3 and 12 months, and there were no significant differences in success among the three groups. Greene [47] and Laskin [48] studied the placebo effect using mock/sham occlusal appliances and sham occlusal adjustments. They found that non-occluding appliances/orthotics helped over 40% of patients and mock/sham occlusal adjustments helped almost two-thirds of patients. Furthermore, the use of occlusal appliances/orthotics may increase the parafunctional habit in some resulting in a patient complaining of increased pain and/or stiffness after use. In addition, partial coverage devices may result in occlusal changes if used for more than a few months due to eruption of teeth. Therefore, our perception of occlusal appliances/orthotics must take into consideration the current evidence-based literature.

Table 63.3 Nonsurgical management

Patient education (explain the condition)
Patient home care instructions
• Soft diet • Awareness and avoid clenching habits • Night time bruxism—night guard/orthotic • Range of motion • Heat and massage to muscles
Pharmacotherapy
• NSAIDs, muscle relaxants, tricyclics, sedatives, Botox
Occlusal appliance/orthotic
• For nighttime parafunctional habits
Physical therapy
• Posture training • Mobilization/manipulation/joint distraction • Massage/muscle conditioning • Physical agents or modalities • TENS , ultrasound, iontophoresis, phonophoresis, electrogalvanic stimulation, thermal
Stress reduction
• Psychologist • Counselor • Psychiatrist

In review of evidence-based literature on occlusal appliance/orthotics [45–47, 49, 50], we can conclude:

- Symptoms of myalgia and arthralgia may be decreased by occlusal appliances.
- Wear on the dentition caused by parafunctional habits may be reduced.
- Risk is low if they are not worn 24 h a day.
- The disc position is not changed by the appliance.
- Over time, many patients show improvement in signs and symptoms.
- There is no appreciable significant difference between the nontreatment and treatment group.
- Palliative care (NSAIDs, education, diet modification, exercises) seem to be as effective as more expensive appliance therapy.
- All treatments have a powerful placebo effect.

In Klasser's review [50] of occlusal appliances/orthotics, he concludes that rather than trying to establish new horizontal or vertical jaw relationships, occlusal appliance/orthotics today should be viewed as "oromandibular crutches," which are analogous to back braces or ankle support orthotics because they support the joint and provide symptomatic relief while the joints are recovering. Table 63.4 outlines Klasser's conclusions on occlusal appliance use and limitations.

Most often, painful internal derangement causes a reactive muscle response. This muscle response and myalgia can be treated by soft diet, heat, and massage to the affected muscles, limiting the range of motion to within the pain-free range, NSAIDs, muscle relaxants, physical therapy, and even botulinum toxin injections (e.g., Botox).

Table 63.4 Occlusal appliance/orthotic device limitations [50]

Can do	Can't do
• Protect teeth/restorations from fracture due to bruxism/clenching • Reduce/change the loading of the TMJ by reducing intensity, frequency, and duration of bruxism/clenching • Adding a foreign body into the occlusion briefly reduces muscle activity • Reduce headaches related to bruxism/clenching • Reduce internal derangement symptoms related to bruxism/clenching upon awakening • Change the neuromuscular engrams deprogramming	• Unload the disc by pivoting the mandible on the molars and distracting the condyle • Retrain muscle to be less active upon cessation of the appliance • Recapture and reposition discs • Permanently reduce bruxism/clenching • Relieve headaches that are neurovascular or vascular in origin

63.6.2 Surgical Treatment (Fig. 63.10)

The vast majority (approximately 90%) of TMD patients will experience symptom resolution either spontaneously or with nonsurgical treatment [51]. This resolution of symptoms occurs due to the underlying adaptive capacity of the TMJ. Given that internal derangement is a common MRI finding in 32–38% of asymptomatic patients and volunteers [16, 17] and that arthrocentesis or arthroscopy without disc repositioning is so successful, it is evident that the TMJ has the ability to adapt to the disc displacement in the vast majority of patients. Those patients with internal derangement and disc displacement that do not adapt are potential surgical candidates. It is the authors' preference to follow a surgical pyramid algorithm with most patients beginning with arthroscopy unless there are specific indications otherwise (e.g., ankylosis). Since no single surgical procedure carries a 100% success rate, patients who fail one level (phase 1) on the algorithm progress further up the pyramid to a second (phase 2) surgical procedure with phase 2 procedure being determined by the arthroscopic findings of phase 1.

63.6.3 Arthrocentesis

This minimally invasive procedure was introduced after the success of simple arthroscopy was recognized. Arthrocentesis in the TMJ was first described in 1987 by Murakami using a single needle pumping technique to create a hydraulic distention of the upper joint space [52]. Nitzan and Dolwick [18] subsequently modified the technique and used two needles. It provides lysis and lavage of the upper joint space

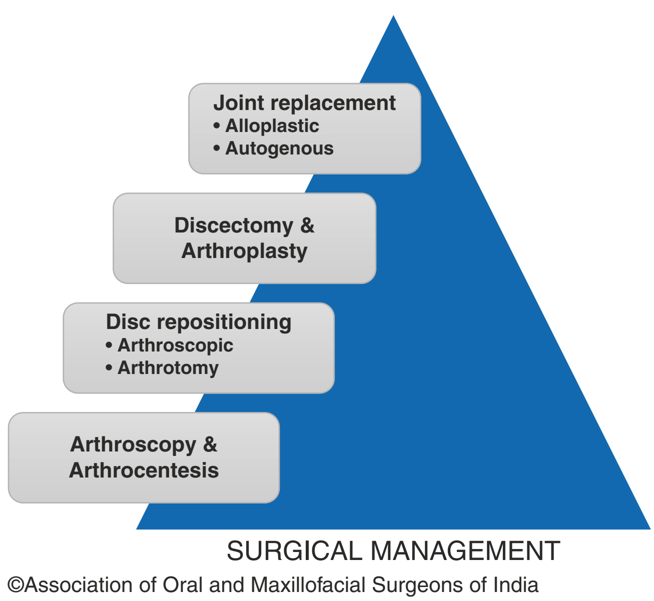

Fig. 63.10 Surgical treatment options

Fig. 63.11 Arthrocentesis—using the Holmlund-Hellsing markings measured along the trago-canthal line (10 mm forward from mid-tragus and 2 mm down correspond to the glenoid fossa entry site)

using an inflow needle, an outflow needle, and at least 300 ml Lactated Ringer's irrigation solution (Fig. 63.11). The lysis is accomplished by the hydraulic distention of the superior joint space, while the lavage removes inflammatory mediators, cytokines, and debris (Fig. 63.12). It is through the lysis and lavage that the adhesions are separated and the inflammatory mediators and debris are removed. Several authors have since reported success rates of arthrocentesis in the management of internal derangement ranging from 70 to 95% [18–22].

63.6.4 Arthroscopy

Minimally invasive arthroscopic surgery for the TMJ was first performed by Ohnishi in 1974 and subsequently developed in the 1980s by several surgeons (Murakami, Holmlund, McCain, Saunders, and others). TMJ arthroscopy has proven to be an effective and reliable alternative to open joint surgery for many patients, resulting in reduced pain and improved maximum incisal opening [10–15] with success rates as high as 91% [12]. TMJ arthroscopy can be as simple as a visually assisted lysis and lavage or as complex as performing disc repositioning and fixation. The author uses McCain's terminology to categorize different levels of arthroscopy according to complexity and number of portals of entry (Table 63.5).

The authors preferred surgical sequence for performing a level 1 arthroscopy as outlined in Table 63.6 (Video 63.1). All arthroscopy should begin with an examination under anesthesia of the TMJ. The EUA allows the surgeon to anticipate what might be encountered upon entering the joint arthroscopically. The range of condylar translation is noted, and whether translation is onto the peak of the articular eminence stops short of the peak or beyond the peak of the eminence as in subluxation and even dislocation. In addition, if there is very limited translation or just hinging, the surgeon might expect a tight joint space filled with adhesions and a fibrous arthrosis potentially making the arthroscopic puncture, joint access, and visualization difficult. Joint noises (clicking and crepitation) should be noted, and bone-on-bone crepitations are indicative of a perforation in the retrodiscal tissue.

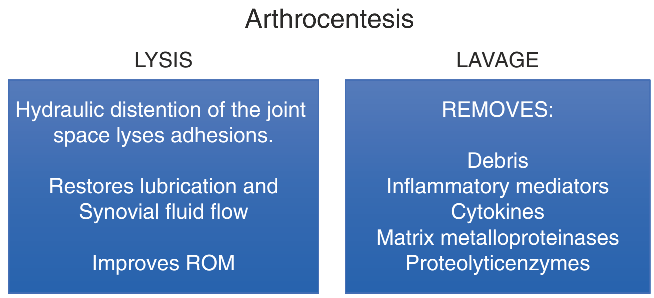

Fig. 63.12 Arthrocentesis—lysis and lavage

Table 63.5 Levels of TMJ arthroscopy (McCain's terminology)

Level I Arthroscopy
• Single puncture & outflow needle
• Lysis& lavage
• Diagnostic sweep
• Needle/scope adhesiolysis
Level II Arthroscopy
• Double puncture & outflow needle
• Level I
• Instrumentation port (laser, coblation, grasper, probe etc.)
Level III Arthroscopy
• Triple puncture & outflow needle
• Level II
• Discopexy(suture/screw)

Table 63.6 Level 1 arthroscopy sequence

• Examination under anesthesia
• Marking landmarks
• Superior joint space insufflation
• Trocar and cannula puncture
• Backwash
• Insert scope (confirm entry)
• Establish outflow
• Diagnostic sweep
• Medications (Steroid, hyaluronic acid or PRP etc.)
• Manipulation

In addition to the lysis and lavage as in arthrocentesis (Table 63.6), a level 1 arthroscopy provides a diagnosis and identifies intra-articular pathology (Fig. 63.13a–f). A systematic diagnostic sweep through the entire superior joint space is performed to obtain the diagnostic information. Level 1 arthroscopy can be accomplished using a standard operative arthroscope (usually 1.9–2.7 mm) or the more recently available disposable scopes (1.2 mm). While the image quality from a disposable scope is currently not as good as the traditional operative arthroscopes, it does allow for adequate visualization and a diagnosis.

Level 2 arthroscopy includes a second puncture with an operative cannula and allows for additional procedures such as disc mobilization, biopsy, laser ablation, or coblation to be performed. Video 63.2 shows the second cannula being inserted, disc mobilization with a probe, and laser ablation of hyperplastic polypoid synovitis.

Level 3 arthroscopy with multiple cannulas allows for more advanced techniques and disc repositioning with fixation, using sutures, wires, pins, or screws. The author uses a suture technique to anchor the repositioned disc as shown in the Video 63.3. Figure 63.14a, b shows the suture placed through the posterior band of the disc anchoring it into the reduced position. The arthroscopic suture video clearly shows how tightening the suture reduces the anteriorly displaced disc.

Several surgeons have described and published techniques to reposition and fixate the displaced disc [53–59]. Success in the early reports of arthroscopic disc repositioning was not high. Yang reported better success rates with partial and later complete anterior release of the disc from its anterior attachment and suggested that relapse rates without complete anterior release are high [55]. While more recent success rates of disc repositioning as high as 95.3% [60] have been reported, many of these studies have relatively short-term follow-up and/or no MRI confirmation of long-term stability of the disc repositioning.

It is the authors' opinion that level 3 arthroscopy should be performed primarily for functional reasons, e.g., a mechanically obstructive click, closed lock, or subluxation. In McCain's publication on arthroscopic discopexy [59], the

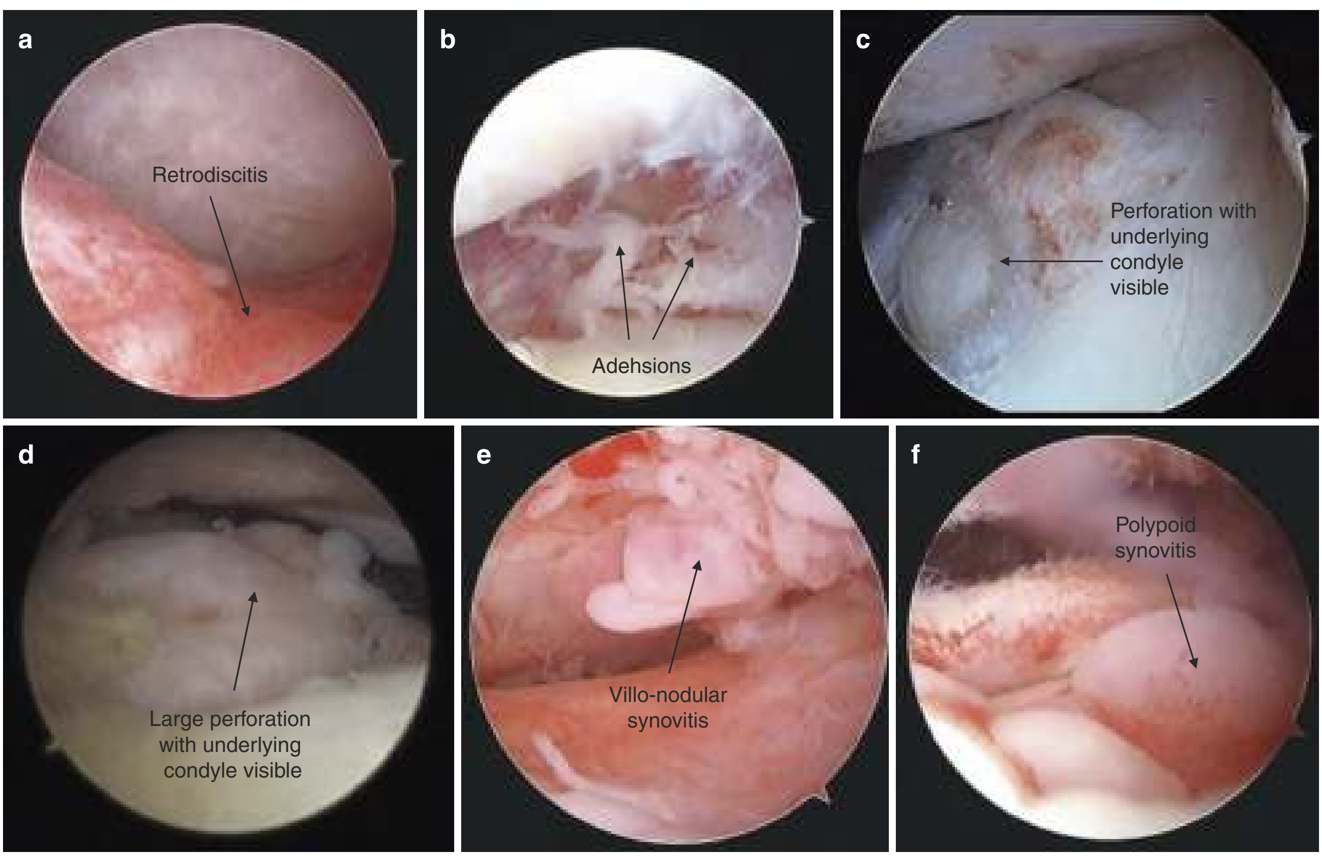

Fig. 63.13 (**a**–**f**) Arthroscopic pathology. (**a**) Retrodiscitis (**b**) Adhesions (**c**) Small disc tear/perforation (**d**) Large perforation with condyle visible (**e**) Villonodular synovitis (**f**) Polypoid synovitis

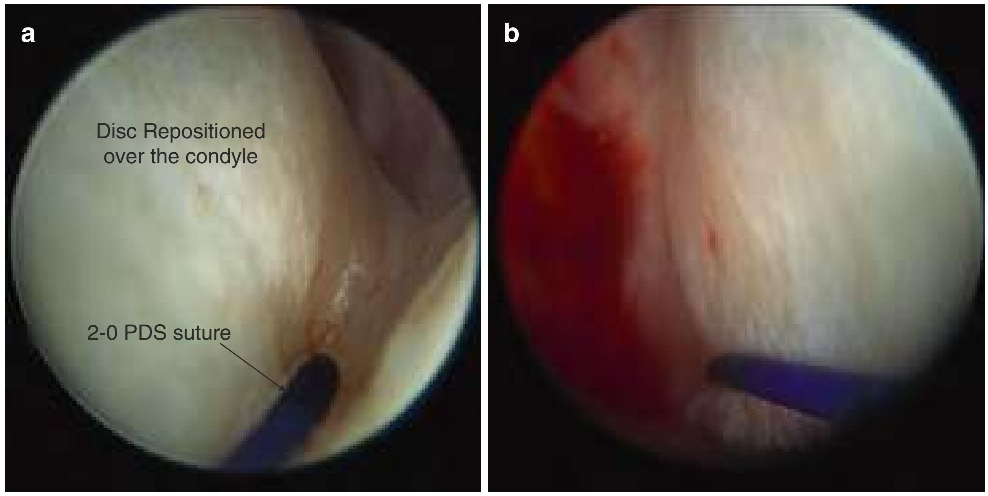

©Association of Oral and Maxillofacial Surgeons of India

Fig. 63.14 (**a**, **b**) Arthroscopic suture discopexy—suture placed through the posterior band of the disc anchoring it into the correct reduced position

success rate in 42 joints was 86.7% in Wilkes II and III but only 25% in Wilkes IV and V which emphasizes that case selection is a key element to success. For disc repositioning to be indicated and have good outcomes, the disc must be salvageable, and there must be sufficient posterior joint space height in which to reposition the disc. In other words, the disc must be intact, and MRI evaluation must confirm normal disc morphology with adequate posterior joint space height in which to reposition the disc. If the joint space has collapsed as is often the case in longer-standing/chronic disc displacement, the load placed during function on the repositioned disc will be excessive, and the fixation will likely fail, leading to displacement again. Postoperatively, all patients will notice a malocclusion with slight mandibular deviation to the contralateral side. However, the majority of these malocclusions will resolve within 3 weeks. Additional factors to success are the postoperative physical therapy and dietary instructions. The author instructs his patients to perform "limited range of motion" exercises for the first 3 weeks to minimize the risk of the fixation failing or tearing through the disc. This is achieved by instructing the patient to keep the tongue on the roof of the mouth while performing opening exercises. The diet should be soft with minimal chewing and as for all surgical cases and any parafunctional habits should be well controlled. After 3 weeks, the patients gradually increase their mouth opening with daily stretching exercises. Associated myalgias may improve once the joint pain and function improve following arthroscopy, but often concomitant nonsurgical treatment of the muscle disorder is also required.

At the end of the arthroscopic procedure, the surgeon has the option of injecting medications including steroid, hyaluronic acid (HA), and platelet-rich plasma (PRP).

63.6.4.1 Viscosupplementation with Hyaluronic Acid

Hyaluronic acid is a glycosaminoglycan polysaccharide naturally found in synovial fluid. It is produced by the chondrocytes and synoviocytes and plays an important role in joint function and nutrition. HA is the main contributor to the viscosity of synovial fluid and provides protection under joint loading. Inflammatory disorders of the TMJ including internal derangement are associated with reduced quantity and quality of HA through a process of destruction and also the production of HA that is lower in molecular weight [61, 62]. The short half-life of injected HA makes it unlikely that its effectiveness is due to restoration of the viscosity of the synovial fluid [63]. It is suggested that supplementation with injectable HA could have anti-inflammatory and analgesic effects [64]. Altman suggested that injection of HA could lead to repair of the articular cartilage/fibrocartilage and normalize the synthesis of endogenous HA [65].

Viscosupplementation has been described in orthopedic literature for many years, but there are discrepancies in the evidence to support the widespread use of intra-articular hyaluronic acid to treat knee osteoarthritis. However, several recent studies have shown hyaluronic acid to be a viable treatment option showing longer-term improvement in both knee pain and function. Unfortunately, similar uncertainty exists regarding the effectiveness of viscosupplementation using hyaluronic acid in the TMJ [66–68]. Beyond viscosupplementation, there are some additional benefits to using HA in TMJ arthroscopy. If the surgeon is having difficulty maneuvering the scope because of a tight joint space, the lubricant properties of HA may be helpful in minimizing iatrogenic damage to the joint surfaces and disc. It is also helpful at the end of the procedure in reducing the bleeding from a hyperemic joint.

63.6.4.2 Platelet-Rich Plasma

Is a concentration of platelets and growth factors taken from autologous blood. It has reported beneficial effects in joint degeneration and tendinopathy [69–72], and there is both literature supporting its effectiveness in TMJ arthroscopy [73–75] and conflicting literature reporting no benefit [76, 77]. Therefore, the use of PRP after TMJ arthroscopy remains controversial, and further studies are needed [78].

63.6.4.3 Open Joint Surgery and Arthroplasty

The effectiveness of minimally invasive procedures such as arthrocentesis and arthroscopy has significantly reduced the frequency and volume of open joint surgery (disc repositioning or discectomy). However, currently there are very few surgeons trained in the advanced technique of arthroscopic discopexy, and so for patients who fail level 1 or 2 arthroscopy and require disc repositioning surgery, open joint surgery with disc repositioning may be the next surgical step in moving up the surgical pyramid. Annandale first published "On displacement of the inter-articular cartilage of the lower jaw and its treatment by operation" in 1887 [3], but it wasn't until later that surgery for internal derangement became popular. Surgical interest in disc displacement began with reports from McCarty and Farrar [5] claiming disc repositioning success rates of 94% using a wedge resection and suture plication technique. However, other surgeons were not as successful, and the long-term stability of suture plication techniques was low, leading to multiple variations of open surgical disc repositioning and methods of fixation [79–82]. In 2001, Wolford reported a more rigid fixation technique using a Mitek mini-bone anchor to fixate the repositioned disc [83]. In this technique, the anterior and lateral disc attachments are released allowing passive disc repositioning. The disc is separated at its junction with the retrodiscal tissue, and Mitek anchor is inserted into a 2-mm hole drilled into the posterior condyle 8–10mm below articulating surface. Two 0-Ethibond braided sutures are inserted through the posterior band of the disc in a mattress suture fashion fixing the disc to the Mitek anchor (Fig. 63.15a–c). Although radiographs at the longest follow-up showed no condylar resorption and stable position of the metal anchor, the stability of the disc repositioning was not evaluated by MRI. Despite this, Wolford reported that there was a statistically significant reduction in TMJ pain, facial pain, headaches, TMJ noises, and disability and improvement in jaw function and diet.

Alternative fixation and anchoring devices are available on the market today. He et al. use a self-drilling miniscrew and have modified the technique to include a complete anterior release and overcorrection of the disc position for better stability of the repositioning. They report stable short-term (mean 10 months) disc position on MRI in 98.6% of patients [84]. Zhou et al. evaluated the same technique in 149 joints and the long-term stability of the repositioned disc on MRI at a mean longest follow-up of 23.4 months (range 12–84 months) and reported that 95.3% of discs were still in position, whereas 4.7% had relapsed anteriorly [85]. They also reported new condylar bone formation in 74.5% of joints and even greater in young patients (under the age of 20), 90% of whom had new bone formation, suggesting that adolescents may have growth ability after disc repositioning which might reduce facial asymmetry. Mandibular asymmetry in unilateral disc displacement has been reported in the literature. Xie et al. [86] reported mandibular asymmetry in 72% of 165 patients with anterior disc displacement and the severity of the asymmetry correlated with the degree of disc displacement, disc deformity, and condylar shortening. Therefore, disc repositioning may allow for condylar bone formation and reduce mandibular asymmetry that may develop as a result of the displaced disc. The overall clinical outcomes of disc repositioning surgery are good with reduced pain, improved diet, and improved range of motion with 94% of patients reporting improved quality of life [87].

For those patients with discs that are not salvageable, discectomy is the next step in the surgical pyramid. This involves removal of the disc and the area surrounding any perforation in the retrodiscal tissue, and possible replacement of the disc is an option. There are several long-term studies demonstrating greater than 80% success rates following discectomy [88–91] with a few following patients for more than 20 years [92–94] with almost complete resolution of pain and restoration of normal diet. A 5-year follow-up study of discectomy without any disc replacement reported 87% of patients fulfilling the criteria for success with reduced pain on function and increased mouth opening, although pain at rest was unchanged [95]. Following discectomy, radiographs will show altered condylar morphology in the operated joint, and this is thought to be an adaptive process of remodeling because the reduced symptoms do not correlate with the radiographic changes [96, 97]. While the literature demonstrates the long-term success of discectomy without replacement [89, 90], disc replacement options have been explored in attempts to reduce the crepitation these patients experience and also with the intent to reduce the

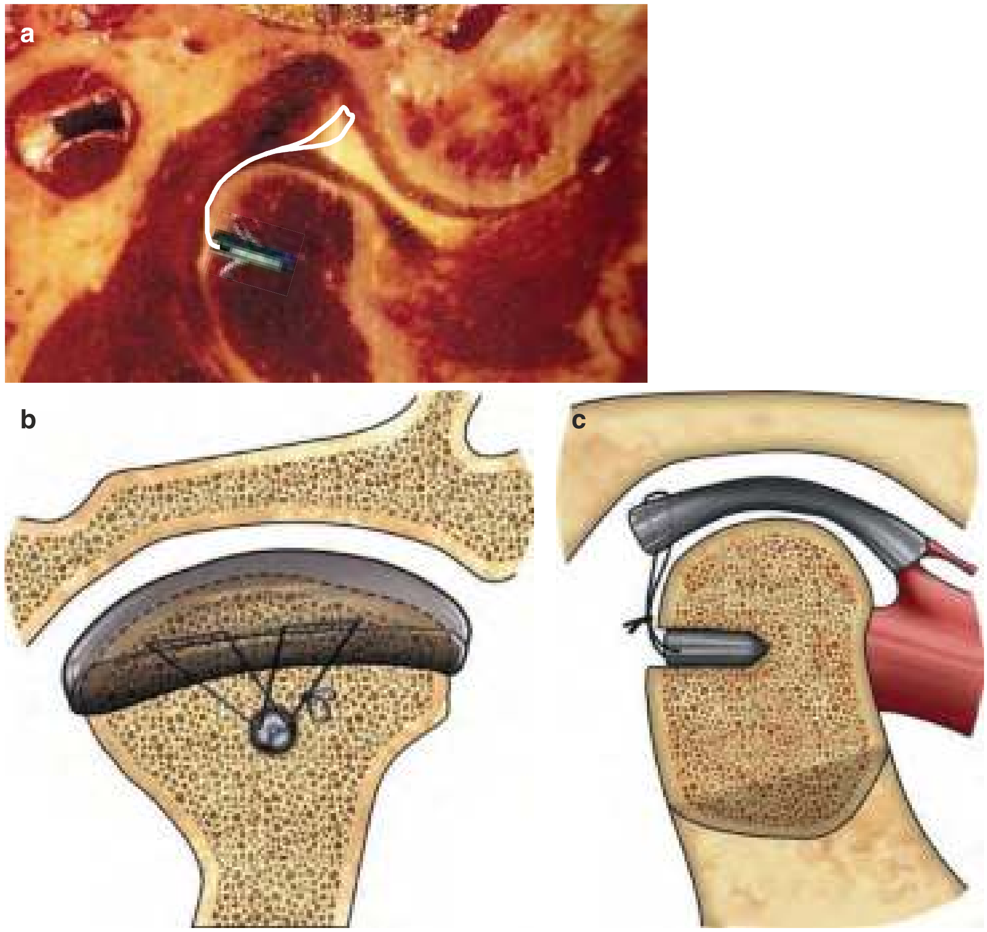

Fig. 63.15 (**a**–**c**) Use of a Mitek anchor according to Wolford's technique

remodeling. Many autogenous, allogeneic, and alloplastic disc replacements have been tried with varying degrees of success (Table 63.7), and some such as Proplast have caused joint destruction necessitating joint reconstruction and replacement [99]. At the current time, there is a lack of evidence to support the routine use of any disc replacement after discectomy.

The use of tissue engineering is emerging as a promising option to repair or potentially replace the diseased tissues of the TMJ and may provide additional treatment options in the future. Progress has already been made toward the development of appropriate tools for TMJ tissue engineering. The goal is to develop an approach to produce new tissues de novo (neotissues) with qualities similar to the native TMJ. This may be accomplished by (1) in situ tissue engineering, which involves an acellular scaffold matrix attracting local cells (cell homing) guiding the process of regeneration, and (2) ex vivo cell seeding on the scaffold, which provides enough competent cells to orchestrate the regenerative process. The second strategy appears better suited for TMJ regeneration because of its limited capacities of self-repair and the rapid regeneration expected [100].

Table 63.7 Disc replacement options [98]

Alloplastic	Methyl methacrylate Silastic Proplast-Teflon Fossa prosthesis
Allogenic	Dura (cryopreserved) Cartilage (lyophilized, freeze-dried)
Autogenous	Temporalis muscle/fascia Ear/rib cartilage Dermis skin grafts Abdominal fat
Xenograft	Bovine collagen/cartilage

63.7 Conclusion

Internal derangement of the TMJ is a common problem resulting in pain and limited function for some patients. While the vast majority of patients adapt to the internal derangement over time or with nonsurgical treatment, surgery may be indicated for those with ongoing problems. There are no surgical procedures for the TMJ that have a 100% success rate; it therefore makes sense to undertake the least invasive procedures first. The surgical pyramid presented in this chapter provides a stepwise progression for TMJ surgical patients. In the authors' clinical practice, most surgical patients begin with a level 1 or 2 arthroscopic surgery and only step up the pyramid if this fails. If the diagnosis after arthroscopy is Wilkes II, III, or early IV, phase 2 procedure would be disc repositioning and discopexy if the disc is intact and has normal morphology and there is sufficient posterior joint space in which to reposition it. In Wilkes IV and V, phase 2 procedure would be joint debridement and discectomy (Table 63.8).

Finally, Table 63.9 presents an algorithm and decision framework that guides the progression through the various surgical procedures discussed in this chapter.

64 Temporomandibular Joint Dislocation

V. B. Krishnakumar Raja

64.1 Introduction

Hypermobility disorders of the temporomandibular joint (TMJ) present in two major forms:

1. Dislocation
2. Subluxation [1]

The differences between dislocation and subluxation have been highlighted in Box 64.1.

The condyle may be displaced either anteriorly, posteriorly, medially, or laterally of which anterior dislocation is the most common [1]. The incidence of TMJ dislocation constitutes about 3% of the dislocations occurring in other joints of the body with female predilection. The reported incidence of TMJ dislocation is 7% with a preponderance in people in the second and third decades [2].

Box 64.1 Definition of Dislocation and Subluxation
Dislocation refers the phenomenon in which condyle is displaced out of the glenoid fossa and traverses in front of the articular eminence. In contrast, subluxation is the condition in which the dislocated condyle can be reduced back into the normal position by patient themselves, without any professional assistance.

64.2 Classification (Box 64.2)

Dislocation has been classified by numerous methods. Rowe and Killey [3] based it on the duration of the dislocation episode as:

Box 64.2 Classification of Dislocation
Based on duration of displacement
- Acute dislocation
- Habitual dislocation/subluxation
- Chronic recurrent dislocation
- Long-standing/chronic protracted dislocation

Based on direction of displacement
- Anterior
- Posterior
- Medial
- Lateral
- Superior

Based on side of displacement
- Unilateral
- Bilateral

1. Acute
2. Chronic

Dislocation recurring more than once is termed as chronic recurrent dislocation. The term *chronic protracted dislocation* is used to describe dislocation persisting for more than 1 month, while dislocation present for more than 6 months is called *extra-long-standing dislocation* [4].

Based on the direction of displacement [2], dislocation may be categorized as:

- Anterior
- Posterior
- Lateral
- Superior

Anterior dislocation is the most common type of dislocation due the weakness of the capsule in the anterior region.

K. Bonanthaya et al. (eds.), *Oral and Maxillofacial Surgery for the Clinician*, https://doi.org/10.1007/978-981-15-1346-6_64

Fig. 64.1 Lateral dislocation of condyle, Post trauma, on the right side. (**a**) Frontal view showing lateral dislocation on right side (**b**) Posterior view showing lateral dislocation on right side

Posterior dislocation occurs following fracture of the external auditory canal and skull base. Allen and Young classified lateral dislocation into Type I and Type II. This type of dislocation occurs in mandibular trauma (Fig. 64.1a, b):

- Type I refers to lateral subluxation.
- Type II indicated lateral and superior dislocation into the temporal fossa [2].

Superior dislocation results when condyle is pushed into the middle cranial fossa accompanied by glenoid fossa fracture. Small and round-shaped condyle is predisposed to this type of dislocation [2].

64.3 Etiopathogenesis (Table 64.1)

A multitude of causes have been described in the etiopathogenesis of TMJ dislocation including congenital, iatrogenic, anatomical aberrations, spontaneous, pharmacological, neurological, neuromuscular, etc. Proper diagnosis of the etiology is important to institute problem-specific treatment.

Table 64.1 Etiology of dislocation

Trauma	
Medical and surgical procedures	Dental procedures which require wide mouth opening for prolonged time Intubation procedures, gastrointestinal endoscopy, laryngoscopy/bronchoscopy ENT procedures
Spontaneous	Laughing Yawning Biting Vomiting Singing Epileptic seizures
Anatomical aberrations	Small condyle Poorly grooved glenoid fossa, shallow/steep articular eminence, laxity of ligaments and capsule for more prone for dislocation
Systemic disorders	Ehlers-Danlos disease Marfan's syndrome Huntington disease Parkinson disease Multiple sclerosis Muscle dystrophies or dystonias
Medications	Antipsychiatric Antiemetic
Occlusal conditions	Edentulous posterior region

Daily activities which involve wide mouth opening such as laughing, yawning, and biting may induce TMJ dislocation. It may also occur spontaneously during epileptic seizures, vomiting, yawning, and singing. Trauma is another cause which might cause posterior, superior, and lateral dislocation in addition to anterior dislocation [5]. Iatrogenic causes include dental procedures which require wide mouth opening for prolonged time, intubation procedures, gastrointestinal endoscopy, and laryngoscopy/bronchoscopy. Anatomical aberrations such as small condyle, underdeveloped glenoid fossa, shallow/steep articular eminence and laxity of ligaments and capsule are more prone for dislocation.

Predisposing risk factors include connective tissue disorders such as Ehlers-Danlos disease and Marfan's syndrome which predispose to laxity of the joint and hypermobility. Muscle spasms occur in neurodegenerative or neurodysfunctional diseases, namely, Huntington disease, Parkinson disease, multiple sclerosis, muscle dystrophies, or dystonias.

Medications which induce dislocation are antipsychiatric (phenothiazines) and antiemetic (metoclopramide) drugs which produce unwanted extrapyramidal reactions which eventually lead to muscular imbalance attributed to dislocation.

Reduced vertical dimension due to loss of posterior teeth in advanced age may also predispose an individual to dislocation [5].

Though various theories of pathogenesis have been described in literature, the most accepted was muscular incoordination during mandibular movements. In the initial stages of mouth closure, elevators are activated prior to the relaxation of depressors mainly lateral pterygoid which pulls the condyle forward. This initial dislocation facilitates the further dislocation [5].

64.4 Clinical Features (Mentioned in Box 64.3; Figs. 64.2a, b, 64.3, 64.4a, b, and 64.5a, b)

Box 64.3 Clinical Features of Dislocation

The classical clinical features of dislocation are:
1. Pain in the preauricular and surrounding region.
2. Preauricular depression/hollowing.
3. Protruding chin.
4. Inability to close mouth.
5. Drooling of saliva.
6. Inability to speak, swallow, or masticate.
7. Tense masticatory muscles are also a characteristic feature [6]

Unilateral dislocation is associated with deviation of chin towards contralateral side.

Fig. 64.2 (**a**, **b**) Bilateral TMJ dislocation. (**a**) Before reduction (**b**) After reduction

64.5 Investigations

- *Orthopantomogram* (OPG) (open and closed) (Fig. 64.6)
  This is the commonly used screening modality for the examination of TMJ. Morphology of condyle, articular eminence, and joint space can be evaluated. Open mouth OPG shows the position of the condyle in relation to the articular eminence.
- *TMJ tomogram*
  Open and closed mouth TMJ images can be obtained in different slices.
- *Computed tomography(CT)*
  Evaluation of the morphology of osseous TMJ components—condyle, articular eminence and the glenoid fossa—are better assessed with CT.
- *Cone beam computed tomography* CBCT
  CBCT facilitates accurate measurement of condylar height, width, and length as well as inclination of articular eminence.
- *Magnetic resonance imaging (MRI)*
  MRI demonstrates the soft tissue morphology, particularly disc shape, displacement, and effusion of the joint frequently associated with dislocation.
- *Electromyography (EMG)*
  EMG evaluates the activity of the muscles which may be hypoactive, normoactive, or hyperactive.
- *Ultrasonography (USG)*
  Thickness and length of the muscles can be evaluated both at rest and clenching by USG.

64.6 Management of Dislocation (Box 64.4)

64.6.1 Acute Dislocation

Reducing the dislocated condyle poses a great challenge. Reduction is more complicated with the accompanied muscle spasm persisting for longer duration. In difficult situations, reduction can be facilitated with the help of local anesthesia, conscious sedation, and general anesthesia. Following reduction, a Barton's bandage, chin strap, or intermaxillary fixation is advised for 3–6 weeks to prevent further dislocation. Several reduction techniques have been employed with varying rates of success.

Box 64.4 Management of Acute Dislocation

- Conventional technique—Hippocratic/Nelaton's method
- Wrist pivot technique
- Extraoral technique
- Gag reflex

64.6.1.1 Hippocratic/Nelaton's Technique (Fig. 64.7)

This is the conventional method of reduction of acute dislocation in which physician stands in front of the patient, with the thumb placed either on the external oblique ridge or on the lower molars and other fingers positioned along the lower border of the mandible. A steady downward, backward, and superior force should be given to reduce the dislocated condyle. The thumb should be protected either with a plastic splint or gauze wrapped around it to prevent injury to the thumb while reducing dislocation.

64.6.1.2 Gag Reflex [3]

Gag reflex is induced by probing the soft palate using mouth mirror. In alert individuals, this reflex relaxes the lateral pterygoid muscle through coordinated neuromuscular activities which reduces dislocation in natural way.

64.6.1.3 Wrist Pivot Method [7] (Fig. 64.8)

This method utilizes existing myospasm of the elevators for reduction. The thumb is placed under the chin, while other fingers are placed over the occlusal surfaces of lower teeth.

Fig. 64.7 Nelaton's method. A: Thumb intraorally on the occlusal surface lower teeth. B: Other fingers at the inferior border of body and angle of the mandible

Fig. 64.8 Wrist-pivot method. A: Other fingers intraorally on the occlusal surface lower teeth. B: Thumb on the chin

Then upward movement is applied by the thumb, and concomitant inferior force is given by other fingers with pivoting the wrist. The advantage of this technique is that it utilizes the force created by the muscles of mastication rather than overcoming this force as in Nelaton's technique.

64.6.1.4 Extraoral Method [8] (Fig. 64.9a, b)

Intraoral methods described previously have the risk of human bite in which there are chances of infection transmission. To overcome this, extraoral method has been described. In the dislocated mandible, coronoid process comes forward which is easy to palpate. On one side, the thumb is positioned over the coronoid process which pushes the mandible backward, while the other fingers are located over the mastoid process to deliver counteracting force (Fig. 64.9a). On the other side, the mandible is pulled further forward with the thumb on the malar eminence and rest of the fingers on the mandibular angle (Fig. 64.9b). Pulling the mandible on one side with simultaneous pushing of the mandible on the other side reduces the dislocation on one side first and then subsequently on the other side. This technique is applicable in unilateral dislocation as one side is reduced first and then the other is reduced thereafter.

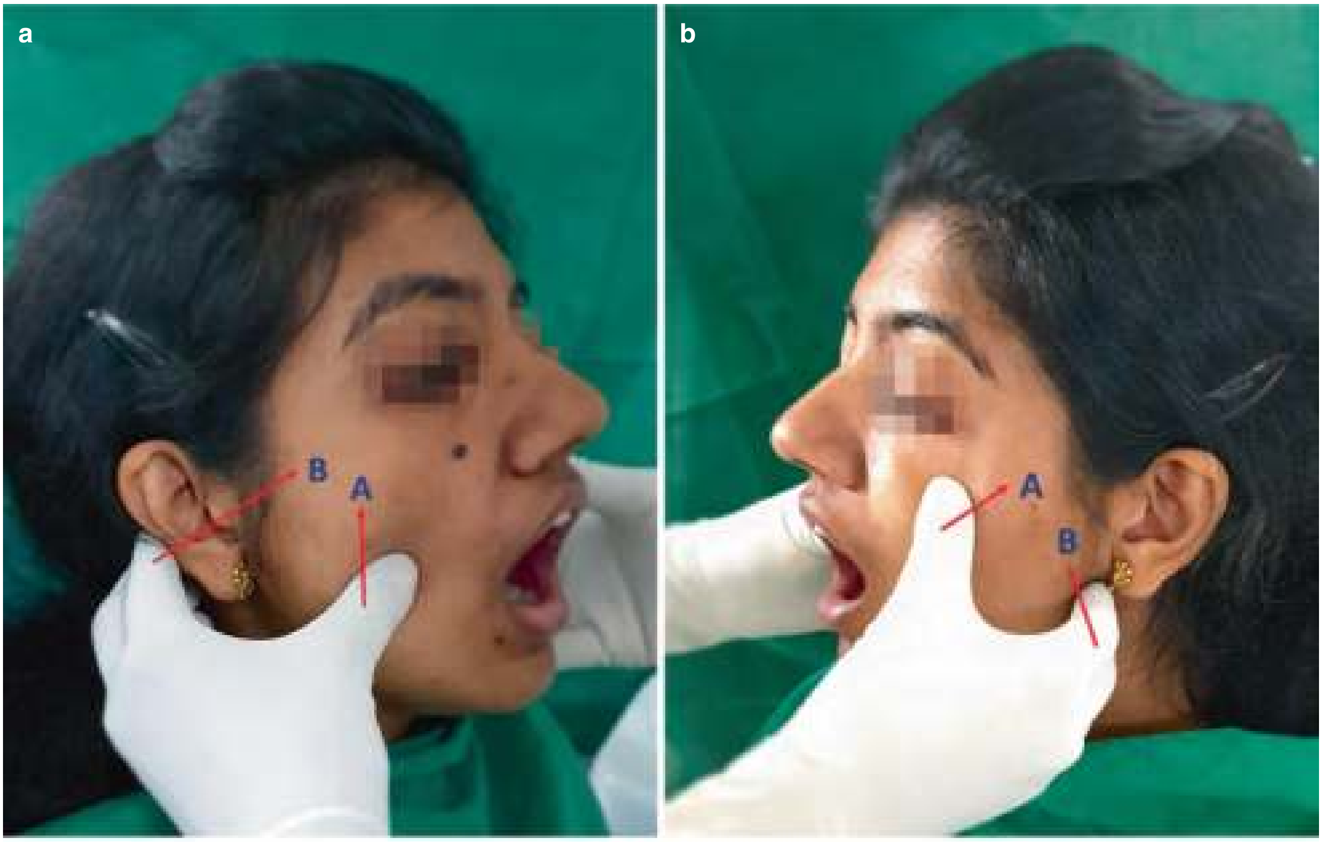

Fig. 64.9 (**a**, **b**) Extraoral method for reduction of dislocation. (**a**) A: Thumb on coronoid process. B: Other fingers on mastoid process. (**b**) A: Thumb on malar eminence. B: Other fingers on angle of the mandible

64.6.2 Management of Chronic Recurrent Dislocation/Subluxation (Box 64.5 and 64.6)

Box 64.5 Management of Chronic Recurrent Dislocation/Subluxation

Conservative

1. Physiotherapy
2. Intermaxillary fixation
3. Chin straps
4. Barton's bandage
5. Kinesio taping

Minimally invasive

1. Injection of sclerosing agents
2. Autologous blood injection
3. Prolotherapy
4. Botulinum toxin injection

Box 64.6 Management of Chronic Recurrent Dislocation/Subluxation

Surgical procedures

1. Capsular tightening procedure
   (a) Capsulorrhaphy
2. Creation of mechanical obstacle
   (a) Dautrey's procedure
   (b) Glenotemporal osteotomy
3. Removal of mechanical obstacle

   (b) Condylectomy
4. Creation of new muscular balance
   (a) Temporalis scarification
   (b) Lateral pterygoid myotomy
   (c) Pterygoid dysjunction

Numerous treatment modalities have been described for TMJ dislocation, as it has multifactorial etiology. Miller and Murphy [9] proposed a comprehensive list of treatment options which targeted specific anatomical sites of the joint that exhibited abnormality: the capsule, eminence, and condylar head.

For practical purposes, the types of management may be broadly classified based on the degree of invasiveness as:

1. Conservative
2. Minimally invasive
3. Surgical

64.6.2.1 Conservative Methods

Conservative methods may be used following reduction of dislocation to prevent further dislocation, such as:

1. Physiotherapy
2. Intermaxillary fixation
3. Chin straps
4. Barton's bandage (Fig. 64.10)
5. Kinesio taping

Fig. 64.10 Barton's bandage

Intermaxillary fixation, chin strap, and Barton's bandage are done for 4 weeks to induce fibrosis of soft tissues around the joint so that further dislocation is prevented. Physiotherapy including ultrasound and infrared therapy are advised to reduce pain. Isotonic and isometric exercise are advised to strength the muscle involved in TMJ function [9].

Kinesio Taping (Fig. 64.11)

In the year 1970, Dr. Kenzo Kase, a Japanese chiropractor, first described the techniques of Kinesio taping. The thin elastic tape acts by lifting the skin which increases the blood and lymphatic flow, thereby reducing inflammation and accumulation of pain mediators. It also helps in better muscle function and joint realignment which is utilized in reduction of TMJ dislocation.

64.6.2.2 Minimally Invasive Treatment

Injection of Sclerosing Solutions [9]

This procedure involves repeated injection of sclerosing solution into the capsule aimed at fibrosis of the capsule which would eventually limit the mouth opening. The solutions commonly used to perform the procedure are:

- Sodium psylliate
- Sodium tetradecylsulfate
- Sodium morrhuate
- Ethanolamine oleate 5%
- Tincture of iodine
- OK-432 (Picibanil)

Fig. 64.11 Kinesio taping

These injections are usually given intra-articularly and in pericapsular region and can be repeated every 2–3 weeks till the fibrosis occurs. However, the outcome of this technique is not satisfactory and is also associated with complications such as TMJ ankylosis and facial nerve injury [9].

OK-432 which is a streptococcal derivative inactivated by penicillin G is used as sclerosing agent for the treatment of TMJ dislocation. A 21-gauge needle is used to inject 1.25 KE/ml concentration of OK-432 into the superior joint space and pericapsular region. 2 ml of the solution is injected in each region. This produces fibrosis in and around the joint by inducing local inflammation and formation of granulation tissue. Mouth opening is restricted for 4 days following injection by elastic bandage.

Autologous Blood Injection [1]

This procedure works by producing fibrosis which restricts the opening of the mouth wide. It involves injection of patient's own blood into the superior joint space and pericapsular region following two puncture arthrocentesis. Prior to the injection of blood into the joint, lavage should be done using two needles in the superior joint space, and then one needle is removed. Blood is injected through the other needle into the joint and around the joint. It may be injected either unilaterally or bilaterally. It can be given as a single or multiple injections with intervals.

Injection of Platelet Rich Plasma (PRP) (Refer suggested reading at the end of the chapter)

Platelet rich plasma is a yet another minimally invasive technique used to treat various Temporomandibular joint disorders. It is prepared from 10 ml of patient's own blood which was centrifuged at 3200 rpm for 12 minutes. The 2ml solution was then injected it to the superior joint space which was located 10 mm forward and 2 mm downward on the canthotragal line. Another 1ml of the solution was injected into the pericapsular tissues. Patients were advised for various mandibular movements for a minute following injection for the equal distribution of PRP in the joint. Elastic bandage is given for a week followed by mandibular exercise advised. PRP has 3-8 folds concentration of platelets and various growth factors such as platelet derived growth factor, transforming growth factor beta and vascular endothelial growth factor which helps in healing of the tissues. In a comparative study between autologous blood injection and PRP for TMJ dislocation demonstrated both groups were equally effective in decreasing mouth opening in TMJ dislocation.

Prolotherapy [1]

It is also called as regenerative injection therapy. This involves injection of solutions into the joint to stimulate regeneration potential. Various prolotherapy solutions are available such as psyllium oil, glycerin, phenol, etc. of which dextrose is the most commonly used solution. 2 ml of 10–50% dextrose can be injected in and around the joint space. Either single or multiple injections are needed based on severity of dislocation. This technique is indicated in laxity of the ligaments and capsule. It induces low-grade inflammation which releases growth factors. These growth factors stimulate fibroblasts which deposit new collagen fibers that strengthen ligaments and tendons.

Fig. 64.12 Injection sites for prolotherapy. A: Posterior joint space. B: Anterior attachment of disc to lateral pterygoid muscle. C: Most tender point of masseter muscle

Landmarks—prolotherapy solutions are given in the following three points (Fig. 64.12):

A. Posterior joint space—palpate the depression posterior to condyle when mouth is opened.
B. Attachment of disc to lateral pterygoid muscle—depression felt anterior to the condyle when mouth is closed.
C. Tender spot in the masseter tendon.

Injection of Botulinum Toxin [1]

The first reported use of botulinum toxin for TMJ dislocation was described by Daelen et al. in the year 1995. Botulinum toxin type A weakens the skeletal muscle when injected by preventing the release of acetylcholine at the neuromuscular junction. It can be injected into any of the masticatory muscle, but injection into lateral pterygoid muscle is effective because forward movement of condyle is prevented. The dosage used is 25–50 units of botulinum toxin. It can be injected either by extraoral or intraoral route with or without EMG guidance (Refer Chap. 33 on Botox injections).

Extraoral Technique
A 30-gauge needle is inserted into the skin 1 cm below the central zygomatic arch to the depth of 3–4 cm based on the measurements obtained from computed tomogram of the patient. The 25–50 units of toxin is deposited into the lateral pterygoid muscle following aspiration.

Intraoral Technique
Hypodermic needle electrode is inserted in the mucobuccal fold of distal root of upper second molar directed superiorly and posteriorly to the depth of 25–30 mm; the position of the needle in the lateral pterygoid muscle is confirmed by EMG reading. After aspiration, 25–50 units of toxin is deposited into the muscle.

The injection should be repeated every 3–6 months as the action of this toxin lasts within 6 months. Complications of this technique included dysphagia, dysarthria, and hemorrhage.

Arthroscopy [1] **(Refer** Chap. 63 **on Internal Derangements of TMJ)**
Arthroscopic capsulorrhaphy is done by using either laser or cautery which produces contractions. Sclerosing solutions may be injected into the joint and capsule under direct visualization using arthroscopy.

Arthroscopic Capsulorrhaphy
A 1.7 mm TMJ arthroscope is introduced into the fossa portal following the double puncture technique described by McCain. Once the arthroscope reached the anterior recess, the second puncture is done using triangulation technique. Deep lesional burns are created in the oblique protuberance, laterally and the posterior wall using either bipolar cautery or holmium laser which causes shortening of the capsule.

Arthroscopic Eminectomy
The arthroscope is introduced into the joint through infero-lateral approach, and then the articular eminence is reduced by electronic shaver which is introduced by triangulation technique.

64.6.2.3 Surgical Treatment
The following is a brief description of surgical procedures which are commonly employed for treating TMJ dislocation.

Capsular Tightening Procedure
Temporomandibular joint is completely covered by capsule which is attached superiorly from all around the rim of the glenoid fossa and inferiorly till the neck of the condyle. This capsule holds the joint components in position, which is later-

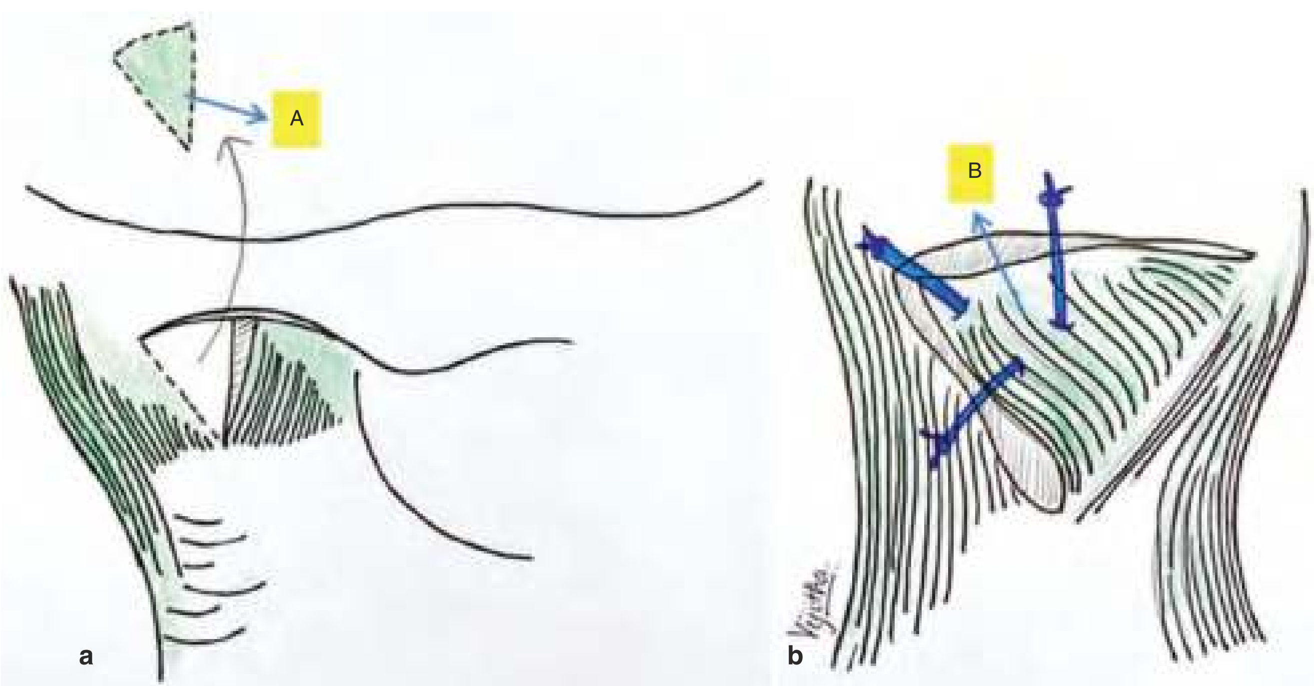

Fig. 64.13 (**a**–**b**) Capsulorrhaphy. Excised margin of the capsule. (**A**) Capsule is tightened by suturing it to the adjacent soft tissues (**B**)

ally strengthened by lateral ligament. Lax capsule is considered as one of the reasons for TMJ dislocation. So, capsular tightening procedures are done to address this problem.

Capsulorrhaphy (Fig. 64.13a, b)
This procedure was first implemented in the year 1907 by Perthes who excised a portion of the lateral capsule and sutured it together to increase the tautness of the capsule and thus restrain condyle. Later on, many modifications had been proposed including suturing of the capsule to zygomatic arch and overlapping of the capsule after making vertical incision on the capsule [9].

Creation of Mechanical Obstacle

Excessive translation of the condyle which is observed in dislocation is prohibited by creating impediment in the path of the condyle. Konjetzny (1921) had used articular disc as a mechanical impediment by bringing it forward and suturing it anteriorly. Lindemann and Mayer used articular tubercle to prevent condylar dislocation by either bending it down or placing a graft obtained from zygoma [9].

Dautrey's Procedure [10] (Fig. 64.14a, b)
Mayer (1933) created a mechanical obstacle by dislocating a part of the zygomatic arch down, in front of the articular eminence. Vertical osteotomy of the zygomatic arch and repositioning the osteotomized arch downward as a mechanical impediment has been described by LeClerc and Girard in the year 1943.

In 1967 Gosserez and Dautrey made an oblique osteotomy of the arch in front of the articular eminence extending from posterior-superior to the anterior-inferior direction. With gentle pressure towards inferior direction, a greenstick fracture was created at the zygomatico-temporal suture. The segment was then pushed downwards to create obstruction for the condylar movement. If this downfractured segment is unstable, plating can be done to prevent displacement (Fig. 64.15).

Fig. 64.15 Fixation of downfractured zygomatic arch segment using miniplates

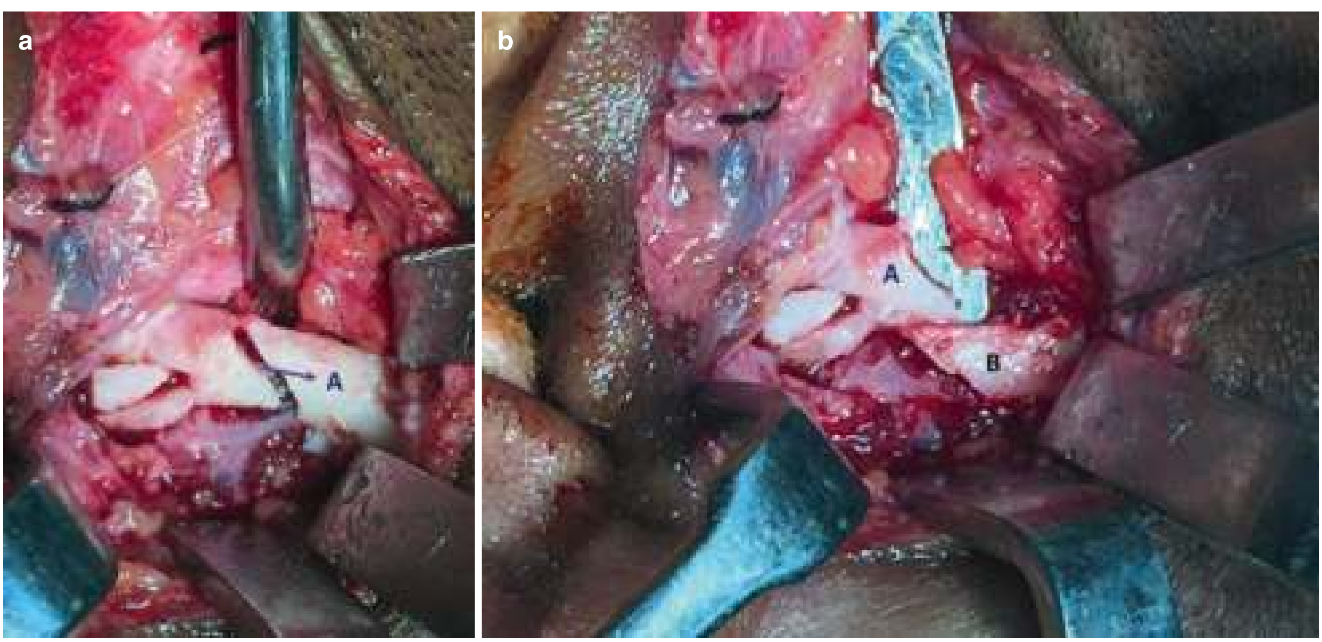

Fig. 64.14 (**a**, **b**) Dautrey's procedure. (**a**) A: Osteotomy of zygomatic arch (**b**) A: Proximal segment of zygomatic arch. B: Downfractured distal segment of zygomatic arch

The limitations of the technique include the following:

1. Not suitable for elderly individual as it may cause fracturing of the arch instead of greenstick fracture at the zygomatico-temporal suture.
2. Relocation of the fragments after repositioning [10].
3. Medial escape of the condyle as the width of the zygomatic arch is narrow.
4. Presence of a small condyle.

Glenotemporal Osteotomy (Fig. 64.16a, b and c)

Norman [10] described glenotemporal osteotomy as a definitive technique for dislocation. TMJ is exposed through any of the open surgical approaches described for TMJ, without violating the capsule. An oblique osteotomy on the articular eminence is made, following which the fragment is gently moved downwards to create a wedge-shaped defect which is grafted using bone taken from ilium, calvarium, symphysis, etc. Usually it is not necessary to fix these grafts as they stay in that wedge-shaped space created by osteotomy. Miniplates or screws can be placed on the eminence so that excessive condylar translation is prevented. Long-term results of this technique showed screw loosening and fracture of the plate.

Modifications of Norman's Procedure

Sharma et al. [11] added two modifications to the conventional glenotemporal osteotomy. Temporalis fascial flap was used to strengthen the capsule, and pterygoid dysjunction was performed to address the TMJ pain due to internal derangement which coexists with dislocation.

Fig. 64.16 (**a**, **b**, **c**) Glenotemporal osteotomy. (**a**) A: Articular eminence. (**b**) A: Osteotomy of articular eminence. (**c**) A: Chin graft in position. B: Downfractured articular eminence

Removal of Mechanical Obstacle

Eminectomy (Fig. 64.17a, b)

The first reported evidence of eminectomy for the treatment of TMJ dislocation was performed by Hilmar Myrhaug in the year 1951. This procedure is generally accomplished under general anesthesia or local anesthesia, or conscious sedation has also been used for patients with systemic conditions that prohibit general anesthesia. Though there are many techniques available to address this condition, this particular technique may be considered for those patients with neurological disorder, epilepsy, and advanced age [12].

Hall et al. [13] had studied the eminence configuration using 38 cadavers. The observations included the following:

1. Anteroposterior width of eminence—9–18 mm
2. Latero-medial width of eminence—16–25 mm
3. Articular tubercle to temporal bone measurement—5–14 mm
4. Deepest portion of the glenoid fossa thickness—0.1–8 mm

Articular eminence thicknesses in anterior and posterior regions were also mentioned [6]. These measurements provide guidelines while performing eminectomy procedure to avoid complications.

According to this technique, the joint may be approached through any of the incisions indicated for TMJ surgeries. Following exposure of the eminence, rotary instruments, osteotome, chisel, or piezo surgery device can be used to reduce the height of the eminence. Either total eminectomy or partial eminectomy may be done. Irregular bony surfaces and edges should be smoothened well. Segami et al. [14] described arthroscopic eminectomy where double puncture technique has been used. Motorized shaver was used to reduce the eminence.

Navigation system has also been used for accurate reduction of eminence especially on the medial side and superior surface to avoid intracranial exposure [6].

Eminectomy works by allowing free movement of the condyle over the eminence so that locking of the condyle is prevented. There are observations of reduced mouth opening following eminectomy that might be due to adhesions formed in and around the joint. This can be performed unilaterally or bilaterally [6].

The major problem associated with this technique is the excessive forward movement of the condyle than what is actually needed which leads to stretching of muscles and ligaments which is potentially injurious to the articular structures [11].

Condylotomy and Condylectomy (Fig. 64.18a, b)

Closed condylotomy is a blind procedure in which Gigli saw is used to cut the condyle as described by Kostecka [2].

Part of the condyle is removed to prevent the obstruction; at the same time, it allows the free translation of the condyle along the articular eminence.

Preauricular incision is used to approach the condyle, and then the condyle is sectioned at the inferior level of the articular eminence.

Creating New Muscular Balance

- *Temporalis Scarification* [1]
  A portion of the temporalis muscle is removed by this technique so that the scarring and fibrosis induced by surgery restrict the mouth opening.
- *Lateral Pterygoid Myotomy* [1] (Fig. 64.19a, b)

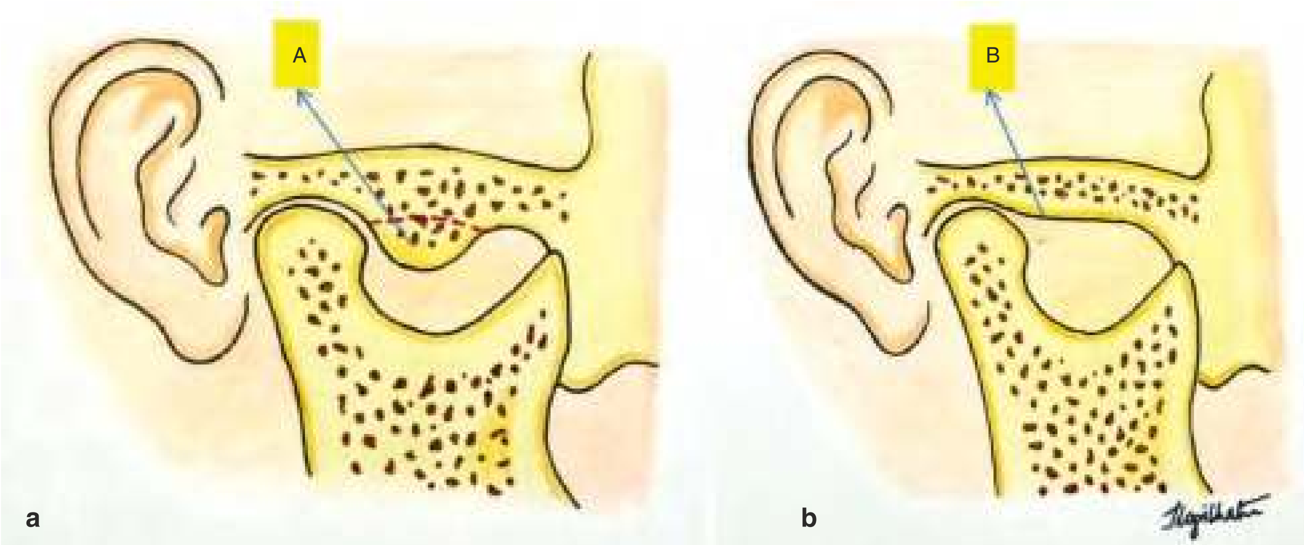

Fig. 64.17 (**a–b**) Eminectomy. (**A**) Articular eminence (**B**) Eminence removed

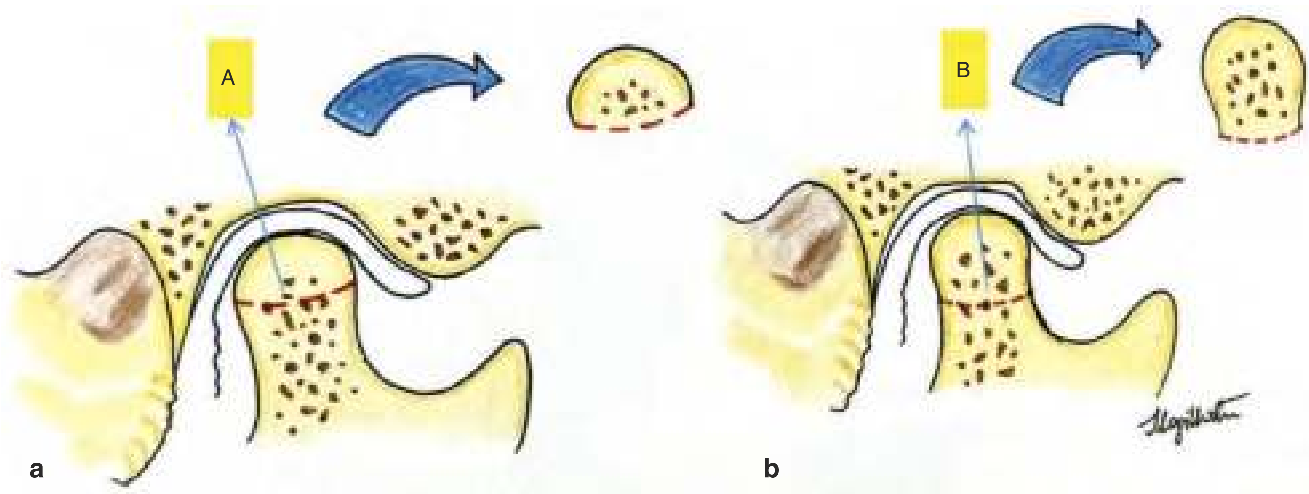

Fig. 64.18 (**a**–**b**) Condylectomy. (**A**) High condylectomy (**B**) Low condylectomy

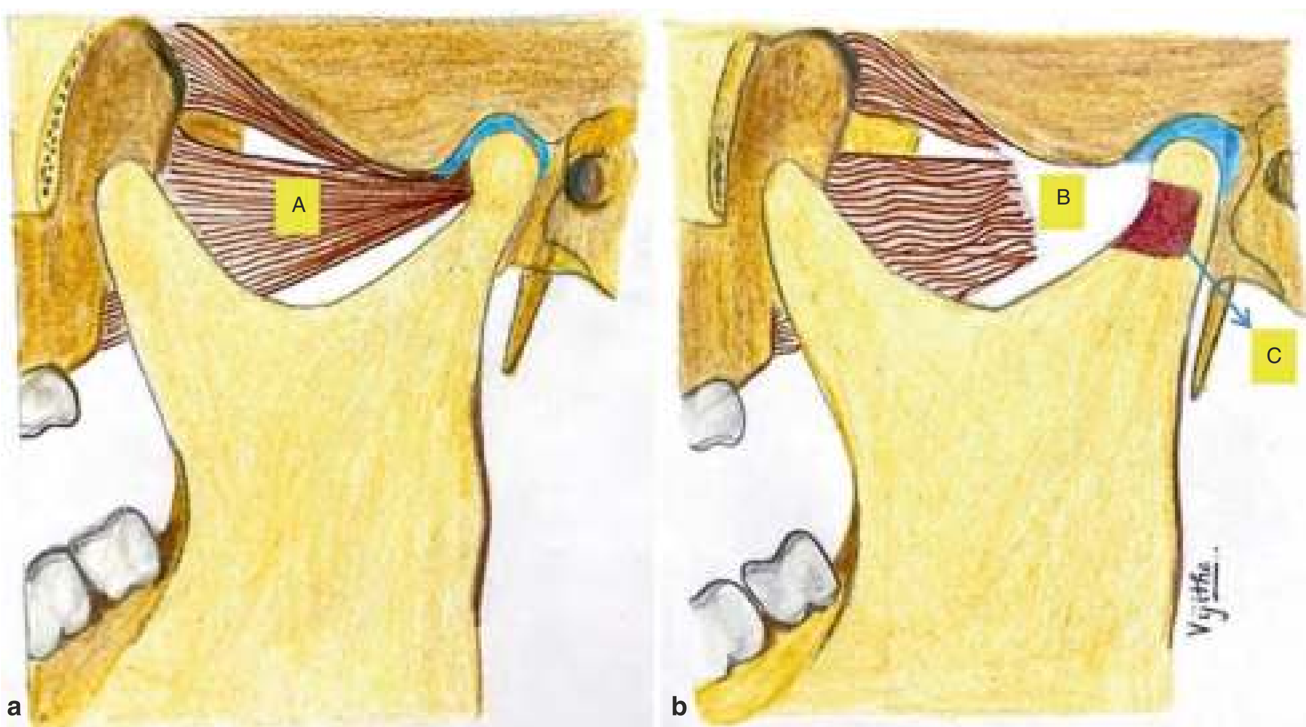

Fig. 64.19 (**a**–**b**) Lateral pterygoid myotomy. (**A**) Lateral pterygoid muscle (**B**) Part of the lateral pterygoid muscle excised (**C**) Barrier is placed

This technique was described by Bowman in 1949. This procedure may be performed through either intraoral by making incision along the anterior border of the ramus from coronoid to the third molar region or extraoral route through preauricular approach. Dissection is carried out to visualize the attachment of lateral pterygoid to condyle and capsule, and the attachment is then severed and then silastic sheet fixed to the anterior surface of the condyle. This results in restriction of mouth opening for short period of time.

Pterygoid Dysjunction

It is an intraoral procedure done to reduce the activity of the lateral pterygoid on the condyle so that forward movement of the condyle is reduced [11].

Intraoral vestibular incision is made in relation to the upper molars, and dissection is done to expose the posterolateral wall of the maxilla and pterygomaxillary suture. Pterygoid chisel is used to separate the pterygoid plates from maxilla, so that lateral pterygoid muscle along with pterygoid plate is detached.

64.6.3 Chronic Protracted Dislocation (Box 64.7)

Box 64.7 Management of Long Standing Dislocation

Conservative

1. Manual reduction
2. Continuous elastic traction using bite block
3. Indirect reduction
   (a) Using a wire passing in the mandibular angle region
   (b) Using a hook in the sigmoid notch

Surgical procedures

1. Joint procedures
   (a) Condylotomy, condylectomy
   (b) Myotomy
   (c) Joint prostheses
2. Procedures not involving the joint
   (a) Sagittal split osteotomy
   (b) Vertical ramus osteotomy
   (c) Inverted L osteotomy
   (d) Midline mandibulotomy

Initially conservative method is employed to reduce dislocation. Manual reduction is attempted either using local anesthesia, sedation, or general anesthesia. Continuous elastic traction may also be applied with the bite block in the posterior region which might reduce the dislocation [15].

Indirect reduction can be performed by inserting wire into the mandibular angle region, or bone hook is passed into the sigmoid notch through a small incision made on the angle region (Rowe and Killey 1968) [4]. Lewis in 1981 used Bristow's elevator for the reduction by giving downward and posterior force.

In long-standing persistent dislocation, patient might have functional movement due to pseudo joint formation in front of the articular eminence. In this scenario, the goal is to establish the occlusion by osteotomy procedures such as sagittal split osteotomy or vertical ramus osteotomy.

Adekeye (1976) [4] suggested inverted L osteotomy instead of vertical and horizontal osteotomies due to the coronoid hindrance. Lateral and medial surface of the ramus is exposed either through submandibular incision or intraoral incision extending from the coronoid process along the anterior border of the ramus to the vestibule of second molar region. Medial osteotomy (horizontal cut) is performed 4–5 mm above and posterior to the lingula and parallel to the occlusal plane. Vertical cut is performed from the distal aspect of the horizontal cut to the mandibular angle. Then the dentate segment is manipulated to get the desired occlusion. Proximal and distal segments are fixed with miniplates.

Other methods such as condylectomy, condylotomy, and myotomy (as described in previous sections) and TMJ prostheses are proposed to treat this condition [4].

Ratten et al. described midline mandibulotomy to reduce the dislocation [16].

Through the intraoral approach, the mandible is sectioned in the midline, and then each hemimandible is manipulated to reduce the dislocation on each side separately. Following reduction, mandibular midline is fixed with miniplates.

64.7 Recent Advances

64.7.1 Raja's Coronoid Repositioning Technique [17]

This is a new technique performed for the management of TMJ dislocation. Intraoral vertical incision extending from the coronoid process to the molar region is made, and the coronoid and anterior border of ramus is exposed, and then coronoid is osteotomized and inferiorly pulled along with temporalis muscle and fixed with miniplates on the lateral surface of the ramus. The advantage of this technique is that the temporalis is stretched to give new muscle balance and restricts the excessive opening of the mouth.

64.7.2 Wolford's Anchoring Technique [18] (Fig. 63.15)

This technique prevents the dislocation by using two Mitek screw with attached suture material. One screw is attached to the zygomatic arch and another to the posterolateral surface of the condyle, and the sutures are tied together to get the desired mouth opening. These suture materials act as artificial ligaments that control condylar movement.

Acknowledgment I would like to acknowledge Dr. Vijitha and Dr. Logitha for illustrations.

Disclosure Authors have no financial conflicts to disclose.

64.8 Case Scenarios

Case 1 (Fig. 64.20a–d)

Patient A 24-year-old male, with complaints of locking of the jaw after wide mouth opening

Preoperative open mouth OPG revealed bilateral TMJ dislocation (Fig. 64.20a)

OPG demonstrates:

- Displacement of condyle out of the glenoid fossa bilaterally
- Condylar head is antero-superior to articular eminence on both sides

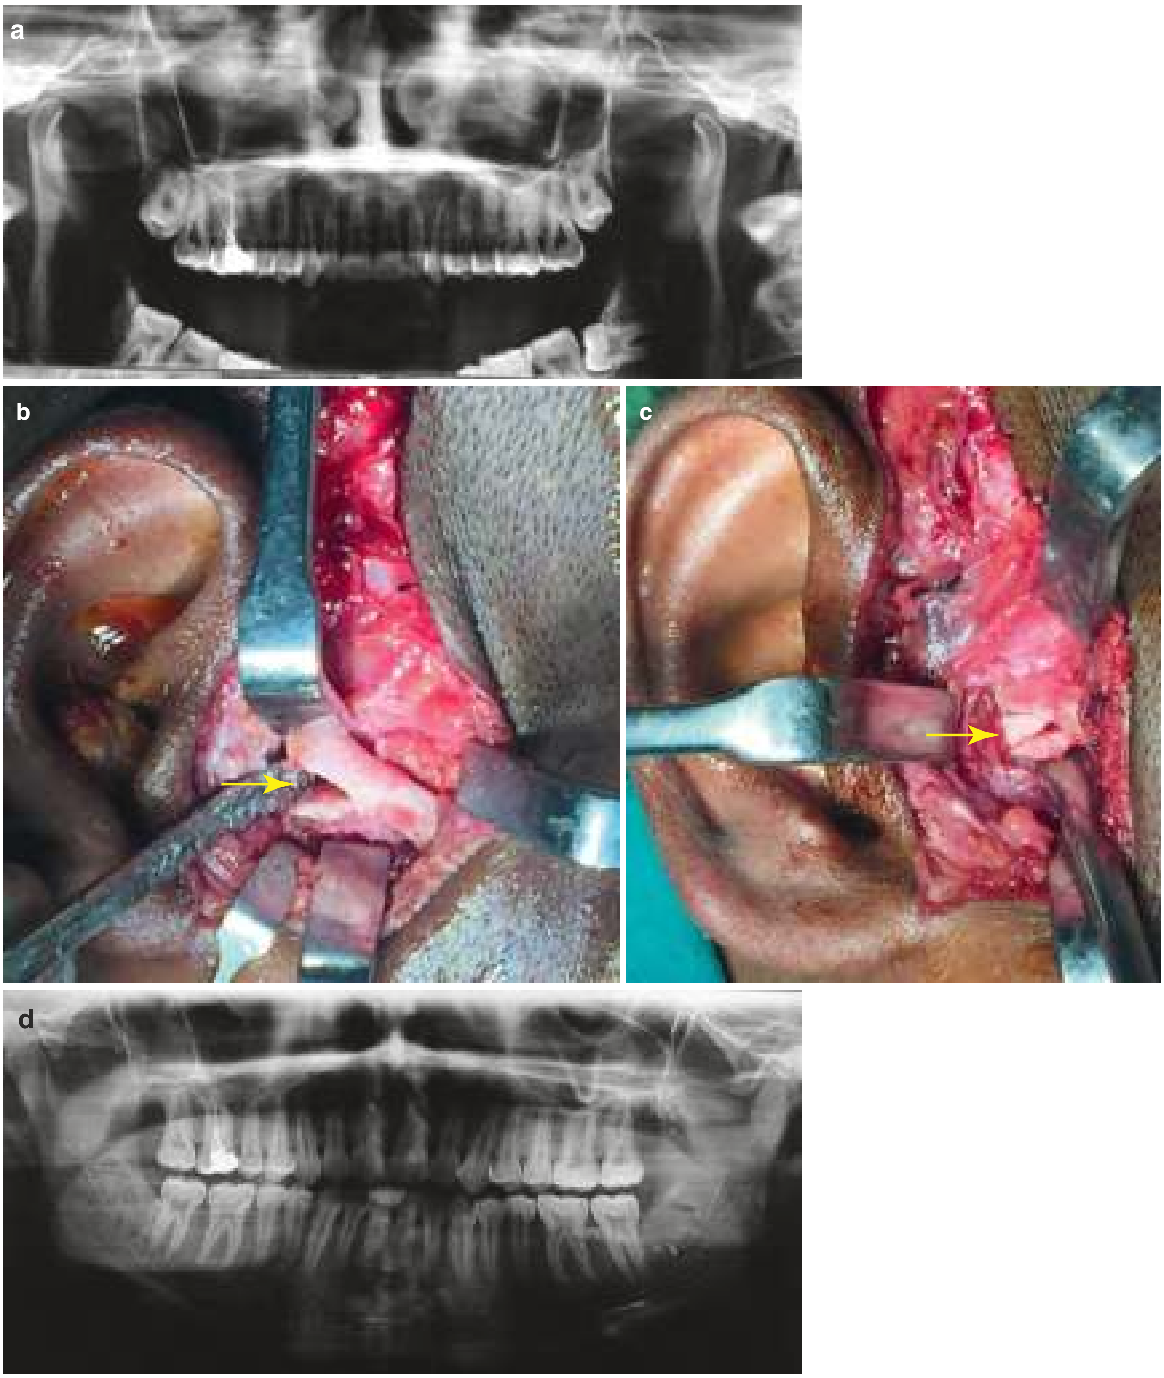

Fig. 64.20 Case scenario 1 (**a**) Pre op "open mouth "OPG showing bilateral dislocation of TMJ. (**b**) Osteotomy of articular eminence (yellow arrow). (**c**) Chin graft sandwiched between segments (yellow arrow). (**d**) Post op OPG showing increase in the height of articular eminence on right side

Surgical plan Augmentation of articular eminence by glenotemporal osteotomy on the right side. The right side was chosen for intervention as the symptoms were pronounced on that side

Surgical procedure

- Right TMJ was approached through preauricular incision with temporal extension
- Osteotomy of articular eminence (Fig. 64.20b)
- Wedging the chin graft between the osteotomy cut of articular eminence (Fig. 64.20c)

Postoperative OPG
OPG demonstrating increase in the height of articular eminence on the right side of TMJ (Fig. 64.20d)

Case 2 (Fig. 64.21a–d)

Patient A 54-year-old female, with pain in front of the ear and difficulty in closing the mouth following yawning

Preoperative open mouth OPG demonstrated bilateral TMJ dislocation (Fig. 64.21a)

OPG demonstrates:

- Displacement of condyle out of the glenoid fossa on both sides
- Condylar head is antero-superior to articular eminence

Surgical plan Inferior repositioning of the coronoid on the right side. The right side was chosen for surgery as the patient complained of more pain on that side

Surgical procedure

- Right coronoid was exposed through vestibular incision extending from lower second molar to anterior border of the ramus.
- Osteotomy cut was made from sigmoid notch to anterior border of the ramus (Fig. 64.21b).
- Trough was created on the lateral surface of the ramus just below the osteotomy cut.
- Coronoid was pulled down over the trough and fixed with miniplate (Fig. 64.21c).

Postoperative OPG (Fig. 64.21d)
Open mouth OPG demonstrating the condyle within the glenoid fossa on both the sides and coronoid fixed inferiorly on the right side

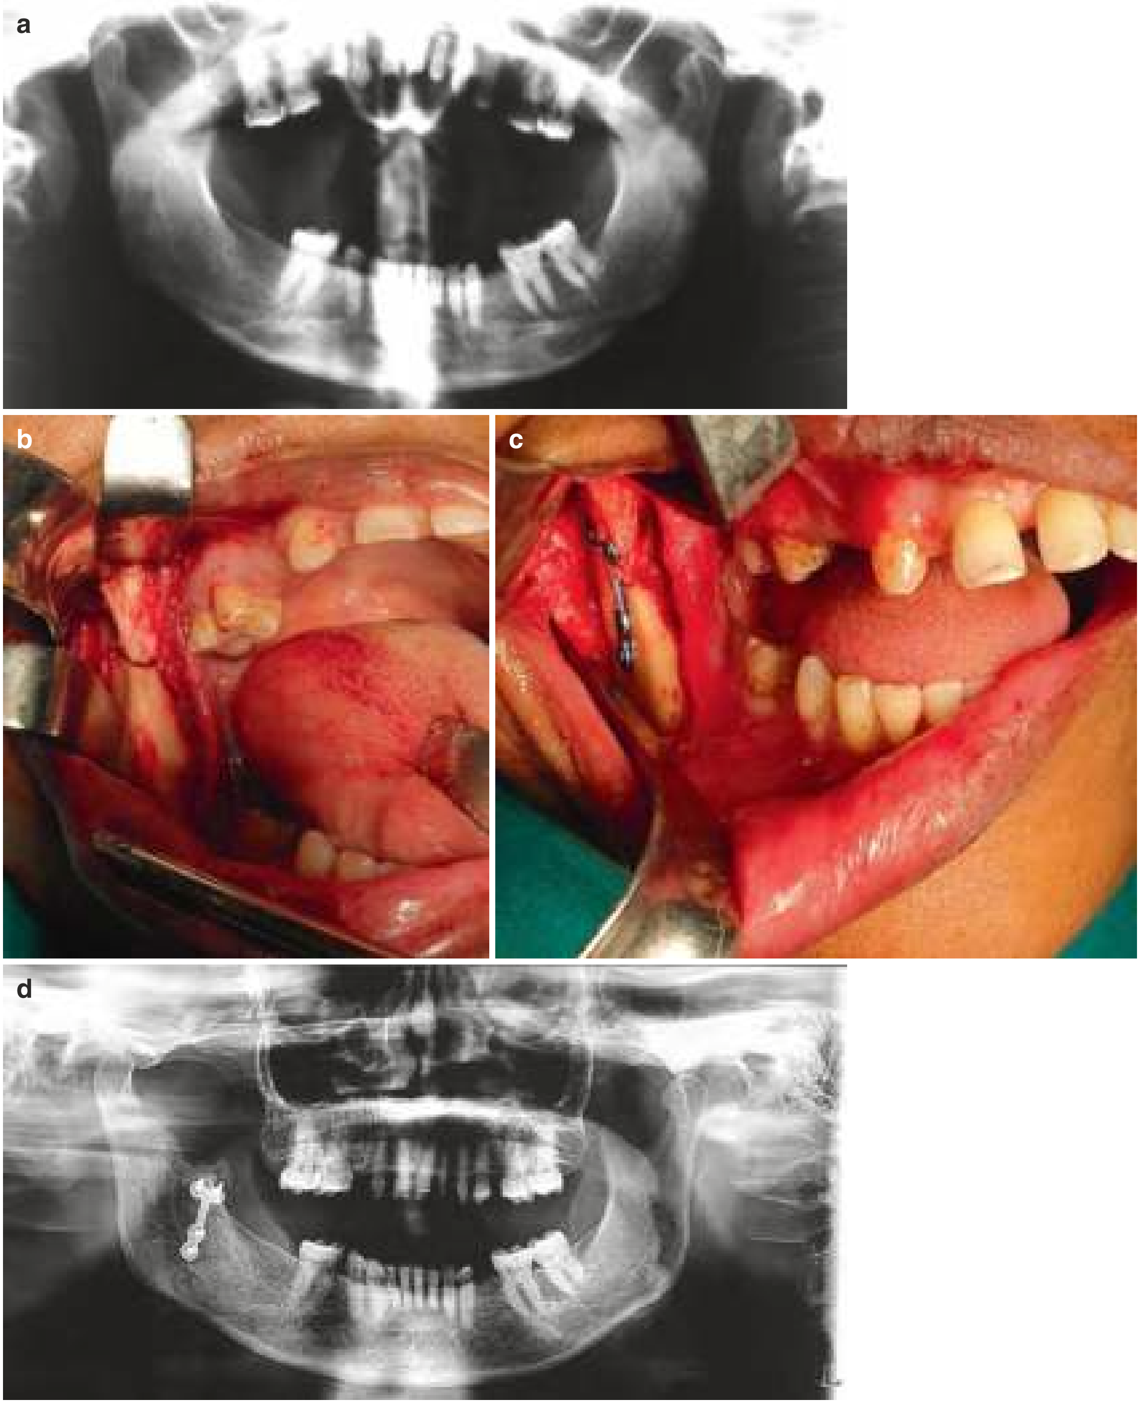

Fig. 64.21 Case scenario 2 (**a**) Pre- op "open mouth" OPG showing bilateral dislocation of TMJ. (**b**) Osteotomy of coronoid. (**c**) Inferiorly positioned coronoid fixed with 2 mm miniplate. (**d**) Post -op "open mouth" OPG showing normal positioning of condyle in relation to articular eminence

Temporomandibular Joint Ankylosis

65

Sonal Anchlia

65.1 Introduction and Etiopathogenesis

Temporomandibular joint (TMJ) ankylosis is defined as bony or fibrous adhesion of the anatomic joint components accompanied by limitation of mouth opening, causing difficulty in mastication, speech, and oral hygiene. This may also influence symmetry of the facial skeleton, especially in cases which occur when patient is still in the growth phase [1].

According to Kaban [2], trauma is the most common cause (31–98%), followed by local or systemic infection (10–49%), and lastly any systemic disease (10%). Infection occurring in the joint commonly occurs due to spread from otitis media or mastoiditis or from the hematogenous route—tuberculosis, gonorrhea, scarlet fever, etc. Systemic etiology may include ankylosing spondylitis, rheumatoid arthritis, or psoriasis.

Classically, hemarthrosis following trauma is the pathogenic factor for bone formation in TMJ ankylosis [3]. Condylar trauma may lead to hemarthrosis due to injury to the periosteum and capsular ligament. When this intracapsular hematoma organizes, hypertrophic bone is formed from the disrupted periosteum or metaplasia of non-osteogenic connective tissue. This may lead to hypomobility, and bony ankylosis may eventually develop.

Yan et al. in 2014 [4] put forth the hypotheses of hypertrophic nonunion. He described the sagittal fracture of condyle along with displacement of the disc. Herein, trauma also occurs in the glenoid fossa, thereby establishing the microenvironment in the articular surfaces for bone healing.

When the condylar trauma is recent, mouth opening will exert a dual effect on new bone formation. This is explained in Fig. 65.1. Restricted jaw movement is not a determinant but rather a promoting agent for ankylosis. Injuries to both the articular disc and the articular surfaces are prerequisites to TMJ ankylosis.

65.2 Clinical Features (Fig. 65.2)

In ankylosis, TMJ movements may be partially or completely restricted in opening, protrusion, and lateral excursions. Palpation of joint movements is better in fibrous than bony ankylosis. In children even in bony ankylosis, joint movements can be palpated because of stretching in the cranial sutures.

Ankylosis results in issues with mastication, digestion, speech, and oral hygiene. This may lead to caries, periodontitis, encumbered eruption of mandibular molars, crowding of teeth, and anterior open bite. Mandibular incisors often show supra-eruption and labial tipping as nature's compensation since the mandible is placed much posterior to the maxilla, thereby reducing lip competence. In severe cases, the lower lip may be trapped under the maxillary incisors.

As the vertical growth of the ramus is restricted, the lower face is significantly shortened. The digastric and mylohyoid muscles produce marked antegonial notching at the inferior part of the mandible just anterior to the insertion of the masseter and medial pterygoid. Failure of condylar growth impedes the forward and downward movement of mandible resulting in localized thickening of the bone at the angle due to subperiosteal apposition which accentuates the antegonion. The mandibular warping is caused due to this, as well as the obtuse angle between the inferior border of the mandible and the base of the skull [5]. The long-standing contractions of the masticatory muscles also give rise to elongation and thickening of the coronoid process, ramal shortening, and chin recession.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-981-15-1346-6_65) contains supplementary material, which is available to authorized users.

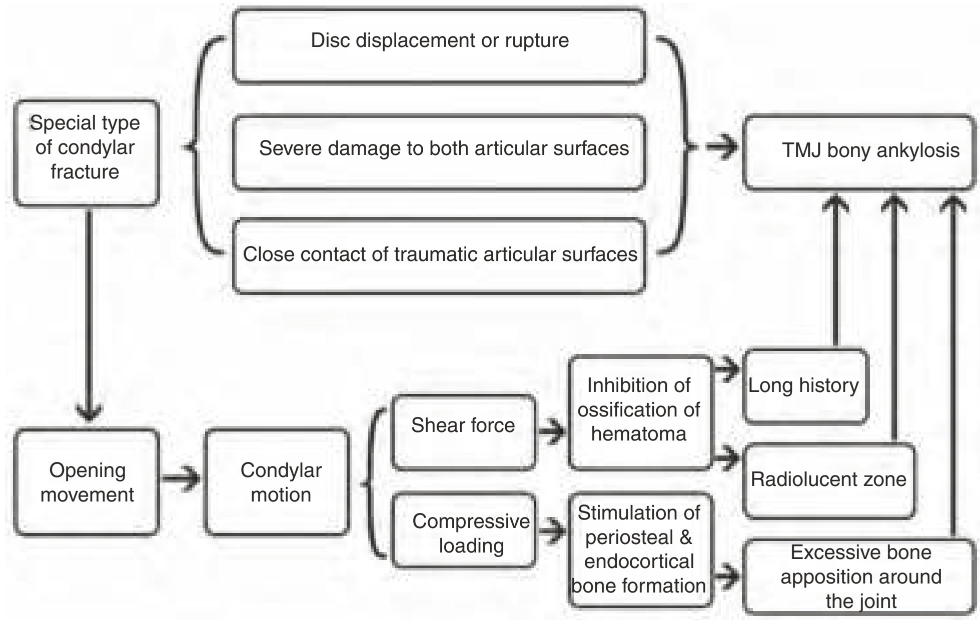

Fig. 65.1 Dual effect of mouth opening on new bone formation in recent condylar trauma

Fig. 65.2 (**a**) Unilateral ankylosis of the right side, (**b**) bilateral ankylosis

In unilateral cases, the chin deviates to the affected side due to restricted mandibular growth on the affected side and normal growth on the unaffected side. In growing patients, this may also restrict ipsilateral growth of the maxilla, although there is normal growth on the unaffected side. In some cases, the growth of the maxilla on the affected side may be normal but that on the unaffected side may be excess, due to uninhibited growth of the normal side. Both these phenomena result in a maxillary cant, though on opposite sides.

In bilateral cases, the mandible is visibly retruded, lacks a chin and the patient presents with an obtuse cervicomental angle. The posterior maxillary height is shortened, giving rise to steep occlusal planes. This convex facial profile or the bird face deformity is also described as the "Andy Gump deformity." Andy Gump was a cartoon character with a very insignificant chin, who first appeared in the Chicago Tribune in 1917, created by cartoonist Sidney Smith [6].

Worsened aesthetics of their appearance often becomes a reason for depressive disorders, psychological problems such as stubbornness, low self-esteem, and an inferiority complex.

The longer the duration of hypomobility, the more severe is the muscle atrophy and facial asymmetry. The prognosis for a favorable outcome with treatment is inversely related to the number of years of ankylosis.

65.2.1 Importance of Obstructive Sleep Apnea-Hypopnea Syndrome (OSAHS)

The presence of retruded mandible and micrognathia in patients with TMJ ankylosis creates narrowing of the pharyngeal airway space (PAS) with mechanical obstruction to respiration, more so in the supine position and during sleep. This process forms a complex syndrome of apneic episodes with significant reduction in the mean oxygen saturation levels and secondary cardiac and respiratory problems, known as OSAHS [7]. Therefore, for patients in whom the release of TMJ ankylosis is carried out without the advancement of the mandible for the correction of OSA, there is worsening of an already compromised airway. In such cases wide mouth opening during post-operative jaw exercises can lead to upper airway collapse—a sense of choking, bradycardia, and restlessness or apnea-like episodes, hence increasing chances of ankylosis [8].

65.2.2 Radiographic Features of Bony Ankylosis (Fig. 65.3)

According to Yan et al. [4], the deformed TMJ is characterized by an enlarged condyle, thickened temporal bone, excessive bone formation, and a radiolucent zone in the bony fusion area. No scattered calcified dots are found in the radiolucent zone, showing that ossification occurs only in the existing bones.

Bony fusion is located in the lateral part of the joint with decreased/absent bone marrow cavity and osteosclerosis. The medial non-bony fusion area shows the atrophic condylar head and rudimentary joint space. Here, the morphology of the bone marrow cavity and bone mineral density is similar to that of normal bone.

Wu et al. [9] demonstrated that in fibrous ankylosis, there is fibrous tissue intruding into the bone marrow of the condyle as well as degeneration of the condylar cartilage. In bony ankylosis, there occurs new bone formation on the rough ankylotic surface of the condyle and slight bone degeneration.

65.3 Classifications

Ankylosis has been classified by various authors according to its extent, site, development, heterotrophic bone formation, symptoms, and most recently, the extent of ankylosis guiding the treatment plan (Table 65.1).

65.4 Preoperative Assessment

65.4.1 Investigations

1. Detailed history, complete clinical examination, professional photographs, for documenting the:
   (a) Age of onset of ankylosis
   (b) Type, duration, and extent of ankylosis
   (c) Type of joint injury or infection
   (d) Maximal interincisal opening
   (e) Dental characteristics and occlusion
   (f) Type of facial deformity
   (g) Previous surgery
2. Routine hemogram and pre-op major investigations
3. Radiological examinations for evaluation of extent of ankylotic mass, discrepancy of jaws, and treatment planning (Fig. 65.4)
   (a) Orthopantomogram:
      (i) Decreased joint space
      (ii) Absence/presence of normal condylar and coronoid anatomy
      (iii) Prominent antegonial notch
      (iv) Markings for osteotomy cuts (for distraction)
   (b) PA cephalogram:
      (i) Chin deviation—Cg-ANS-Me (Crista Galli - Anterior Nasal Spine - Menton)
      (ii) Occlusal cant
      (iii) Grummon's analysis

Fig. 65.3 The computerized tomographic features of TMJ bony ankylosis. The blue circle refers to the bony fusion area located in the lateral part of the joint; in this area, a radiolucent zone can be observed. The red circle refers to the atrophic condylar head and rudimentary joint space located in the medial part of the joint. The green arrow indicates that bone mineral density and morphology of the bone marrow cavity in the non-bony fusion area were normal. The white arrows indicate excessive bone formation around the joint

   (c) Lateral cephalogram:
      (i) Ramal length: Ar-Go (Articulare-Gonion)
      (ii) Corpus length: Go-Pog (Gonion-Pogonion)
      (iii) Pharyngeal airway space (PAS)
      (iv) N perpendicular to Pog (Nasion perpendicular to Pogonion)
   (d) Facial CT scan:
      (i) Three-dimensional anatomy of bony morphology
      (ii) Any anatomical measurements as and when required, e.g., size of ankylotic mass, location of ligula, airway space volume, etc.
   (e) CT Angiography may be required to assess the relationship of internal maxillary artery to the ankylotic mass. There are chances of the vessel being inside the bone, especially in re-ankylosis cases.
4. Assessment of OSA may be done using Epworth sleepiness scale, Pittsburgh sleep quality index, and polysomnography (PSG) for:
   (a) Apneic-hypopneic index (AHI)
   (b) Nocturnal desaturation episodes
   (c) Average respiratory disturbance index
   (d) Average lowest arterial oxygen saturation
5. 3D stereolithographic models printed, with the help of CT scan, may be used in treatment planning. Patient-specific surgical guides aid planning, precise control during operation, and thus more foreseeable treatment results.

65.4.2 Airway Implications of TMJ Ankylosis

65.4.2.1 Assessment

McNamara's airway analysis on lateral cephalogram helps to assess the PAS, CT provides volumetric assessment of the same, whereas PSG helps to assess the AHI. Moderate to severe AHI may require delayed extubation/tracheostomy.

65.4.2.2 Types of Intubation According to Clinical Situations

Blind nasal intubation was done historically, but it was traumatic, unpredictable, and unsafe. Tracheostomy is a traumatic experience, but nowadays, awake intubation is performed using midazolam and fentanyl [10]. Fiberoptic-assisted nasotracheal intubation has become the gold standard for such patients.

However, emergency tracheostomy during/after extubation may be required if:

(a) Bilateral ankylosis release is performed, but RCU reconstruction for ramal height rehabilitation has not been done.
(b) OSA is severe and release precedes mandibular advancement.

In these two situations, the mandible may fall back as there is no posterosuperior stop for the ramus and may impinge on the airway, causing further increase in OSA.

65.5 Surgical Anatomy [11]

65.5.1 Nerve Anatomy (Figs. 46.6 and 65.5)

65.5.1.1 Facial Nerve

The main trunk of the facial nerve exits from the skull at the stylomastoid foramen. Approximately 1.3 cm of the facial nerve is visible until it divides into temporofacial and cervicofacial branches.

According to Al-Kayat and Bramley (1979) [12], the distance from the lowest point of the bony external auditory canal (EAC) to this bifurcation measures 1.5–2.8 cm (mean 2.3 cm). The postglenoid tubercle to the bifurcation measures 2.4–3.5 cm (mean 3.0 cm). However, the point at which the upper trunk crosses the zygomatic arch is the most vari-

Table 65.1 Classifications

I. Topazian (1964)	
• Stage 1: Ankylotic bone limited to the condylar process • Stage 2: Ankylotic bone extending to the sigmoid notch • Stage 3: Ankylotic bone extending to the coronoid process	
II. Sawhney's classification (1986)	
• Type 1: Minimal bony fusion but extensive fibrous adhesions around the joint • Type 2: Bony fusion at the outer edge of the articular surface but no fusion on medial area of the joint • Type 3: Bridge of bone between the mandible and temporal bone • Type 4: Joint is replaced by a mass of bone	
III. Turlington and Durr (1993)	
According to heterotopic bone formation within the ankylotic mass • Grade 0: No bone islands visible • Grade 1: Islands of bone visible within the soft tissue around the joint • Grade 2: Periarticular bone formation • Grade 3: Apparent bony ankylosis	
Grades 1, 2, and 3 are further classified as symptomatic (S) and asymptomatic (A)	
IV. Recent advances: Dongmei He and Colleagues (2011)	
Type of Ankylosis	**Suggested Treatment Plan**
• **Type A1**: Fibrous ankylosis without bony fusion of joint	• Ankylosis release temporalis muscle flap, costochondral graft
• **Type A2**: Bony fusion on lateral side of joint, residual condyle bigger than half of condylar head on medial side 	• Lateral arthroplasty
• **Type A3**: Similar to A2 but residual condylar fragment is smaller than half 	• Resection of ankylotic mass, costochondral graft
• **Type A4**: Ankylosis with complete bony fusion of joint 	• Resection of ankylotic mass, costochondral graft
V. Recent advances: Yan and colleagues (2014)	
Based on its development, ankylosis can be classified into three phases: • Fibrous-chondral phase demonstrating fibrous tissue and chondrocytes occupied the joint gap • Chondral-calcified cartilage phase manifesting abundant chondrocytes, cartilage matrix, and neo-formative endochondral ossification in the joint space • Bone-cartilage phase showing compacted bone bridge in the lateral joint gap and cartilage in the medial joint gap	

able in terms of distance. It may be anywhere from 8 to 35 mm anterior to the most anterior portion of the bony EAC (mean 2.0 cm). If the superficial layer of the temporalis fascia and the periosteum over the arch is incised within 8 mm, one can prevent injury to the upper trunk branches.

However, Miloro et al. [13] showed that the average distance anterior to bony EAC was 2.12 cm. (1.68–2.49 cm). His was an MRI-based study as compared to cadaveric dissection-based work of Al-Kayat and Bramley.

The temporal branch of the facial nerve emerges from the parotid gland and crosses the zygoma under the temporoparietal fascia to innervate the frontalis muscle in the forehead. Postsurgical palsy manifests as an inability to raise the eyebrow and ptosis of the brow. Damage to the zygomatic branch results in paralysis to the orbicularis oculi. Nerve damage may necessitate either tarsorrhaphy or gold weight implants into the upper eyelid for gravity-assisted closure. Transcutaneous nerve stimulation may be helpful in cases of neuropraxia.

65.5.1.2 Trigeminal Nerve

The auriculotemporal nerve courses from the medial side of the posterior neck of the condyle and turns superiorly, running over the zygomatic root of the temporal bone.

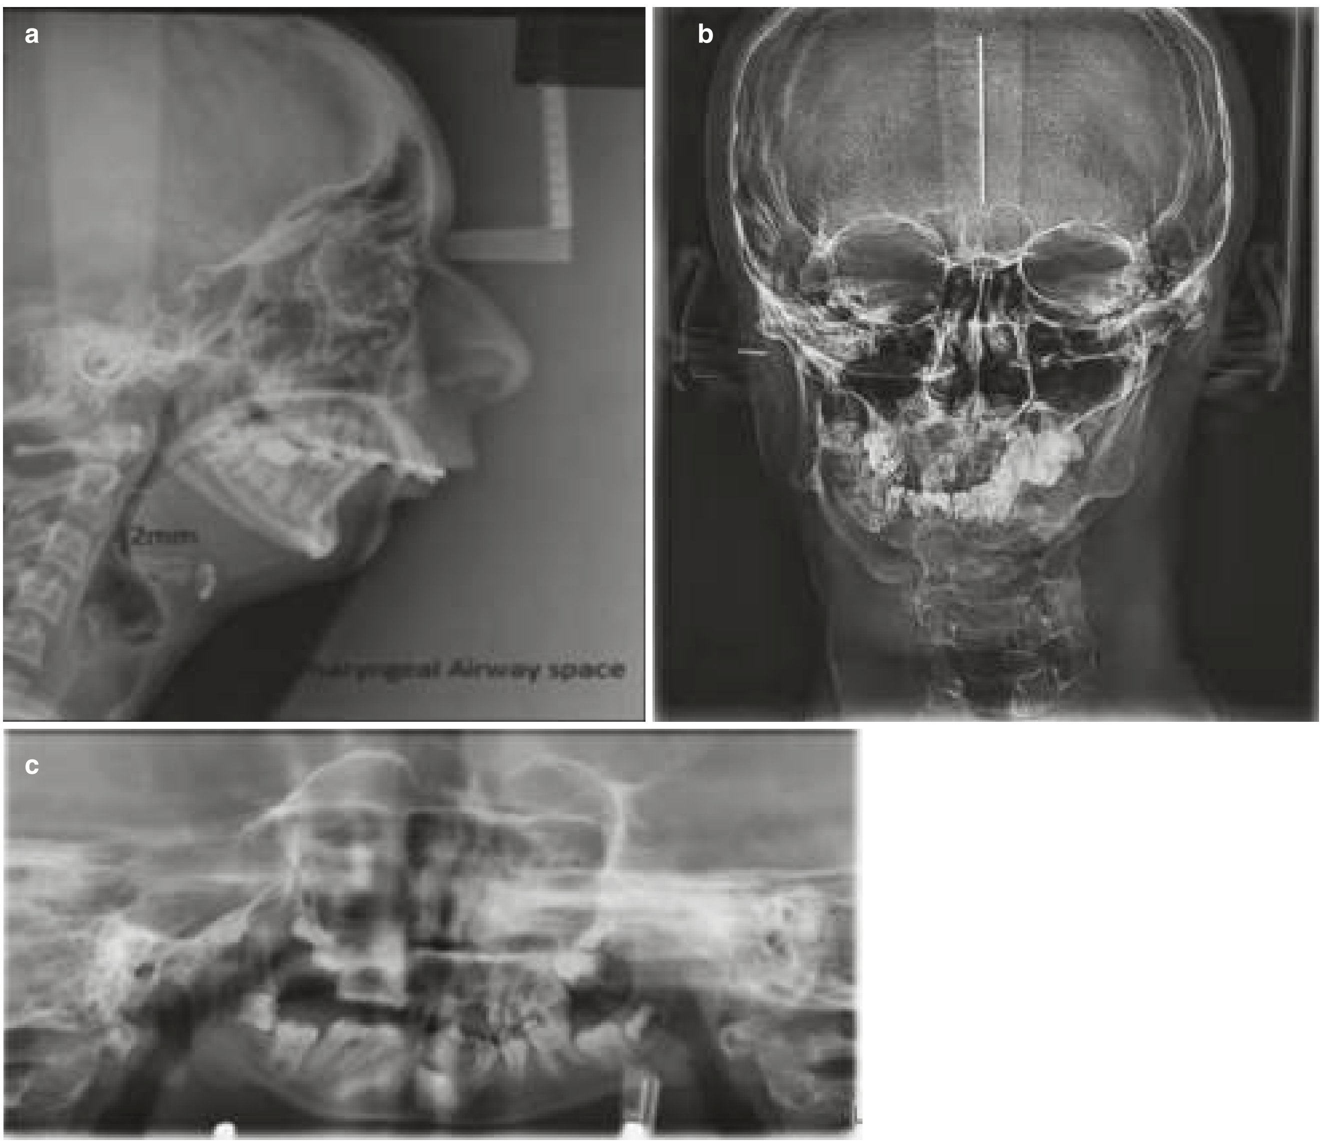

Fig. 65.4 (**a**) Lateral cephalogram, (**b**) PA cephalogram, (**c**) orthopantomogram, (**d**) facial CT scan, (**e**) facial cone beam CT, (**f**) volumetric assessment of pharyngeal airway space on CBCT

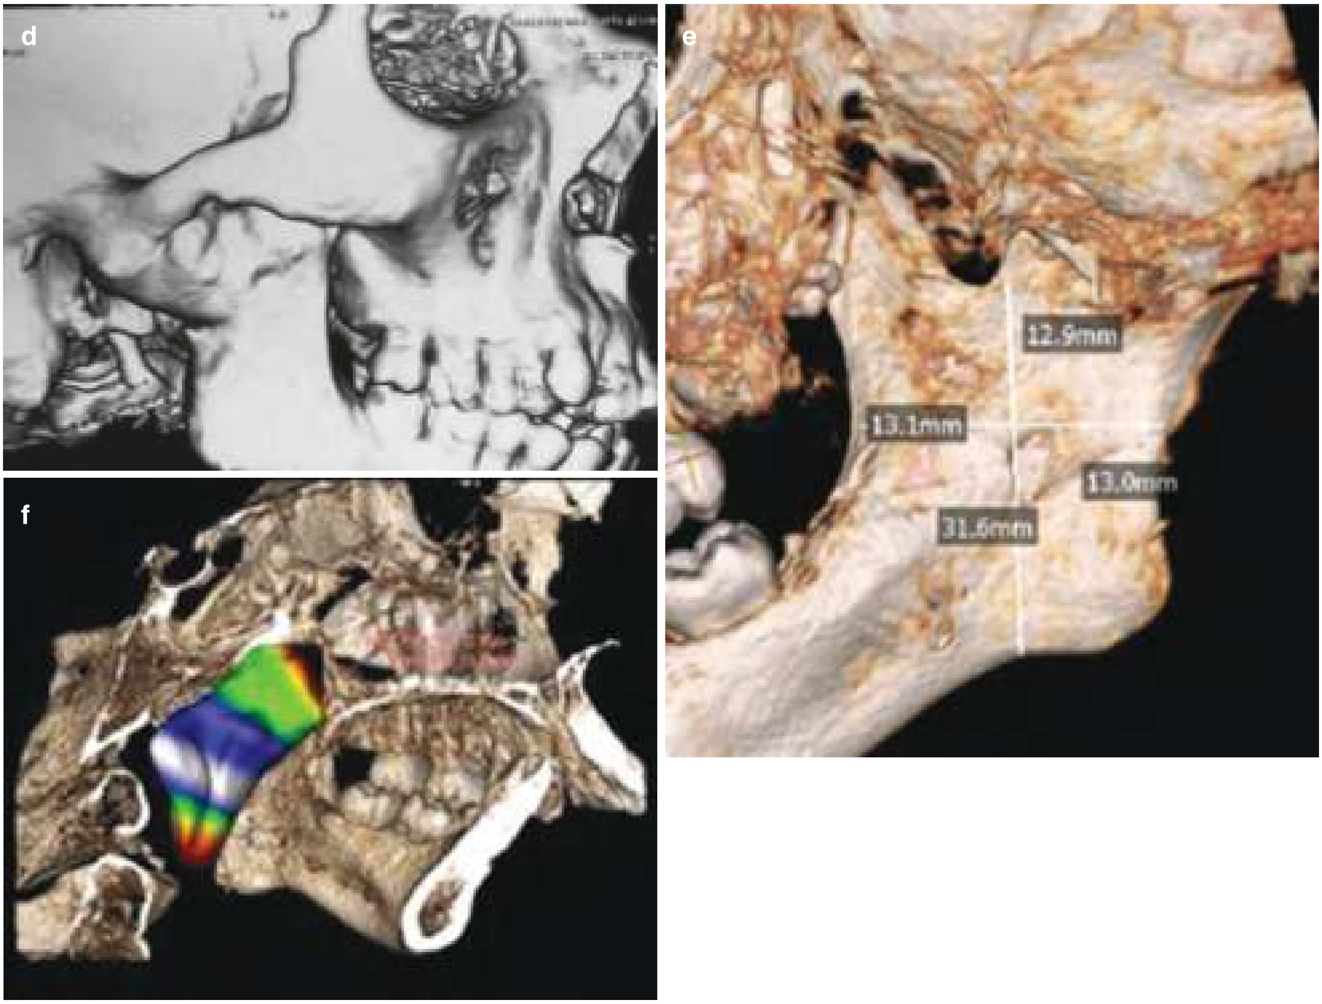

Fig. 65.4 (continued)

Preauricular exposure of the TMJ area invariably injures the nerve. Damage is minimized by incision and dissection in close apposition to the cartilaginous portion of the external auditory meatus.

65.5.2 Vascular Anatomy (Fig. 65.5)

The superficial temporal artery and internal maxillary artery are the terminal branches of the external carotid artery. In the preauricular approach, the internal maxillary artery runs about 3 mm medial to the mid-sigmoid notch.

The most commonly injured artery during temporomandibular procedures is the middle meningeal branch of the internal maxillary artery. Pogrel [14] in a cadaver study of structures medial to the temporomandibular joint found the middle meningeal artery to be a mean of 31 mm (21–43 mm) medial to the zygomatic arch and a mean of 2.4 mm (2–8 mm) anterior from the height of the glenoid fossa.

65.5.3 Incisions (Fig. 65.6) [5]

65.5.3.1 Dingman's Preauricular Approach (Refer video on Pre auricular approach in Chap. 53 and Fig. 53.17)

It is the most commonly used incision with many variations. Classically, the incision begins along the course of the helix, just in front of the tragus till the attachment of the ear lobule. Going through the skin and superficial fascia, about 2 cm above the zygomatic arch, an oblique incision is made through the superficial layer of temporal fascia. Just above the arch, the periosteum of the zygomatic arch is incised and turned forward as one flap with the outer layer of the temporal fascia, superficial fascia containing nerves, and skin. The ankylotic mass now stands exposed.

65.5.3.2 Blair (1914)

It is like the Dingman's incision in preauricular fold, but unlike the former it bends in the region of the zygomatic arch

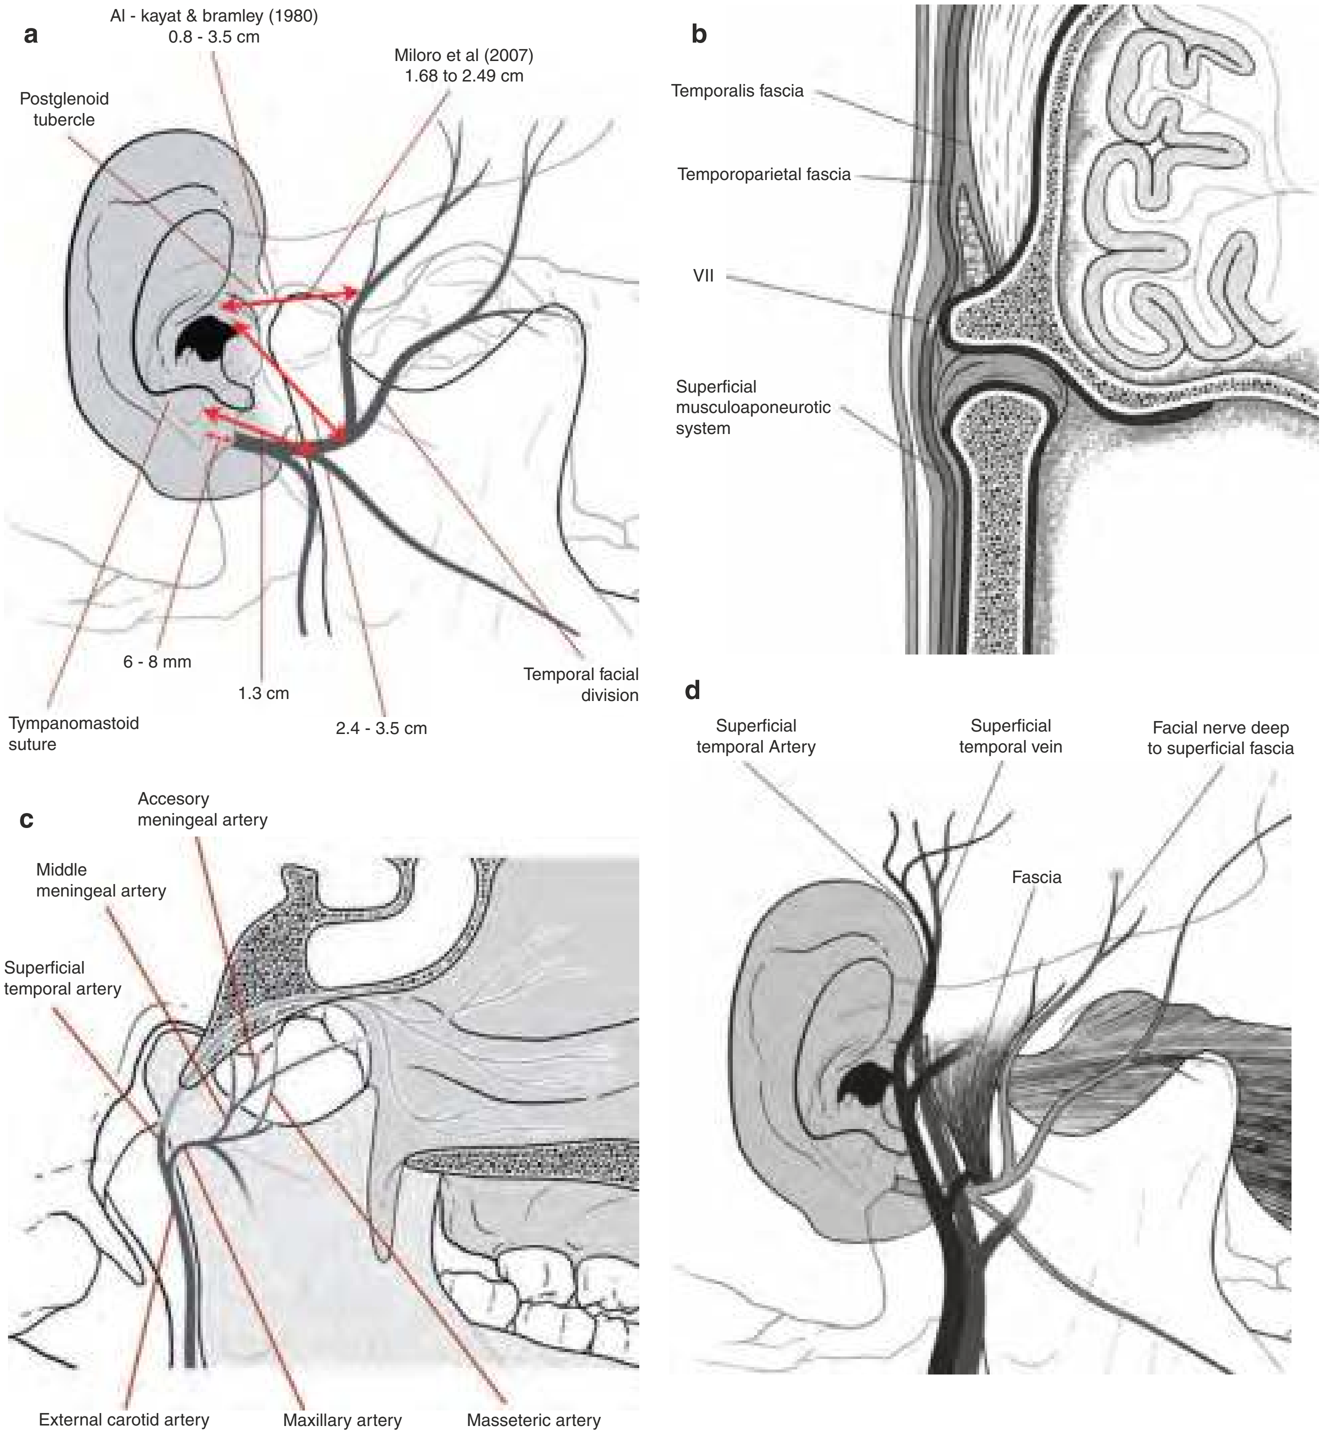

Fig. 65.5 (**a**) Surgical landmarks for identifying the location of main trunk of the facial nerve and the temporal-facial division during temporomandibular arthroplastic dissection. (**b**) Coronal diagram of the fascial layers and facial nerve at the level of the temporoparietal fascia. (**c**) View from medial aspect of the mandible. Note proximity of middle meningeal, external maxillary, and masseteric arteries. Care should be taken to protect these structures at the level of the condylar neck and sigmoid notch during osteotomies. (**d**) Relative position of the superficial temporal artery and vein and the temporal branch of the facial nerve
